# FUNDAMENTAL CONSTANTS

Constant	Symbol	Value		
			Power of 10	Units
Speed of light	$c$	2.997 924 58*	$10^8$	$\text{m s}^{-1}$
Elementary charge	$e$	1.602 176 565	$10^{-19}$	C
Planck's constant	$h$	6.626 069 57	$10^{-34}$	J s
	$\hbar = h/2\pi$	1.054 571 726	$10^{-34}$	J s
Boltzmann's constant	$k$	1.380 6488	$10^{-23}$	J K <sup>-1</sup>
Avogadro's constant	$N_A$	6.022 141 29	$10^{23}$	mol <sup>-1</sup>
Gas constant	$R = N_A k$	8.314 4621		J K <sup>-1</sup> mol <sup>-1</sup>
Faraday's constant	$F = N_A e$	9.648 533 65	$10^4$	C mol <sup>-1</sup>
Mass				
Electron	$m_e$	9.109 382 91	$10^{-31}$	kg
Proton	$m_p$	1.672 621 777	$10^{-27}$	kg
Neutron	$m_n$	1.674 927 351	$10^{-27}$	kg
Atomic mass constant	$m_u$	1.660 538 921	$10^{-27}$	kg
Vacuum permeability	$\mu_0$	$4\pi^*$	$10^{-7}$	J s <sup>2</sup> C <sup>-2</sup> m <sup>-1</sup>
Vacuum permittivity	$\epsilon_0 = 1/\mu_0 c^2$	8.854 187 817	$10^{-12}$	J <sup>-1</sup> C <sup>2</sup> m <sup>-1</sup>
	$4\pi\epsilon_0$	1.112 650 056	$10^{-10}$	J <sup>-1</sup> C <sup>2</sup> m <sup>-1</sup>
Bohr magneton	$\mu_B = e\hbar/2m_e$	9.274 009 68	$10^{-24}$	J T <sup>-1</sup>
Nuclear magneton	$\mu_N = e\hbar/2m_p$	5.050 783 53	$10^{-27}$	J T <sup>-1</sup>
Proton magnetic moment	$\mu_p$	1.410 606 743	$10^{-26}$	J T <sup>-1</sup>
g-Value of electron	$g_e$	2.002 319 304		
Magnetogyric ratio				
Electron	$\gamma_e = -g_e e/2m_e$	-1.001 159 652	$10^{10}$	C kg <sup>-1</sup>
Proton	$\gamma_p = 2\mu_p/\hbar$	2.675 222 004	$10^8$	C kg <sup>-1</sup>
Bohr radius	$a_0 = 4\pi\epsilon_0\hbar^2/e^2m_e$	5.291 772 109	$10^{-11}$	m
Rydberg constant	$\tilde{R}_\infty = m_e e^4/8h^3 c \epsilon_0^2$	1.097 373 157	$10^5$	cm <sup>-1</sup>
	$hc\tilde{R}_\infty/e$	13.605 692 53		eV
Fine-structure constant	$\alpha = \mu_0 e^2 c/2h$	7.297 352 5698	$10^{-3}$	
	$\alpha^{-1}$	1.370 359 990 74	$10^2$	
Second radiation constant	$c_2 = hc/k$	1.438 777 0	$10^{-2}$	m K
Stefan-Boltzmann constant	$\sigma = 2\pi^5 k^4/15h^3 c^2$	5.670 373	$10^{-8}$	W m <sup>-2</sup> K <sup>-4</sup>
Standard acceleration of free fall	$g$	9.806 65*		m s <sup>-2</sup>
Gravitational constant	$G$	6.673 84	$10^{-11}$	N m <sup>2</sup> kg <sup>-2</sup>

\* Exact value. For current values of the constants, see the National Institute of Standards and Technology (NIST) website.

# PREFACE

This new edition is the product of a thorough revision of content and its presentation. Our goal is to make the book even more accessible to students and useful to instructors by enhancing its flexibility. We hope that both categories of user will perceive and enjoy the renewed vitality of the text and the presentation of this demanding but engaging subject.

The text is still divided into three parts, but each chapter is now presented as a series of short and more readily mastered *Topics*. This new structure allows the instructor to tailor the text within the time constraints of the course as omissions will be easier to make, emphases satisfied more readily, and the trajectory through the subject modified more easily. For instance, it is now easier to approach the material either from a ‘quantum first’ or a ‘thermodynamics first’ perspective because it is no longer necessary to take a linear path through chapters. Instead, students and instructors can match the choice of *Topics* to their learning objectives. We have been very careful not to presuppose or impose a particular sequence, except where it is demanded by common sense.

We open with a *Foundations* chapter, which reviews basic concepts of chemistry and physics used through the text. Part 1 now carries the title *Thermodynamics*. New to this edition is coverage of ternary phase diagrams, which are important in applications of physical chemistry to engineering and materials science. Part 2 (*Structure*) continues to cover quantum theory, atomic and molecular structure, spectroscopy, molecular assemblies, and statistical thermodynamics. Part 3 (*Change*) has lost a chapter dedicated to catalysis, but not the material. Enzyme-catalysed reactions are now in Chapter 20, and heterogeneous catalysis is now part of a new Chapter 22 focused on surface structure and processes.

As always, we have paid special attention to helping students navigate and master this material. Each chapter opens with a brief summary of its *Topics*. Then each *Topic* begins with three questions: ‘Why do you need to know this material?’, ‘What is the key idea?’, and ‘What do you need to know already?’. The answers to the third question point to other *Topics* that we consider appropriate to have studied or at least to refer to as background to the current *Topic*. The *Checklists* at the end of each

*Topic* are useful distillations of the most important concepts and equations that appear in the exposition.

We continue to develop strategies to make mathematics, which is so central to the development of physical chemistry, accessible to students. In addition to associating *Mathematical background* sections with appropriate chapters, we give more help with the development of equations: we motivate them, justify them, and comment on the steps taken to derive them. We also added a new feature: *The chemist’s toolkit*, which offers quick and immediate help on a concept from mathematics or physics.

This edition has more worked *Examples*, which require students to organize their thoughts about how to proceed with complex calculations, and more *Brief illustrations*, which show how to use an equation or deploy a concept in a straightforward way. Both have *Self-tests* to enable students to assess their grasp of the material. We have structured the end-of-chapter *Discussion questions*, *Exercises*, and *Problems* to match the grouping of the *Topics*, but have added *Topic- and Chapter-crossing Integrated activities* to show that several *Topics* are often necessary to solve a single problem. The *Resource section* has been restructured and augmented by the addition of a list of integrals that are used (and referred to) throughout the text.

We are, of course, alert to the development of electronic resources and have made a special effort in this edition to encourage the use of web-based tools, which are identified in the *Using the book* section that follows this preface. Important among these tools are *Impact* sections, which provide examples of how the material in the chapters is applied in such diverse areas as biochemistry, medicine, environmental science, and materials science.

Overall, we have taken this opportunity to refresh the text thoroughly, making it even more flexible, helpful, and up to date. As ever, we hope that you will contact us with your suggestions for its continued improvement.

PWA, Oxford  
JdeP, Portland

# USING THE BOOK

For the tenth edition of *Physical Chemistry: Thermodynamics, Structure, and Change* we have tailored the text even more closely to the needs of students. First, the material within each chapter has been reorganized into discrete topics to improve accessibility, clarity, and flexibility. Second, in addition to

the variety of learning features already present, we have significantly enhanced the mathematics support by adding new Chemist's toolkit boxes, and checklists of key concepts at the end of each topic.

## Organizing the information

### ► Innovative new structure

Each chapter has been reorganized into short topics, making the text more readable for students and more flexible for instructors. Each topic opens with a comment on why it is important, a statement of the key idea, and a brief summary of the background needed to understand the topic.

#### ► Why do you need to know this material?

Because chemistry is about matter and the changes that it can undergo, both physically and chemically, the properties of matter underlie the entire discussion in this book.

#### ► What is the key idea?

The bulk properties of matter are related to the identities

### ► Notes on good practice

Our *Notes on good practice* will help you avoid making common mistakes. They encourage conformity to the international language of science by setting out the conventions and procedures adopted by the International Union of Pure and Applied Chemistry (IUPAC).

applicable only to perfect gases (and other idealized systems) are labelled, as here, with a number in blue.

*A note on good practice* Although the term 'ideal gas' is almost universally used in place of 'perfect gas', there are reasons for preferring the latter term. In an ideal system the interactions between molecules in a mixture are all the same. In a perfect gas not only are the interactions all the same but they are in fact zero. Few, though, make this useful distinction.

Equation A.5, the **perfect gas equation**, is a summary of three empirical conclusions, namely Boyle's law ( $p \propto 1/V$  at

### ► Resource section

The comprehensive *Resource section* at the end of the book contains a table of integrals, data tables, a summary of conventions about units, and character tables. Short extracts of these tables often appear in the topics themselves, principally to give an idea of the typical values of the physical quantities we are introducing.

## RESOURCE SECTION

#### Contents

1	Common integrals	964
2	Units	965
3	Data	966
4	Character tables	996

## ► Checklist of concepts

A *Checklist of key concepts* is provided at the end of each topic so that you can tick off those concepts which you feel you have mastered.

### Checklist of concepts

- 1. The **entropy** acts as a signpost of spontaneous change.
- 2. Entropy change is defined in terms of heat transactions (the **Clausius definition**).
- 3. The **Boltzmann formula** defines absolute entropies in terms of the number of ways of achieving a configuration.

## Presenting the mathematics

### ► Justifications

Mathematical development is an intrinsic part of physical chemistry, and to achieve full understanding you need to see how a particular expression is obtained and if any assumptions have been made. The *Justifications* are set off from the text to let you adjust the level of detail to meet your current needs and make it easier to review material.

#### Justification 3A.1 Heating accompanying reversible adiabatic expansion

This *Justification* is based on two features of the cycle. One feature is that the two temperatures  $T_h$  and  $T_c$  in eqn 3A.7 lie on the same adiabat in Fig. 3A.7. The second feature is that the energy transferred as heat during the two isothermal stages are

$$q_h = nRT_h \ln \frac{V_B}{V_A} \quad q_c = nRT_c \ln \frac{V_D}{V_C}$$

We now show that the two volume ratios are related in a very simple way. From the relation between temperature and volume for reversible adiabatic processes ( $VT^\gamma = \text{constant}$ , Topic 2D):

### ► Chemist's toolkits

New to the tenth edition, the *Chemist's toolkits* are succinct reminders of the mathematical concepts and techniques that you will need in order to understand a particular derivation being described in the main text.

#### The chemist's toolkit A.1 Quantities and units

The result of a measurement is a **physical quantity** that is reported as a numerical multiple of a unit:

$$\text{physical quantity} = \text{numerical value} \times \text{unit}$$

It follows that units may be treated like algebraic quantities and may be multiplied, divided, and cancelled. Thus, the expression (physical quantity)/unit is the numerical value (a dimensionless quantity) of the measurement in the specified

### ► Mathematical backgrounds

There are six *Mathematical background* sections dispersed throughout the text. They cover in detail the main mathematical concepts that you need to understand in order to be able to master physical chemistry. Each one is located at the end of the chapter to which it is most relevant.

#### Mathematical background 1 Differentiation

Two of the most important mathematical techniques in the physical sciences are differentiation and integration. They occur throughout the subject, and it is essential to be aware of the procedures involved.

##### MB1.1 Differentiation: definitions

Differentiation is concerned with the slopes of functions, such as the rate of change of a variable with time. The formal definition of the **derivative**,  $df/dx$ , of a function  $f(x)$  is

## ► Annotated equations and equation labels

We have annotated many equations to help you follow how they are developed. An annotation can take you across the equals sign: it is a reminder of the substitution used, an approximation made, the terms that have been assumed constant, the integral used, and so on. An annotation can also be a reminder of the significance of an individual term in an expression. We sometimes color a collection of numbers or symbols to show how they carry from one line to the next. Many of the equations are labelled to highlight their significance.

$$w = -nRT \int_{V_i}^{V_f} \frac{dV}{V} \stackrel{\text{Integral A.2}}{=} -nRT \ln \frac{V_f}{V_i}$$

Perfect gas,  
reversible,  
isothermal

Work of expansion (2A.9)

## ► Checklists of equations

You don't have to memorize every equation in the text. A checklist at the end of each topic summarizes the most important equations and the conditions under which they apply.

### Checklist of equations

Property	Equation
Compression factor	$Z = V_m/V_m^\circ$
Virial equation of state	$pV_m = RT(1 + B/V_m + C/V_m^2 + \dots)$
van der Waals equation of state	$p = nRT/(V - nb) - a(n/V)^2$
Reduced variables	$X_r = X_m/X_c$

## Setting up and solving problems

### ► Brief illustrations

A *Brief illustration* shows you how to use equations or concepts that have just been introduced in the text. They help you to learn how to use data, manipulate units correctly, and become familiar with the magnitudes of properties. They are all accompanied by a Self-test question which you can use to monitor your progress.

#### Brief illustration 1C.5 Corresponding states

The critical constants of argon and carbon dioxide are given in Table 1C.2. Suppose argon is at 23 atm and 200 K, its reduced pressure and temperature are then

$$p_r = \frac{23 \text{ atm}}{48.0 \text{ atm}} = 0.48 \quad T_r = \frac{200 \text{ K}}{150.7 \text{ K}} = 1.33$$

For carbon dioxide to be in a corresponding state, its pressure and temperature would need to be

$$p = 0.48 \times (72.9 \text{ atm}) = 35 \text{ atm} \quad T = 1.33 \times 304.2 \text{ K} = 405 \text{ K}$$

**Self-test 1C.6** What would be the corresponding state of ammonia?

Answer: 53 atm, 539 K

### ► Worked examples

Worked *Examples* are more detailed illustrations of the application of the material, which require you to assemble and develop concepts and equations. We provide a suggested method for solving the problem and then implement it to reach the answer. Worked examples are also accompanied by *Self-test* questions.

#### Example 3A.2 Calculating the entropy change for a composite process

Calculate the entropy change when argon at 25 °C and 1.00 bar in a container of volume 0.500 dm<sup>3</sup> is allowed to expand to 1.000 dm<sup>3</sup> and is simultaneously heated to 100 °C.

**Method** As remarked in the text, use reversible isothermal expansion to the final volume, followed by reversible heating at constant volume to the final temperature. The entropy change in the first step is given by eqn 3A.16 and that of the second step, provided  $C_V$  is independent of temperature, by eqn 3A.20 (with  $C_V$  in place of  $C_p$ ). In each case we need to

### ► Discussion questions

*Discussion questions* appear at the end of every chapter, where they are organized by topic. These questions are designed to encourage you to reflect on the material you have just read, and to view it conceptually.

### ► Exercises and Problems

*Exercises* and *Problems* are also provided at the end of every chapter, and organized by topic. They prompt you to test your understanding of the topics in that chapter. Exercises are designed as relatively straightforward numerical tests whereas the problems are more challenging. The Exercises come in related pairs, with final numerical answers available on the Book Companion Site for the 'a' questions. Final numerical answers to the odd-numbered problems are also available on the Book Companion Site.

### ► Integrated activities

At the end of most chapters, you will find questions that cross several topics and chapters, and are designed to help you use your knowledge creatively in a variety of ways. Some of the questions refer to the Living Graphs on the Book Companion Site, which you will find helpful for answering them.

### ► Solutions manuals

Two solutions manuals have been written by Charles Trapp, Marshall Cady, and Carmen Giunta to accompany this book.

The *Student Solutions Manual* (ISBN 1-4641-2449-3) provides full solutions to the 'a' exercises and to the odd-numbered problems.

## TOPIC 3A Entropy

### Discussion questions

**3A.1** The evolution of life requires the organization of a very large number of molecules into biological cells. Does the formation of living organisms violate the Second Law of thermodynamics? State your conclusion clearly and present detailed arguments to support it.

**3A.2** Discuss the significance of the terms 'dispersal' and 'disorder' in the context of the Second Law.

### Exercises

**3A.1(a)** During a hypothetical process, the entropy of a system increases by 125 J K<sup>-1</sup> while the entropy of the surroundings decreases by 125 J K<sup>-1</sup>. Is the process spontaneous?

**3A.1(b)** During a hypothetical process, the entropy of a system increases by 105 J K<sup>-1</sup> while the entropy of the surroundings decreases by 95 J K<sup>-1</sup>. Is the process spontaneous?

**3A.2(a)** A certain ideal heat engine uses water at the triple point as the hot source and an organic liquid as the cold sink. It withdraws 10.00 kJ of heat from the hot source and generates 3.00 kJ of work. What is the temperature of the organic liquid?

**3A.2(b)** A certain ideal heat engine uses water at the triple point as the hot source and an organic liquid as the cold sink. It withdraws 2.71 kJ of heat from the hot source and generates 0.71 kJ of work. What is the temperature of the organic liquid?

The *Instructor's Solutions Manual* provides full solutions to the 'b' exercises and to the even-numbered problems (available to download from the Book Companion Site for registered adopters of the book only).

# BOOK COMPANION SITE

The Book Companion Site to accompany *Physical Chemistry: Thermodynamics, Structure, and Change*, tenth edition provides a number of useful teaching and learning resources for students and instructors.

The site can be accessed at:

<http://www.whfreeman.com/pchem10e/>

Instructor resources are available only to registered adopters of the textbook. To register, simply visit <http://www.whfreeman.com/pchem10e/> and follow the appropriate links.

Student resources are openly available to all, without registration.

---

## Materials on the Book Companion Site include:

### 'Impact' sections

'Impact' sections show how physical chemistry is applied in a variety of modern contexts. New for this edition, the Impacts are linked from the text by QR code images. Alternatively, visit the URL displayed next to the QR code image.

### Group theory tables

Comprehensive group theory tables are available to download.

### Figures and tables from the book

Instructors can find the artwork and tables from the book in ready-to-download format. These may be used for lectures without charge (but not for commercial purposes without specific permission).

### Molecular modeling problems

PDFs containing molecular modeling problems can be downloaded, designed for use with the Spartan Student™ software. However they can also be completed using any modeling software that allows Hartree-Fock, density functional, and MP2 calculations.

### Living graphs

These interactive graphs can be used to explore how a property changes as various parameters are changed. Living graphs are sometimes referred to in the Integrated activities at the end of a chapter.

# ACKNOWLEDGEMENTS

A book as extensive as this could not have been written without significant input from many individuals. We would like to reiterate our thanks to the hundreds of people who contributed to the first nine editions. Many people gave their advice based on the ninth edition, and others, including students, reviewed the draft chapters for the tenth edition as they emerged. We wish to express our gratitude to the following colleagues:

Oleg Antzutkin, *Luleå University of Technology*  
Mu-Hyun Baik, *Indiana University — Bloomington*  
Maria G. Benavides, *University of Houston — Downtown*  
Joseph A. Bentley, *Delta State University*  
Maria Bohorquez, *Drake University*  
Gary D. Branum, *Friends University*  
Gary S. Buckley, *Cameron University*  
Eleanor Campbell, *University of Edinburgh*  
Lin X. Chen, *Northwestern University*  
Gregory Dicoski, *University of Tasmania*  
Niels Engholm Henriksen, *Technical University of Denmark*  
Walter C. Ermler, *University of Texas at San Antonio*  
Alexander Y. Fadeev, *Seton Hall University*  
Beth S. Guiton, *University of Kentucky*  
Patrick M. Hare, *Northern Kentucky University*  
Grant Hill, *University of Glasgow*  
Ann Hopper, *Dublin Institute of Technology*  
Garth Jones, *University of East Anglia*  
George A. Kaminsky, *Worcester Polytechnic Institute*  
Dan Killelea, *Loyola University of Chicago*

Daniel Zeroka, *Lehigh University*

Because we prepared this edition at the same time as its sister volume, *Physical Chemistry: Quanta, matter, and change*, it goes without saying that our colleague on that book, Ron Friedman, has had an unconscious but considerable impact on this text too, and we cannot thank him enough for his contribution to this book. Our warm thanks also go to Charles Trapp, Carmen Giunta, and Marshall Cady who once again have produced the *Solutions manuals* that accompany this book and whose comments led us to make a number of improvements. Kerry Karukstis contributed helpfully to the Impacts that are now on the web.

Last, but by no means least, we would also like to thank our two commissioning editors, Jonathan Crowe of Oxford University Press and Jessica Fiorillo of W. H. Freeman & Co., and their teams for their encouragement, patience, advice, and assistance.

(b) Enthalpies of chemical change	82	Checklist of equations	130
(c) Hess's law	83	Topic 3C Concentrating on the system	131
2C.2 Standard enthalpies of formation	84	3C.1 The Helmholtz and Gibbs energies	131
(a) The reaction enthalpy in terms of enthalpies of formation	85	(a) Criteria of spontaneity	131
(b) Enthalpies of formation and molecular modelling	85	(b) Some remarks on the Helmholtz energy	133
2C.3 The temperature dependence of reaction enthalpies	86	(c) Maximum work	133
2C.4 Experimental techniques	87	(d) Some remarks on the Gibbs energy	134
(a) Differential scanning calorimetry	87	(e) Maximum non-expansion work	135
(b) Isothermal titration calorimetry	88	3C.2 Standard molar Gibbs energies	136
Checklist of concepts	88	(a) Gibbs energies of formation	136
Checklist of equations	89	(b) The Born equation	137
Topic 2D State functions and exact differentials	90	Checklist of concepts	138
2D.1 Exact and inexact differentials	90	Checklist of equations	138
2D.2 Changes in internal energy	91	Topic 3D Combining the First and Second Laws	140
(a) General considerations	91	3D.1 Properties of the internal energy	140
(b) Changes in internal energy at constant pressure	93	(a) The Maxwell relations	141
2D.3 The Joule–Thomson effect	95	(b) The variation of internal energy with volume	141
(a) Observation of the Joule–Thomson effect	95	3D.2 Properties of the Gibbs energy	142
(b) The molecular interpretation of the Joule–Thomson effect	98	(a) General considerations	142
Checklist of concepts	98	(b) The variation of the Gibbs energy with temperature	144
Checklist of equations	99	(c) The variation of the Gibbs energy with pressure	144
Topic 2E Adiabatic changes	100	(d) The fugacity	146
2E.1 The change in temperature	100	Checklist of concepts	148
2E.2 The change in pressure	101	Checklist of equations	148
Checklist of concepts	102	Discussion questions, exercises, and problems	149
Checklist of equations	102	CHAPTER 4 Physical transformations of pure substances	154
Discussion questions, exercises, and problems	103	Topic 4A Phase diagrams of pure substances	155
Mathematical background 2 Multivariate calculus	109	4A.1 The stabilities of phases	155
CHAPTER 3 The Second and Third Laws	112	(a) The number of phases	155
Topic 3A Entropy	113	(b) Phase transitions	156
3A.1 The Second Law	113	(c) Thermodynamic criteria of phase stability	156
3A.2 The definition of entropy	115	4A.2 Phase boundaries	157
(a) The thermodynamic definition of entropy	115	(a) Characteristic properties related to phase transitions	157
(b) The statistical definition of entropy	116	(b) The phase rule	159
		4A.3 Three representative phase diagrams	160

(a) Carbon dioxide	160	5C.2 Temperature–composition diagrams	206
(b) Water	161	(a) The distillation of mixtures	206
(c) Helium	162	(b) Azeotropes	207
<b>Checklist of concepts</b>	<b>162</b>	(c) Immiscible liquids	208
<b>Checklist of equations</b>	<b>163</b>	5C.3 Liquid–liquid phase diagrams	208
<b>Topic 4B Thermodynamic aspects of phase transitions</b>	<b>164</b>	(a) Phase separation	208
4B.1 The dependence of stability on the conditions	164	(b) Critical solution temperatures	209
(a) The temperature dependence of phase stability	165	(c) The distillation of partially miscible liquids	211
(b) The response of melting to applied pressure	165	5C.4 Liquid–solid phase diagrams	212
(c) The vapour pressure of a liquid subjected to pressure	166	(a) Eutectics	212
4B.2 The location of phase boundaries	167	(b) Reacting systems	214
(a) The slopes of the phase boundaries	167	(c) Incongruent melting	214
(b) The solid–liquid boundary	168	<b>Checklist of concepts</b>	<b>215</b>
(c) The liquid–vapour boundary	169	<b>Checklist of equations</b>	<b>215</b>
(d) The solid–vapour boundary	170	<b>Topic 5D Phase diagrams of ternary systems</b>	<b>216</b>
4B.3 The Ehrenfest classification of phase transitions	171	5D.1 Triangular phase diagrams	216
(a) The thermodynamic basis	171	5D.2 Ternary systems	217
(b) Molecular interpretation	172	(a) Partially miscible liquids	217
<b>Checklist of concepts</b>	<b>173</b>	(b) Ternary solids	218
<b>Checklist of equations</b>	<b>173</b>	<b>Checklist of concepts</b>	<b>219</b>
<b>Discussion questions, exercises, and problems</b>	<b>174</b>	<b>Topic 5E Activities</b>	<b>220</b>
<b>CHAPTER 5 Simple mixtures</b>	<b>178</b>	5E.1 The solvent activity	220
<b>Topic 5A The thermodynamic description of mixtures</b>	<b>180</b>	5E.2 The solute activity	221
5A.1 Partial molar quantities	180	(a) Ideal–dilute solutions	221
(a) Partial molar volume	181	(b) Real solutes	221
(b) Partial molar Gibbs energies	182	(c) Activities in terms of molalities	222
(c) The wider significance of the chemical potential	183	(d) The biological standard state	222
(d) The Gibbs–Duhem equation	183	5E.3 The activities of regular solutions	223
5A.2 The thermodynamics of mixing	184	<b>Checklist of concepts</b>	<b>224</b>
(a) The Gibbs energy of mixing of perfect gases	185	<b>Checklist of equations</b>	<b>225</b>
(b) Other thermodynamic mixing functions	186	<b>Topic 5F The activities of ions</b>	<b>226</b>
5A.3 The chemical potentials of liquids	187	5F.1 Mean activity coefficients	226
(a) Ideal solutions	187	(a) The Debye–Hückel limiting law	227
(b) Ideal–dilute solutions	188	(b) Extensions of the limiting law	228
<b>Checklist of concepts</b>	<b>190</b>	5F.2 The Debye–Hückel theory	229
<b>Checklist of equations</b>	<b>190</b>	(a) The work of charging	229
<b>Topic 5B The properties of solutions</b>	<b>192</b>	(b) The potential due to the charge distribution	229
5B.1 Liquid mixtures	192	(c) The activity coefficient	230
(a) Ideal solutions	192	<b>Checklist of concepts</b>	<b>232</b>
(b) Excess functions and regular solutions	193	<b>Checklist of equations</b>	<b>232</b>
5B.2 Colligative properties	195	<b>Discussion questions, exercises, and problems</b>	<b>233</b>
(a) The common features of colligative properties	195	<b>CHAPTER 6 Chemical equilibrium</b>	<b>244</b>
(b) The elevation of boiling point	196	<b>Topic 6A The equilibrium constant</b>	<b>245</b>
(c) The depression of freezing point	197	6A.1 The Gibbs energy minimum	245
(d) Solubility	198	(a) The reaction Gibbs energy	245
(e) Osmosis	199	(b) Exergonic and endergonic reactions	246
<b>Checklist of concepts</b>	<b>201</b>	6A.2 The description of equilibrium	247
<b>Checklist of equations</b>	<b>201</b>	(a) Perfect gas equilibria	247
<b>Topic 5C Phase diagrams of binary systems</b>	<b>202</b>	(b) The general case of a reaction	248
5C.1 Vapour pressure diagrams	202	(c) The relation between equilibrium constants	251
(a) The composition of the vapour	202	(d) Molecular interpretation of the equilibrium constant	251
(b) The interpretation of the diagrams	203	<b>Checklist of concepts</b>	<b>252</b>
(c) The lever rule	205	<b>Checklist of equations</b>	<b>252</b>

Topic 6B The response of equilibria to the conditions	254	Topic 7C The principles of quantum theory	299
6B.1 The response to pressure	254	7C.1 Operators	299
6B.2 The response to temperature	255	(a) Eigenvalue equations	299
(a) The van 't Hoff equation	256	(b) The construction of operators	300
(b) The value of $K$ at different temperatures	257	(c) Hermitian operators	302
Checklist of concepts	258	(d) Orthogonality	303
Checklist of equations	258	7C.2 Superpositions and expectation values	304
Topic 6C Electrochemical cells	259	7C.3 The uncertainty principle	305
6C.1 Half-reactions and electrodes	259	7C.4 The postulates of quantum mechanics	308
6C.2 Varieties of cells	260	Checklist of concepts	308
(a) Liquid junction potentials	261	Checklist of equations	308
(b) Notation	261	Discussion questions, exercises, and problems	310
6C.3 The cell potential	261	Mathematical background 3 Complex numbers	314
(a) The Nernst equation	262	CHAPTER 8 The quantum theory of motion	316
(b) Cells at equilibrium	264	Topic 8A Translation	317
6C.4 The determination of thermodynamic functions	264	8A.1 Free motion in one dimension	317
Checklist of concepts	265	8A.2 Confined motion in one dimension	318
Checklist of equations	266	(a) The acceptable solutions	318
Topic 6D Electrode potentials	267	(b) The properties of the wavefunctions	320
6D.1 Standard potentials	267	(c) The properties of observables	321
(a) The measurement procedure	268	8A.3 Confined motion in two or more dimensions	322
(b) Combining measured values	269	(a) Separation of variables	322
6D.2 Applications of standard potentials	269	(b) Degeneracy	324
(a) The electrochemical series	269	8A.4 Tunnelling	324
(b) The determination of activity coefficients	270	Checklist of concepts	327
(c) The determination of equilibrium constants	270	Checklist of equations	328
Checklist of concepts	271	Topic 8B Vibrational motion	329
Checklist of equations	271	8B.1 The harmonic oscillator	329
Discussion questions, exercises, and problems	272	(a) The energy levels	330
PART 2 Structure	279	(b) The wavefunctions	331
CHAPTER 7 Introduction to quantum theory	281	8B.2 The properties of oscillators	333
Topic 7A The origins of quantum mechanics	282	(a) Mean values	334
7A.1 Energy quantization	282	(b) Tunnelling	335
(a) Black-body radiation	282	Checklist of concepts	336
(b) Heat capacities	285	Checklist of equations	336
(c) Atomic and molecular spectra	286	Topic 8C Rotational motion	337
7A.2 Wave-particle duality	287	8C.1 Rotation in two dimensions	337
(a) The particle character of electromagnetic radiation	287	(a) The qualitative origin of quantized rotation	337
(b) The wave character of particles	289	(b) The solutions of the Schrödinger equation	338
Checklist of concepts	290	(c) Quantization of angular momentum	340
Checklist of equations	291	8C.2 Rotation in three dimensions	342
Topic 7B Dynamics of microscopic systems	292	(a) The wavefunctions	342
7B.1 The Schrödinger equation	292	(b) The energies	344
7B.2 The Born interpretation of the wavefunction	293	(c) Angular momentum	345
(a) Normalization	295	(d) Space quantization	345
(b) Constraints on the wavefunction	296	(e) The vector model	346
(c) Quantization	297	Checklist of concepts	347
7B.3 The probability density	297	Checklist of equations	347
Checklist of concepts	298	Discussion questions, exercises, and problems	349
Checklist of equations	298	Mathematical background 4 Differential equations	354

CHAPTER 9 Atomic structure and spectra	356	Topic 10B Principles of molecular orbital theory	407
Topic 9A Hydrogenic atoms	357	10B.1 Linear combinations of atomic orbitals	407
9A.1 The structure of hydrogenic atoms	358	(a) The construction of linear combinations	407
(a) The separation of variables	358	(b) Bonding orbitals	409
(b) The radial solutions	359	(c) Antibonding orbitals	411
9A.2 Atomic orbitals and their energies	361	10B.2 Orbital notation	412
(a) The specification of orbitals	361	Checklist of concepts	412
(b) The energy levels	362	Checklist of equations	412
(c) Ionization energies	362	Topic 10C Homonuclear diatomic molecules	413
(d) Shells and subshells	363	10C.1 Electron configurations	413
(e) s Orbitals	364	(a) $\sigma$ Orbitals and $\pi$ orbitals	413
(f) Radial distribution functions	365	(b) The overlap integral	415
(g) p Orbitals	367	(c) Period 2 diatomic molecules	416
(h) d Orbitals	368	10C.2 Photoelectron spectroscopy	418
Checklist of concepts	368	Checklist of concepts	419
Checklist of equations	369	Checklist of equations	419
Topic 9B Many-electron atoms	370	Topic 10D Heteronuclear diatomic molecules	420
9B.1 The orbital approximation	370	10D.1 Polar bonds	420
(a) The helium atom	371	(a) The molecular orbital formulation	420
(b) Spin	371	(b) Electronegativity	421
(c) The Pauli principle	372	10D.2 The variation principle	422
(d) Penetration and shielding	374	(a) The procedure	423
9B.2 The building-up principle	375	(b) The features of the solutions	424
(a) Hund's rules	376	Checklist of concepts	425
(b) Ionization energies and electron affinities	377	Checklist of equations	426
9B.3 Self-consistent field orbitals	379	Topic 10E Polyatomic molecules	427
Checklist of concepts	380	10E.1 The Hückel approximation	427
Checklist of equations	380	(a) An introduction to the method	428
Topic 9C Atomic spectra	381	(b) The matrix formulation of the method	428
9C.1 The spectra of hydrogenic atoms	381	10E.2 Applications	430
9C.2 The spectra of complex atoms	382	(a) Butadiene and $\pi$ -electron binding energy	430
(a) Singlet and triplet states	383	(b) Benzene and aromatic stability	431
(b) Spin-orbit coupling	383	10E.3 Computational chemistry	432
(c) Term symbols	386	(a) Semi-empirical and <i>ab initio</i> methods	433
(d) Hund's rules	389	(b) Density functional theory	434
(e) Selection rules	389	(c) Graphical representations	434
Checklist of concepts	389	Checklist of concepts	435
Checklist of equations	390	Checklist of equations	435
Discussion questions, exercises, and problems	391	Discussion questions, exercises, and problems	436
Mathematical background 5 Vectors	395	Mathematical background 6 Matrices	443
CHAPTER 10 Molecular structure	398	CHAPTER 11 Molecular symmetry	446
Topic 10A Valence-bond theory	399	Topic 11A Symmetry elements	447
10A.1 Diatomic molecules	400	11A.1 Symmetry operations and symmetry elements	448
(a) The basic formulation	400	11A.2 The symmetry classification of molecules	449
(b) Resonance	401	(a) The groups $C_{1v}$ , $C_{2v}$ and $C_{3v}$	450
10A.2 Polyatomic molecules	402	(b) The groups $C_{nv}$ , $C_{nh}$ and $C_{2v}$	451
(a) Promotion	403	(c) The groups $D_{nh}$ , $D_{nd}$ and $D_{nh}$	452
(b) Hybridization	403	(d) The groups $S_n$	452
Checklist of concepts	405	(e) The cubic groups	453
Checklist of equations	406	(f) The full rotation group	454

11A.3 Some immediate consequences of symmetry	454	Checklist of concepts	494
(a) Polarity	454	Checklist of equations	494
(b) Chirality	455		
Checklist of concepts	455	Topic 12C Rotational spectroscopy	495
Checklist of operations and elements	456	12C.1 Microwave spectroscopy	495
		(a) Selection rules	495
Topic 11B Group theory	457	(b) The appearance of microwave spectra	497
11B.1 The elements of group theory	457	12C.2 Rotational Raman spectroscopy	498
11B.2 Matrix representations	458	12C.3 Nuclear statistics and rotational states	500
(a) Representatives of operations	459	Checklist of concepts	502
(b) The representation of a group	459	Checklist of equations	502
(c) Irreducible representations	459		
(d) Characters and symmetry species	460	Topic 12D Vibrational spectroscopy of diatomic molecules	503
11B.3 Character tables	461	12D.1 Vibrational motion	503
(a) Character tables and orbital degeneracy	461	12D.2 Infrared spectroscopy	505
(b) The symmetry species of atomic orbitals	462	12D.3 Anharmonicity	506
(c) The symmetry species of linear combinations of orbitals	463	(a) The convergence of energy levels	506
Checklist of concepts	464	(b) The Birge–Sponer plot	508
Checklist of equations	464	12D.4 Vibration–rotation spectra	509
		(a) Spectral branches	509
Topic 11C Applications of symmetry	465	(b) Combination differences	510
11C.1 Vanishing integrals	465	12D.5 Vibrational Raman spectra	511
(a) Integrals over the product of two functions	466	Checklist of concepts	512
(b) Decomposition of a direct product	467	Checklist of equations	512
(c) Integrals over products of three functions	467		
11C.2 Applications to orbitals	468	Topic 12E Vibrational spectroscopy of polyatomic molecules	514
(a) Orbital overlap	468	12E.1 Normal modes	514
(b) Symmetry-adapted linear combinations	468	12E.2 Infrared absorption spectra	516
11C.3 Selection rules	469	12E.3 Vibrational Raman spectra	518
Checklist of concepts	470	(a) Depolarization	518
Checklist of equations	470	(b) Resonance Raman spectra	518
		(c) Coherent anti-Stokes Raman spectroscopy	519
Discussion questions, exercises, and problems	471	12E.4 Symmetry aspects of molecular vibrations	520
		(a) Infrared activity of normal modes	520
CHAPTER 12 Rotational and vibrational spectra	474	(b) Raman activity of normal modes	521
Topic 12A General features of molecular spectroscopy	476	Checklist of concepts	521
12A.1 The absorption and emission of radiation	477	Checklist of equations	522
(a) Stimulated and spontaneous radiative processes	477		
(b) Selection rules and transition moments	478	Discussion questions, exercises, and problems	523
(c) The Beer–Lambert law	479		
12A.2 Spectral linewidths	480	CHAPTER 13 Electronic transitions	531
(a) Doppler broadening	481	Topic 13A Electronic spectra	532
(b) Lifetime broadening	482	13A.1 Diatomic molecules	533
12A.3 Experimental techniques	482	(a) Term symbols	533
(a) Sources of radiation	482	(b) Selection rules	535
(b) Spectral analysis	483	(c) Vibrational structure	536
(c) Detectors	485	(d) Rotational structure	538
(d) Examples of spectrometers	485	13A.2 Polyatomic molecules	539
Checklist of concepts	486	(a) d-Metal complexes	539
Checklist of equations	487	(b) $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions	540
		(c) Circular dichroism	541
Topic 12B Molecular rotation	488	Checklist of concepts	542
12B.1 Moments of inertia	488	Checklist of equations	542
12B.2 The rotational energy levels	490		
(a) Spherical rotors	490	Topic 13B Decay of excited states	543
(b) Symmetric rotors	491	13B.1 Fluorescence and phosphorescence	543
(c) Linear rotors	493	13B.2 Dissociation and predissociation	545
(d) Centrifugal distortion	493	Checklist of concepts	546

Topic 13C Lasers	547	14D.2 Hyperfine structure	595
13C.1 Population inversion	547	(a) The effects of nuclear spin	595
13C.2 Cavity and mode characteristics	549	(b) The McConnell equation	596
13C.3 Pulsed lasers	550	(c) The origin of the hyperfine interaction	597
13C.4 Time-resolved spectroscopy	552	Checklist of concepts	598
13C.5 Examples of practical lasers	552	Checklist of equations	598
(a) Gas lasers	553	Discussion questions, exercises, and problems	599
(b) Exciplex lasers	554	CHAPTER 15 Statistical thermodynamics	604
(c) Dye lasers	554	Topic 15A The Boltzmann distribution	605
(d) Vibronic lasers	554	15A.1 Configurations and weights	605
Checklist of concepts	555	(a) Instantaneous configurations	605
Checklist of equations	555	(b) The most probable distribution	607
Discussion questions, exercises, and problems	556	(c) The relative population of states	608
CHAPTER 14 Magnetic resonance	560	15A.2 The derivation of the Boltzmann distribution	608
Topic 14A General principles	561	(a) The role of constraints	609
14A.1 Nuclear magnetic resonance	561	(b) The values of the constants	610
(a) The energies of nuclei in magnetic fields	561	Checklist of concepts	611
(b) The NMR spectrometer	563	Checklist of equations	611
14A.2 Electron paramagnetic resonance	564	Topic 15B Molecular partition functions	612
(a) The energies of electrons in magnetic fields	565	15B.1 The significance of the partition function	612
(b) The EPR spectrometer	566	15B.2 Contributions to the partition function	614
Checklist of concepts	567	(a) The translational contribution	615
Checklist of equations	567	(b) The rotational contribution	616
Topic 14B Features of NMR spectra	568	(c) The vibrational contribution	620
14B.1 The chemical shift	568	(d) The electronic contribution	621
14B.2 The origin of shielding constants	570	Checklist of concepts	622
(a) The local contribution	570	Checklist of equations	622
(b) Neighbouring group contributions	571	Topic 15C Molecular energies	624
(c) The solvent contribution	573	15C.1 The basic equations	624
14B.3 The fine structure	573	15C.2 Contributions of the fundamental modes of motion	625
(a) The appearance of the spectrum	573	(a) The translational contribution	625
(b) The magnitudes of coupling constants	575	(b) The rotational contribution	625
(c) The origin of spin-spin coupling	576	(c) The vibrational contribution	626
(d) Equivalent nuclei	577	(d) The electronic contribution	627
(e) Strongly coupled nuclei	579	(e) The spin contribution	628
14B.4 Conformational conversion and exchange processes	580	Check list of concepts	628
Checklist of concepts	581	Checklist of equations	628
Checklist of equations	581	Topic 15D The canonical ensemble	630
Topic 14C Pulse techniques in NMR	582	15D.1 The concept of ensemble	630
14C.1 The magnetization vector	582	(a) Dominating configurations	631
(a) The effect of the radiofrequency field	583	(b) Fluctuations from the most probable distribution	631
(b) Time- and frequency-domain signals	584	15D.2 The mean energy of a system	632
14C.2 Spin relaxation	585	15D.3 Independent molecules revisited	633
(a) Longitudinal and transverse relaxation	585	15D.4 The variation of energy with volume	633
(b) The measurement of $T_1$ and $T_2$	587	Checklist of concepts	635
14C.3 Spin decoupling	588	Checklist of equations	635
14C.4 The nuclear Overhauser effect	589	Topic 15E The internal energy and the entropy	636
14C.5 Two-dimensional NMR	590	15E.1 The internal energy	636
14C.6 Solid-state NMR	592	(a) The calculation of internal energy	636
Checklist of concepts	593	(b) Heat capacity	637
Checklist of equations	593	15E.2 The entropy	638
Topic 14D Electron paramagnetic resonance	594	(a) Entropy and the partition function	638
14D.1 The $g$ -value	594		

(b) The translational contribution	640	CHAPTER 17 Macromolecules and self-assembly	696
(c) The rotational contribution	641	Topic 17A The structures of macromolecules	697
(d) The vibrational contribution	642	17A.1 The different levels of structure	697
(e) Residual entropies	642	17A.2 Random coils	698
Checklist of concepts	643	(a) Measures of size	699
Checklist of equations	644	(b) Constrained chains	702
Topic 15F Derived functions	645	(c) Partly rigid coils	702
15F.1 The derivations	645	17A.3 Biological macromolecules	703
15F.2 Equilibrium constants	647	(a) Proteins	704
(a) The relation between $K$ and the partition function	647	(b) Nucleic acids	705
(b) A dissociation equilibrium	648	Checklist of concepts	706
(c) Contributions to the equilibrium constant	648	Checklist of equations	706
Checklist of concepts	650	Topic 17B Properties of macromolecules	708
Checklist of equations	650	17B.1 Mechanical properties	708
Discussion questions, exercises, and problems	651	(a) Conformational entropy	708
CHAPTER 16 Molecular interactions	659	(b) Elastomers	709
Topic 16A Electric properties of molecules	660	17B.2 Thermal properties	710
16A.1 Electric dipole moments	660	17B.3 Electrical properties	712
16A.2 Polarizabilities	663	Checklist of concepts	712
16A.3 Polarization	664	Checklist of equations	713
(a) The frequency dependence of the polarization	664	Topic 17C Self-assembly	714
(b) Molar polarization	665	17C.1 Colloids	714
Checklist of concepts	667	(a) Classification and preparation	714
Checklist of equations	667	(b) Structure and stability	715
Topic 16B Interactions between molecules	668	(c) The electrical double layer	715
16B.1 Interactions between partial charges	668	17C.2 Micelles and biological membranes	717

# Foundations

Chemistry is the science of matter and the changes it can undergo. Physical chemistry is the branch of chemistry that establishes and develops the principles of the subject in terms of the underlying concepts of physics and the language of mathematics. It provides the basis for developing new spectroscopic techniques and their interpretation, for understanding the structures of molecules and the details of their electron distributions, and for relating the bulk properties of matter to their constituent atoms. Physical chemistry also provides a window on to the world of chemical reactions, and allows us to understand in detail how they take place.

## A Matter

Throughout the text we draw on a number of concepts that should already be familiar from introductory chemistry, such as the ‘nuclear model’ of the atom, ‘Lewis structures’ of molecules, and the ‘perfect gas equation’. This Topic reviews these and other concepts of chemistry that appear at many stages of the presentation.

## B Energy

Because physical chemistry lies at the interface between physics and chemistry, we also need to review some of the

concepts from elementary physics that we need to draw on in the text. This Topic begins with a brief summary of ‘classical mechanics’, our starting point for discussion of the motion and energy of particles. Then it reviews concepts of ‘thermodynamics’ that should already be part of your chemical vocabulary. Finally, we introduce the ‘Boltzmann distribution’ and the ‘equipartition theorem’, which help to establish connections between the bulk and molecular properties of matter.

## C Waves

This Topic describes waves, with a focus on ‘harmonic waves’, which form the basis for the classical description of electromagnetic radiation. The classical ideas of motion, energy, and waves in this Topic and Topic B are expanded with the principles of quantum mechanics (Chapter 7), setting the stage for the treatment of electrons, atoms, and molecules. Quantum mechanics underlies the discussion of chemical structure and chemical change, and is the basis of many techniques of investigation.

### ► Why do you need to know this material?

Because chemistry is about matter and the changes that it can undergo, both physically and chemically, the properties of matter underlie the entire discussion in this book.

### ► What is the key idea?

The bulk properties of matter are related to the identities and arrangements of atoms and molecules in a sample.

### ► What do you need to know already?

This Topic reviews material commonly covered in introductory chemistry.

The presentation of physical chemistry in this text is based on the experimentally verified fact that matter consists of atoms.

In this Topic, which is a review of elementary concepts and language widely used in chemistry, we begin to make connections between atomic, molecular, and bulk properties. Most of the material is developed in greater detail later in the text.

## A.1 Atoms

The atom of an element is characterized by its **atomic number**,  $Z$ , which is the number of protons in its nucleus. The number of neutrons in a nucleus is variable to a small extent, and the **nucleon number** (which is also commonly called the *mass number*),  $A$ , is the total number of protons and neutrons in the nucleus. Protons and neutrons are collectively called **nucleons**. Atoms of the same atomic number but different nucleon number are the **isotopes** of the element.

### (a) The nuclear model

According to the **nuclear model**, an atom of atomic number  $Z$  consists of a nucleus of charge  $+Ze$  surrounded by  $Z$  electrons each of charge  $-e$  ( $e$  is the fundamental charge: see inside the front cover for its value and the values of the other fundamental constants). These electrons occupy **atomic orbitals**, which are regions of space where they are most likely to be found, with no more than two electrons in any one orbital. The atomic orbitals are arranged in **shells** around the nucleus, each shell being characterized by the **principal quantum number**,  $n = 1, 2, \dots$ . A shell consists of  $n^2$  individual orbitals, which are grouped together into  $n$  **subshells**; these subshells, and the orbitals they contain, are denoted s, p, d, and f. For all neutral atoms other than hydrogen, the subshells of a given shell have slightly different energies.

### (b) The periodic table

The sequential occupation of the orbitals in successive shells results in periodic similarities in the **electronic configurations**, the specification of the occupied orbitals, of atoms when they are arranged in order of their atomic number. This periodicity of structure accounts for the formulation of the **periodic table** (see the inside the back cover). The vertical columns of the periodic table are called **groups** and (in the modern convention) numbered from 1 to 18. Successive rows of the periodic table are called **periods**, the number of the period being equal

to the principal quantum number of the **valence shell**, the outermost shell of the atom.

Some of the groups also have familiar names: Group 1 consists of the **alkali metals**, Group 2 (more specifically, calcium, strontium, and barium) of the **alkaline earth metals**, Group 17 of the **halogens**, and Group 18 of the **noble gases**. Broadly speaking, the elements towards the left of the periodic table are **metals** and those towards the right are **non-metals**; the two classes of substance meet at a diagonal line running from boron to polonium, which constitute the **metalloids**, with properties intermediate between those of metals and non-metals.

The periodic table is divided into s, p, d, and f **blocks**, according to the subshell that is last to be occupied in the formulation of the electronic configuration of the atom. The members of the d block (specifically the members of Groups 3–11 in the d block) are also known as the **transition metals**; those of the f block (which is not divided into numbered groups) are sometimes called the **inner transition metals**. The upper row of the f block (Period 6) consists of the **lanthanoids** (still commonly the ‘lanthanides’) and the lower row (Period 7) consists of the **actinoids** (still commonly the ‘actinides’).

### (c) Ions

A monatomic **ion** is an electrically charged atom. When an atom gains one or more electrons it becomes a negatively charged **anion**; when it loses one or more electrons it becomes a positively charged **cation**. The charge number of an ion is called the **oxidation number** of the element in that state (thus, the oxidation number of magnesium in  $\text{Mg}^{2+}$  is +2 and that of oxygen in  $\text{O}^{2-}$  is -2). It is appropriate, but not always done, to distinguish between the oxidation number and the **oxidation state**, the latter being the physical state of the atom with a specified oxidation number. Thus, the oxidation number of magnesium is +2 when it is present as  $\text{Mg}^{2+}$ , and it is present *in* the oxidation state  $\text{Mg}^{2+}$ .

The elements form ions that are characteristic of their location in the periodic table: metallic elements typically form cations by losing the electrons of their outermost shell and acquiring the electronic configuration of the preceding noble gas atom. Nonmetals typically form anions by gaining electrons and attaining the electronic configuration of the following noble gas atom.

## A.2 Molecules

A **chemical bond** is the link between atoms. Compounds that contain a metallic element typically, but far from universally, form **ionic compounds** that consist of cations and anions in a crystalline array. The ‘chemical bonds’ in an ionic compound

are due to the Coulombic interactions between all the ions in the crystal and it is inappropriate to refer to a bond between a specific pair of neighbouring ions. The smallest unit of an ionic compound is called a **formula unit**. Thus  $\text{NaNO}_3$ , consisting of a  $\text{Na}^+$  cation and a  $\text{NO}_3^-$  anion, is the formula unit of sodium nitrate. Compounds that do not contain a metallic element typically form **covalent compounds** consisting of discrete molecules. In this case, the bonds between the atoms of a molecule are **covalent**, meaning that they consist of shared pairs of electrons.

*A note on good practice* Some chemists use the term ‘molecule’ to denote the smallest unit of a compound with the composition of the bulk material regardless of whether it is an ionic or covalent compound and thus speak of ‘a molecule of  $\text{NaCl}$ ’. We use the term ‘molecule’ to denote a discrete covalently bonded entity (as in  $\text{H}_2\text{O}$ ); for an ionic compound we use ‘formula unit’.

### (a) Lewis structures

The pattern of bonds between neighbouring atoms is displayed by drawing a **Lewis structure**, in which bonds are shown as lines and **lone pairs** of electrons, pairs of valence electrons that are not used in bonding, are shown as dots. Lewis structures are constructed by allowing each atom to share electrons until it has acquired an **octet** of eight electrons (for hydrogen, a *duplet* of two electrons). A shared pair of electrons is a **single bond**, two shared pairs constitute a **double bond**, and three shared pairs constitute a **triple bond**. Atoms of elements of Period 3 and later can accommodate more than eight electrons in their valence shell and ‘expand their octet’ to become **hypervalent**, that is, form more bonds than the octet rule would allow (for example,  $\text{SF}_6$ ), or form more bonds to a small number of atoms (see *Brief illustration A.1*). When more than one Lewis structure can be written for a given arrangement of atoms, it is supposed that **resonance**, a blending of the structures, may occur and distribute multiple-bond character over the molecule (for example, the two Kekulé structures of benzene). Examples of these aspects of Lewis structures are shown in Fig. A.1.

Figure A.1 Examples of Lewis structures.

### Brief illustration A.1 Octet expansion

Octet expansion is also encountered in species that do not necessarily require it, but which, if it is permitted, may acquire a lower energy. Thus, of the structures (1a) and (1b) of the  $\text{SO}_4^{2-}$  ion, the second has a lower energy than the first. The actual structure of the ion is a resonance hybrid of both structures (together with analogous structures with double bonds in different locations), but the latter structure makes the dominant contribution.

**Self-test A.1** Draw the Lewis structure for  $\text{XeO}_4$ .

Answer: See 2

### (b) VSEPR theory

Except in the simplest cases, a Lewis structure does not express the three-dimensional structure of a molecule. The simplest approach to the prediction of molecular shape is **valence-shell electron pair repulsion theory** (VSEPR theory). In this approach, the regions of high electron density, as represented by bonds—whether single or multiple—and lone pairs, take up orientations around the central atom that maximize their separations. Then the position of the attached atoms (not the lone pairs) is noted and used to classify the shape of the molecule. Thus, four regions of electron density adopt a tetrahedral arrangement; if an atom is at each of these locations (as in  $\text{CH}_4$ ), then the molecule is tetrahedral; if there is an atom at only three of these locations (as in  $\text{NH}_3$ ), then the molecule is

**Figure A.2** The shapes of molecules that result from application of VSEPR theory.

trigonal pyramidal, and so on. The names of the various shapes that are commonly found are shown in Fig. A.2. In a refinement of the theory, lone pairs are assumed to repel bonding pairs more strongly than bonding pairs repel each other. The shape a molecule then adopts, if it is not determined fully by symmetry, is such as to minimize repulsions from lone pairs.

### Brief illustration A.2 Molecular shapes

In  $\text{SF}_4$  the lone pair adopts an equatorial position and the two axial S–F bonds bend away from it slightly, to give a bent see-saw shaped molecule (Fig. A.3).

**Figure A.3** (a) In  $\text{SF}_4$  the lone pair adopts an equatorial position. (b) The two axial S–F bonds bend away from it slightly, to give a bent see-saw shaped molecule.

**Self-test A.2** Predict the shape of the  $\text{SO}_3^{2-}$  ion.

Answer: Trigonal pyramid

### (c) Polar bonds

Covalent bonds may be **polar**, or correspond to an unequal sharing of the electron pair, with the result that one atom has a partial positive charge (denoted  $\delta^+$ ) and the other a partial negative charge ( $\delta^-$ ). The ability of an atom to attract electrons to itself when part of a molecule is measured by the **electronegativity**,  $\chi$  (chi), of the element. The juxtaposition of equal and opposite partial charges constitutes an **electric dipole**. If those charges are  $+Q$  and  $-Q$  and they are separated by a distance  $d$ , the magnitude of the **electric dipole moment**,  $\mu$ , is

$$\mu = Qd \quad \text{Definition} \quad \text{Magnitude of the electric dipole moment} \quad (\text{A.1})$$

### Brief illustration A.3 Nonpolar molecules with polar bonds

Whether or not a molecule as a whole is polar depends on the arrangement of its bonds, for in highly symmetrical molecules there may be no net dipole. Thus, although the linear  $\text{CO}_2$  molecule (which is structurally  $\text{OCO}$ ) has polar  $\text{CO}$  bonds, their effects cancel and the molecule as a whole is nonpolar.

**Self-test A.3** Is  $\text{NH}_3$  polar?

Answer: Yes

## A.3 Bulk matter

**Bulk matter** consists of large numbers of atoms, molecules, or ions. Its physical state may be solid, liquid, or gas:

A **solid** is a form of matter that adopts and maintains a shape that is independent of the container it occupies.

A **liquid** is a form of matter that adopts the shape of the part of the container it occupies (in a gravitational field, the lower part) and is separated from the unoccupied part of the container by a definite surface.

A **gas** is a form of matter that immediately fills any container it occupies.

A liquid and a solid are examples of a **condensed state** of matter. A liquid and a gas are examples of a **fluid** form of matter: they flow in response to forces (such as gravity) that are applied.

### (a) Properties of bulk matter

The state of a bulk sample of matter is defined by specifying the values of various properties. Among them are:

The **mass**,  $m$ , a measure of the quantity of matter present (unit: 1 kilogram, 1 kg).

The **volume**,  $V$ , a measure of the quantity of space the sample occupies (unit: 1 cubic metre, 1 m<sup>3</sup>).

The **amount of substance**,  $n$ , a measure of the number of specified entities (atoms, molecules, or formula units) present (unit: 1 mole, 1 mol).

#### Brief illustration A.4 Volume units

Volume is also expressed as submultiples of 1 m<sup>3</sup>, such as cubic decimetres (1 dm<sup>3</sup> = 10<sup>-3</sup> m<sup>3</sup>) and cubic centimetres (1 cm<sup>3</sup> = 10<sup>-6</sup> m<sup>3</sup>). It is also common to encounter the non-SI unit litre (1 L = 1 dm<sup>3</sup>) and its submultiple the millilitre (1 mL = 1 cm<sup>3</sup>). To carry out simple unit conversions, simply replace the fraction of the unit (such as 1 cm) by its definition (in this case, 10<sup>-2</sup> m). Thus, to convert 100 cm<sup>3</sup> to cubic decimetres (litres), use 1 cm = 10<sup>-1</sup> dm, in which case 100 cm<sup>3</sup> = 100 (10<sup>-1</sup> dm)<sup>3</sup>, which is the same as 0.100 dm<sup>3</sup>.

**Self-test A.4** Express a volume of 100 mm<sup>3</sup> in units of cm<sup>3</sup>.

Answer: 0.100 cm<sup>3</sup>

An **extensive property** of bulk matter is a property that depends on the amount of substance present in the sample; an **intensive property** is a property that is independent of the amount of substance. The volume is extensive; the mass density,  $\rho$  (rho), with

$$\rho = \frac{m}{V} \quad \text{Mass density (A.2)}$$

is intensive.

The **amount of substance**,  $n$  (colloquially, ‘the number of moles’), is a measure of the number of specified entities present in the sample. ‘Amount of substance’ is the official name of the quantity; it is commonly simplified to ‘chemical amount’ or simply ‘amount’. The unit 1 mol is currently defined as the number of carbon atoms in exactly 12 g of carbon-12. (In 2011 the decision was taken to replace this definition, but the change has not yet, in 2014, been implemented.) The number of entities per mole is called **Avogadro’s constant**,  $N_A$ ; the currently accepted value is  $6.022 \times 10^{23} \text{ mol}^{-1}$  (note that  $N_A$  is a constant with units, not a pure number).

The **molar mass of a substance**,  $M$  (units: formally kilograms per mole but commonly grams per mole, g mol<sup>-1</sup>) is the mass per mole of its atoms, its molecules, or its formula units. The amount of substance of specified entities in a sample can readily be calculated from its mass, by noting that

$$n = \frac{m}{M} \quad \text{Amount of substance (A.3)}$$

*A note on good practice* Be careful to distinguish atomic or molecular mass (the mass of a single atom or molecule; units kg) from molar mass (the mass per mole of atoms or molecules; units kg mol<sup>-1</sup>). *Relative molecular masses* of atoms and molecules,  $M_r = m/m_u$ , where  $m$  is the mass of the atom or molecule and  $m_u$  is the atomic mass constant (see inside front cover), are still widely called ‘atomic weights’ and ‘molecular weights’ even though they are dimensionless quantities and not weights (the gravitational force exerted on an object).

A sample of matter may be subjected to a **pressure**,  $p$  (unit: 1 pascal, Pa; 1 Pa = 1 kg m<sup>-1</sup> s<sup>-2</sup>), which is defined as the force,  $F$ , it is subjected to divided by the area,  $A$ , to which that force is applied. A sample of gas exerts a pressure on the walls of its container because the molecules of gas are in ceaseless, random motion, and exert a force when they strike the walls. The frequency of the collisions is normally so great that the force, and therefore the pressure, is perceived as being steady.

Although 1 pascal is the SI unit of pressure (*The chemist’s toolkit* A.1), it is also common to express pressure in bar (1 bar = 10<sup>5</sup> Pa) or atmospheres (1 atm = 101 325 Pa exactly), both of which correspond to typical atmospheric pressure. Because many physical properties depend on the pressure acting on a sample, it is appropriate to select a certain value of the pressure to report their values. The **standard pressure** for reporting physical quantities is currently defined as  $p^\ominus = 1 \text{ bar}$  exactly.

### The chemist's toolkit A.1 Quantities and units

The result of a measurement is a **physical quantity** that is reported as a numerical multiple of a unit:

$$\text{physical quantity} = \text{numerical value} \times \text{unit}$$

It follows that units may be treated like algebraic quantities and may be multiplied, divided, and cancelled. Thus, the expression (physical quantity)/unit is the numerical value (a dimensionless quantity) of the measurement in the specified units. For instance, the mass  $m$  of an object could be reported as  $m = 2.5 \text{ kg}$  or  $m/\text{kg} = 2.5$ . See Table A.1 in the *Resource section* for a list of units. Although it is good practice to use only SI units, there will be occasions where accepted practice is so deeply rooted that physical quantities are expressed using other, non-SI units. By international convention, all physical quantities are represented by oblique (sloping) symbols; all units are roman (upright).

Units may be modified by a prefix that denotes a factor of a power of 10. Among the most common SI prefixes are those listed in Table A.2 in the *Resource section*. Examples of the use of these prefixes are:

$$1 \text{ nm} = 10^{-9} \text{ m} \quad 1 \text{ ps} = 10^{-12} \text{ s} \quad 1 \mu\text{mol} = 10^{-6} \text{ mol}$$

Powers of units apply to the prefix as well as the unit they modify. For example,  $1 \text{ cm}^3 = 1 (\text{cm})^3$ , and  $(10^{-2} \text{ m})^3 = 10^{-6} \text{ m}^3$ . Note that  $1 \text{ cm}^3$  does not mean  $1 \text{ c}(\text{m}^3)$ . When carrying out numerical calculations, it is usually safest to write out the numerical value of an observable in scientific notation (as  $n.nnn \times 10^n$ ).

There are seven SI base units, which are listed in Table A.3 in the *Resource section*. All other physical quantities may be expressed as combinations of these base units (see Table A.4 in the *Resource section*). *Molar concentration* (more formally, but very rarely, *amount of substance concentration*) for example, which is an amount of substance divided by the volume it occupies, can be expressed using the derived units of  $\text{mol dm}^{-3}$  as a combination of the base units for amount of substance and length. A number of these derived combinations of units have special names and symbols and we highlight them as they arise.

To specify the state of a sample fully it is also necessary to give its **temperature**,  $T$ . The temperature is formally a property that determines in which direction energy will flow as heat when two samples are placed in contact through thermally conducting walls: energy flows from the sample with the higher temperature to the sample with the lower temperature. The symbol  $T$  is used to denote the **thermodynamic temperature** which is an absolute scale with  $T=0$  as the lowest point. Temperatures above  $T=0$  are then most commonly expressed by using the **Kelvin scale**, in which the gradations of temperature are expressed as multiples of the unit 1 kelvin (1 K). The Kelvin scale is currently defined by setting the triple point of

water (the temperature at which ice, liquid water, and water vapour are in mutual equilibrium) at exactly 273.16 K (as for certain other units, a decision has been taken to revise this definition, but it has not yet, in 2014, been implemented). The freezing point of water (the melting point of ice) at 1 atm is then found experimentally to lie 0.01 K below the triple point, so the freezing point of water is 273.15 K. The Kelvin scale is unsuitable for everyday measurements of temperature, and it is common to use the **Celsius scale**, which is defined in terms of the Kelvin scale as

$$\theta / ^\circ\text{C} = T / \text{K} - 273.15 \quad \text{Definition} \quad \text{Celsius scale} \quad (\text{A.4})$$

Thus, the freezing point of water is  $0^\circ\text{C}$  and its boiling point (at 1 atm) is found to be  $100^\circ\text{C}$  (more precisely  $99.974^\circ\text{C}$ ). Note that in this text  $T$  invariably denotes the thermodynamic (absolute) temperature and that temperatures on the Celsius scale are denoted  $\theta$  (theta).

*A note on good practice* Note that we write  $T=0$ , not  $T=0 \text{ K}$ . General statements in science should be expressed without reference to a specific set of units. Moreover, because  $T$  (unlike  $\theta$ ) is absolute, the lowest point is 0 regardless of the scale used to express higher temperatures (such as the Kelvin scale). Similarly, we write  $m=0$ , not  $m=0 \text{ kg}$  and  $l=0$ , not  $l=0 \text{ m}$ .

### (b) The perfect gas equation

The properties that define the state of a system are not in general independent of one another. The most important example of a relation between them is provided by the idealized fluid known as a **perfect gas** (also, commonly, an ‘ideal gas’):

$$pV = nRT \quad \text{Perfect gas equation} \quad (\text{A.5})$$

Here  $R$  is the **gas constant**, a universal constant (in the sense of being independent of the chemical identity of the gas) with the value  $8.3145 \text{ J K}^{-1} \text{ mol}^{-1}$ . Throughout this text, equations applicable only to perfect gases (and other idealized systems) are labelled, as here, with a number in blue.

*A note on good practice* Although the term ‘ideal gas’ is almost universally used in place of ‘perfect gas’, there are reasons for preferring the latter term. In an ideal system the interactions between molecules in a mixture are all the same. In a perfect gas not only are the interactions all the same but they are in fact zero. Few, though, make this useful distinction.

Equation A.5, the **perfect gas equation**, is a summary of three empirical conclusions, namely Boyle’s law ( $p \propto 1/V$  at constant temperature and amount), Charles’s law ( $p \propto T$  at constant volume and amount), and Avogadro’s principle ( $V \propto n$  at constant temperature and pressure).

**Example A.1** Using the perfect gas equation

Calculate the pressure in kilopascals exerted by 1.25 g of nitrogen gas in a flask of volume 250 cm<sup>3</sup> at 20 °C.

**Method** To use eqn A.5, we need to know the amount of molecules (in moles) in the sample, which we can obtain from the mass and the molar mass (by using eqn A.3) and to convert the temperature to the Kelvin scale (by using eqn A.4).

**Answer** The amount of N<sub>2</sub> molecules (of molar mass 28.02 g mol<sup>-1</sup>) present is

$$n(\text{N}_2) = \frac{m}{M(\text{N}_2)} = \frac{1.25 \text{ g}}{28.02 \text{ g mol}^{-1}} = \frac{1.25}{28.02} \text{ mol}$$

The temperature of the sample is

$$T/\text{K} = 20 + 273.15, \text{ so } T = (20 + 273.15)\text{K}$$

Therefore, after rewriting eqn A.5 as  $p = nRT/V$ ,

$$p = \frac{\overbrace{(1.25/28.02) \text{ mol}}^n \times \overbrace{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1})}^R \times \overbrace{(20+273.15) \text{ K}}^T}{\underbrace{(2.50 \times 10^{-4}) \text{ m}^3}_V}$$

$$= \frac{(1.25/28.02) \times (8.3145) \times (20+273.15) \text{ J}}{2.50 \times 10^{-4} \text{ m}^3}$$

$1 \text{ J m}^{-3} = 1 \text{ Pa}$

$$\hat{=} 4.35 \times 10^5 \text{ Pa} = 435 \text{ kPa}$$

*A note on good practice* It is best to postpone a numerical calculation to the last possible stage, and carry it out in a single step. This procedure avoids rounding errors. When

we judge it appropriate to show an intermediate result without committing ourselves to a number of significant figures, we write it as *n.nnn...*

**Self-test A.5** Calculate the pressure exerted by 1.22 g of carbon dioxide confined in a flask of volume 500 dm<sup>3</sup> ( $5.00 \times 10^2 \text{ dm}^3$ ) at 37 °C.

Answer: 143 Pa

All gases obey the perfect gas equation ever more closely as the pressure is reduced towards zero. That is, eqn A.5 is an example of a **limiting law**, a law that becomes increasingly valid in a particular limit, in this case as the pressure is reduced to zero. In practice, normal atmospheric pressure at sea level (about 1 atm) is already low enough for most gases to behave almost perfectly, and unless stated otherwise, we assume in this text that the gases we encounter behave perfectly and obey eqn A.5.

A mixture of perfect gases behaves like a single perfect gas. According to **Dalton's law**, the total pressure of such a mixture is the sum of the pressures to which each gas would give rise if it occupied the container alone:

$$p = p_A + p_B + \dots \quad \text{Dalton's law (A.6)}$$

Each pressure,  $p_j$ , can be calculated from the perfect gas equation in the form  $p_j = n_j RT/V$ .

## Checklist of concepts

- 1. In the **nuclear model** of an atom negatively charged electrons occupy atomic orbitals which are arranged in shells around a positively charged nucleus.
- 2. The **periodic table** highlights similarities in electronic configurations of atoms, which in turn lead to similarities in their physical and chemical properties.
- 3. **Covalent compounds** consist of discrete molecules in which atoms are linked by covalent bonds.
- 4. **Ionic compounds** consist of cations and anions in a crystalline array.
- 5. **Lewis structures** are useful models of the pattern of bonding in molecules.
- 6. The **valence-shell electron pair repulsion theory** (VSEPR theory) is used to predict the three-dimensional shapes of molecules from their Lewis structures.
- 7. The electrons in **polar covalent bonds** are shared unequally between the bonded nuclei.
- 8. The physical states of bulk matter are solid, liquid, or gas.
- 9. The state of a sample of bulk matter is defined by specifying its properties, such as mass, volume, amount, pressure, and temperature.
- 10. The **perfect gas equation** is a relation between the pressure, volume, amount, and temperature of an idealized gas.
- 11. A **limiting law** is a law that becomes increasingly valid in a particular limit.

## Checklist of equations

Property	Equation	Comment	Equation number
Electric dipole moment	$\mu = Qd$	$\mu$ is the magnitude of the moment	A.1

### ► Why do you need to know this material?

Energy is the central unifying concept of physical chemistry, and you need to gain insight into how electrons, atoms, and molecules gain, store, and lose energy.

### ► What is the key idea?

Energy, the capacity to do work, is restricted to discrete values in electrons, atoms, and molecules.

### ► What do you need to know already?

You need to review the laws of motion and principles of electrostatics normally covered in introductory physics and concepts of thermodynamics normally covered in introductory chemistry.

Much of chemistry is concerned with transfers and transformations of energy, and from the outset it is appropriate to define this familiar quantity precisely. We begin here by reviewing **classical mechanics**, which was formulated by Isaac Newton in the seventeenth century, and establishes the vocabulary used to describe the motion and energy of particles. These classical ideas prepare us for **quantum mechanics**, the more fundamental theory formulated in the twentieth century for the study of small particles, such as electrons, atoms, and molecules. We develop the concepts of quantum mechanics throughout the text. Here we begin to see why it is needed as a foundation for understanding atomic and molecular structure.

## B.1 Force

Molecules are built from atoms and atoms are built from subatomic particles. To understand their structures we need to know how these bodies move under the influence of the forces they experience.

### (a) Momentum

'Translation' is the motion of a particle through space. The **velocity**,  $v$ , of a particle is the rate of change of its position  $r$ :

$$v = \frac{dr}{dt} \quad \text{Definition Velocity (B.1)}$$

For motion confined to a single dimension, we would write  $v_x = dx/dt$ . The velocity and position are vectors, with both direction and magnitude (vectors and their manipulation are treated in detail in *Mathematical background 5*). The magnitude of the velocity is the **speed**,  $v$ . The **linear momentum**,  $p$ , of a particle of mass  $m$  is related to its velocity,  $v$ , by

$$p = mv \quad \text{Definition Linear momentum (B.2)}$$

Like the velocity vector, the linear momentum vector points in the direction of travel of the particle (Fig. B.1); its magnitude is denoted  $p$ .

The description of rotation is very similar to that of translation. The rotational motion of a particle about a central point is described by its **angular momentum**,  $J$ . The angular

**Figure B.1** The linear momentum  $\mathbf{p}$  is denoted by a vector of magnitude  $p$  and an orientation that corresponds to the direction of motion.

**Figure B.2** The angular momentum  $\mathbf{J}$  of a particle is represented by a vector along the axis of rotation and perpendicular to the plane of rotation. The length of the vector denotes the magnitude  $J$  of the angular momentum. The direction of motion is clockwise to an observer looking in the direction of the vector.

momentum is a vector: its magnitude gives the rate at which a particle circulates and its direction indicates the axis of rotation (Fig. B.2). The magnitude of the angular momentum,  $J$ , is

$$J = I\omega \quad \text{Angular momentum} \quad (\text{B.3})$$

where  $\omega$  is the **angular velocity** of the body, its rate of change of angular position (in radians per second), and  $I$  is the **moment of inertia**, a measure of its resistance to rotational acceleration. For a point particle of mass  $m$  moving in a circle of radius  $r$ , the moment of inertia about the axis of rotation is

$$I = mr^2 \quad \text{Point particle} \quad \text{Moment of inertia} \quad (\text{B.4})$$

#### Brief illustration B.1 The moment of inertia

There are two possible axes of rotation in a  $\text{C}^{16}\text{O}_2$  molecule, each passing through the C atom and perpendicular to the axis of the molecule and to each other. Each O atom is at a distance  $R$  from the axis of rotation, where  $R$  is the length of a CO

bond, 116 pm. The mass of each  $^{16}\text{O}$  atom is  $16.00m_u$ , where  $m_u = 1.66054 \times 10^{-27}$  is the atomic mass constant. The C atom is stationary (it lies on the axis of rotation) and does not contribute to the moment of inertia. Therefore, the moment of inertia of the molecule around the rotation axis is

$$I = 2m(^{16}\text{O})R^2 = 2 \times \left[ \overbrace{16.00 \times 1.66054 \times 10^{-27} \text{ kg}}^{m(^{16}\text{O})} \right] \times \left( \overbrace{1.16 \times 10^{-10} \text{ m}}^R \right)^2 \\ = 7.15 \times 10^{-46} \text{ kg m}^2$$

Note that the units of moments of inertia are kilograms-metre squared ( $\text{kg m}^2$ ).

**Self-test B.1** The moment of inertia for rotation of a hydrogen molecule,  $^1\text{H}_2$ , about an axis perpendicular to its bond is  $4.61 \times 10^{-48} \text{ kg m}^2$ . What is the bond length of  $\text{H}_2$ ?

Answer: 74.14 pm

### (b) Newton's second law of motion

According to **Newton's second law of motion**, the rate of change of momentum is equal to the force acting on the particle:

$$\frac{d\mathbf{p}}{dt} = \mathbf{F} \quad \text{Newton's second law of motion} \quad (\text{B.5a})$$

For motion confined to one dimension, we would write  $dp_x/dt = F_x$ . Equation B.5a may be taken as the definition of force. The SI units of force are newtons (N), with

$$1 \text{ N} = 1 \text{ kg m s}^{-2}$$

Because  $\mathbf{p} = m(d\mathbf{r}/dt)$ , it is sometimes more convenient to write eqn B.5a as

$$m\mathbf{a} = \mathbf{F} \quad \mathbf{a} = \frac{d^2\mathbf{r}}{dt^2} \quad \text{Alternative form} \quad \text{Newton's second law of motion} \quad (\text{B.5b})$$

where  $\mathbf{a}$  is the **acceleration** of the particle, its rate of change of velocity. It follows that if we know the force acting everywhere and at all times, then solving eqn B.5 will give the **trajectory**, the position and momentum of the particle at each instant.

#### Brief illustration B.2 Newton's second law of motion

A *harmonic oscillator* consists of a particle that experiences a 'Hooke's law' restoring force, one that is proportional to its displacement from equilibrium. An example is a particle of

mass  $m$  attached to a spring or an atom attached to another by a chemical bond. For a one-dimensional system,  $F_x = -k_f x$ , where the constant of proportionality  $k_f$  is called the *force constant*. Equation B.5b becomes

$$m \frac{d^2 x}{dt^2} = -k_f x$$

(Techniques of differentiation are reviewed in *Mathematical background 1* following Chapter 1.) If  $x=0$  at  $t=0$ , a solution (as may be verified by substitution) is

$$x(t) = A \sin(2\pi\nu t) \quad \nu = \frac{1}{2\pi} \left( \frac{k_f}{m} \right)^{1/2}$$

This solution shows that the position of the particle varies *harmonically* (that is, as a sine function) with a frequency  $\nu$ , and that the frequency is high for light particles ( $m$  small) attached to stiff springs ( $k_f$  large).

**Self-test B.2** How does the momentum of the oscillator vary with time?

$$\text{Answer: } p = 2\pi\nu A m \cos(2\pi\nu t)$$

To accelerate a rotation it is necessary to apply a **torque**,  $T$ , a twisting force. Newton's equation is then

$$\frac{dT}{dt} = T \quad \text{Definition Torque (B.6)}$$

The analogous roles of  $m$  and  $I$ , of  $\nu$  and  $\omega$ , and of  $p$  and  $J$  in the translational and rotational cases respectively should be remembered because they provide a ready way of constructing and recalling equations. These analogies are summarized in Table B.1.

Table B.1 Analogies between translation and rotation

Translation		Rotation	
Property	Significance	Property	Significance
Mass, $m$	Resistance to the effect of a force	Moment of inertia, $I$	Resistance to the effect of a torque
Speed, $v$	Rate of change of position	Angular velocity, $\omega$	Rate of change of angle
Magnitude of linear momentum, $p$	$p = mv$	Magnitude of angular momentum, $J$	$J = I\omega$
Translational kinetic energy, $E_k$	$E_k = \frac{1}{2}mv^2$ $= p^2/2m$	Rotational kinetic energy, $E_k$	$E_k = \frac{1}{2}I\omega^2$ $= J^2/2I$
Equation of motion	$dp/dt = F$	Equation of motion	$dJ/dt = T$

## B.2 Energy: a first look

Before defining the term 'energy', we need to develop another familiar concept, that of 'work', more formally. Then we preview the uses of these concepts in chemistry.

### (a) Work

**Work**,  $w$ , is done in order to achieve motion against an opposing force. For an infinitesimal displacement through  $ds$  (a vector), the work done is

$$dw = -F \cdot ds \quad \text{Definition Work (B.7a)}$$

where  $F \cdot ds$  is the 'scalar product' of the vectors  $F$  and  $ds$ :

$$F \cdot ds = F_x dx + F_y dy + F_z dz \quad \text{Definition Scalar product (B.7b)}$$

For motion in one dimension, we write  $dw = -F_x dx$ . The total work done along a path is the integral of this expression, allowing for the possibility that  $F$  changes in direction and magnitude at each point of the path. With force in newtons and distance in metres, the units of work are joules (J), with

$$1 \text{ J} = 1 \text{ N m} = 1 \text{ kg m}^2 \text{ s}^{-2}$$

### Brief illustration B.3 The work of stretching a bond

The work needed to stretch a chemical bond that behaves like a spring through an infinitesimal distance  $dx$  is

$$dw = -F_x dx = -(-k_f x) dx = k_f x dx$$

The total work needed to stretch the bond from zero displacement ( $x=0$ ) at its equilibrium length  $R_e$  to a length  $R$ , corresponding to a displacement  $x = R - R_e$ , is

$$w = \int_0^{R-R_e} k_f x dx = k_f \int_0^{R-R_e} x dx = \frac{1}{2} k_f (R - R_e)^2$$

We see that the work required increases as the square of the displacement: it takes four times as much work to stretch a bond through 20 pm as it does to stretch the same bond through 10 pm.

**Self-test B.3** The force constant of the H-H bond is about  $575 \text{ N m}^{-1}$ . How much work is needed to stretch this bond by 10 pm?

$$\text{Answer: } 28.8 \text{ zJ}$$

### (b) The definition of energy

**Energy** is the capacity to do work. The SI unit of energy is the same as that of work, namely the joule. The rate of

supply of energy is called the **power** ( $P$ ), and is expressed in watts (W):

$$1 \text{ W} = 1 \text{ J s}^{-1}$$

Calories (cal) and kilocalories (kcal) are still encountered in the chemical literature. The calorie is now defined in terms of the joule, with  $1 \text{ cal} = 4.184 \text{ J}$  (exactly). Caution needs to be exercised as there are several different kinds of calorie. The ‘thermochemical calorie’,  $\text{cal}_{15}$ , is the energy required to raise the temperature of 1 g of water at  $15^\circ\text{C}$  by  $1^\circ\text{C}$  and the ‘dietary Calorie’ is 1 kcal.

A particle may possess two kinds of energy, kinetic energy and potential energy. The **kinetic energy**,  $E_k$ , of a body is the energy the body possesses as a result of its motion. For a body of mass  $m$  travelling at a speed  $v$ ,

$$E_k = \frac{1}{2}mv^2 \quad \text{Definition Kinetic energy (B.8)}$$

It follows from Newton’s second law that if a particle of mass  $m$  is initially stationary and is subjected to a constant force  $F$  for a time  $\tau$ , then its speed increases from zero to  $F\tau/m$  and therefore its kinetic energy increases from zero to

$$E_k = \frac{F^2\tau^2}{2m} \quad \text{(B.9)}$$

The energy of the particle remains at this value after the force ceases to act. Because the magnitude of the applied force,  $F$ , and the time,  $\tau$ , for which it acts may be varied at will, eqn B.9 implies that the energy of the particle may be increased to any value.

The **potential energy**,  $E_p$  or  $V$ , of a body is the energy it possesses as a result of its position. Because (in the absence of losses) the work that a particle can do when it is stationary in a given location is equal to the work that had to be done to bring it there, we can use the one-dimensional version of eqn B.7 to write  $dV = -F_x dx$ , and therefore

$$F_x = -\frac{dV}{dx} \quad \text{Definition Potential energy (B.10)}$$

No universal expression for the potential energy can be given because it depends on the type of force the body experiences. For a particle of mass  $m$  at an altitude  $h$  close to the surface of the Earth, the gravitational potential energy is

$$V(h) = V(0) + mgh \quad \text{Gravitational potential energy (B.11)}$$

where  $g$  is the **acceleration of free fall** ( $g$  depends on location, but its ‘standard value’ is close to  $9.81 \text{ m s}^{-2}$ ). The zero of potential energy is arbitrary. For a particle close to the surface of the Earth, it is common to set  $V(0) = 0$ .

The **total energy** of a particle is the sum of its kinetic and potential energies:

$$E = E_k + E_p, \text{ or } E = E_k + V \quad \text{Definition Total energy (B.12)}$$

We make use of the apparently universal law of nature that *energy is conserved*; that is, energy can neither be created nor destroyed. Although energy can be transferred from one location to another and transformed from one form to another, the total energy is constant. In terms of the linear momentum, the total energy of a particle is

$$E = \frac{p^2}{2m} + V \quad \text{(B.13)}$$

This expression may be used in place of Newton’s second law to calculate the trajectory of a particle.

#### Brief illustration B.4 The trajectory of a particle

Consider an argon atom free to move in one direction (along the  $x$ -axis) in a region where  $V=0$  (so the energy is independent of position). Because  $v = dx/dt$ , it follows from eqns B.1 and B.8 that  $dx/dt = (2E_k/m)^{1/2}$ . As may be verified by substitution, a solution of this differential equation is

$$x(t) = x(0) + \left(\frac{2E_k}{m}\right)^{1/2} t$$

The linear momentum is

$$p(t) = mv(t) = m \frac{dx}{dt} = (2mE_k)^{1/2}$$

and is a constant. Hence, if we know the initial position and momentum, we can predict all later positions and momenta exactly.

**Self-test B.4** Consider an atom of mass  $m$  moving along the  $x$  direction with an initial position  $x_1$  and initial speed  $v_1$ . If the atom moves for a time interval  $\Delta t$  in a region where the potential energy varies as  $V(x)$ , what is its speed  $v_2$  at position  $x_2$ ?

$$\text{Answer: } v_2 = v_1 \left| \frac{dV(x)}{dx} \right|_{x_1} \Delta t / m$$

### (c) The Coulomb potential energy

One of the most important kinds of potential energy in chemistry is the **Coulomb potential energy** between two electric charges. The Coulomb potential energy is equal to the work that must be done to bring up a charge from infinity to a distance  $r$  from a second charge. For a point charge  $Q_1$  at a

distance  $r$  in a vacuum from another point charge  $Q_2$ , their potential energy is

$$V(r) = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \quad \text{Definition} \quad \text{Coulomb potential energy} \quad (\text{B.14})$$

Charge is expressed in coulombs (C), often as a multiple of the fundamental charge,  $e$ . Thus, the charge of an electron is  $-e$  and that of a proton is  $+e$ ; the charge of an ion is  $ze$ , with  $z$  the **charge number** (positive for cations, negative for anions). The constant  $\epsilon_0$  (epsilon zero) is the **vacuum permittivity**, a fundamental constant with the value  $8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$ . It is conventional (as in eqn B.14) to set the potential energy equal to zero at infinite separation of charges. Then two opposite charges have a negative potential energy at finite separations whereas two like charges have a positive potential energy.

#### Brief illustration B.5 The Coulomb potential energy

The Coulomb potential energy resulting from the electrostatic interaction between a positively charged sodium cation,  $\text{Na}^+$ , and a negatively charged chloride anion,  $\text{Cl}^-$ , at a distance of 0.280 nm, which is the separation between ions in the lattice of a sodium chloride crystal, is

$$V = \frac{\overbrace{(-1.602 \times 10^{-19} \text{ C})}^{Q(\text{Cl}^-)} \times \overbrace{(1.602 \times 10^{-19} \text{ C})}^{Q(\text{Na}^+)}}{4\pi \times \underbrace{(8.854 \times 10^{-12} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1})}_{\epsilon_0} \times \underbrace{(0.280 \times 10^{-9} \text{ m})}_r} = -8.24 \times 10^{-19} \text{ J}$$

This value is equivalent to a molar energy of

$$V \times N_A = (-8.24 \times 10^{-19} \text{ J}) \times (6.022 \times 10^{23} \text{ mol}^{-1}) = -496 \text{ kJ mol}^{-1}$$

*A note on good practice:* Write units at every stage of a calculation and do not simply attach them to a final numerical value. Also, it is often sensible to express all numerical quantities in scientific notation using exponential format rather than SI prefixes to denote powers of ten.

**Self-test B.5:** The centres of neighbouring cations and anions in magnesium oxide crystals are separated by 0.21 nm. Determine the molar Coulomb potential energy resulting from the electrostatic interaction between a  $\text{Mg}^{2+}$  and an  $\text{O}^{2-}$  ion in such a crystal.

Answer: 2600 kJ mol<sup>-1</sup>

In a medium other than a vacuum, the potential energy of interaction between two charges is reduced, and the vacuum permittivity is replaced by the **permittivity**,  $\epsilon$ , of the medium. The permittivity is commonly expressed as a multiple of the vacuum permittivity:

$$\epsilon = \epsilon_r \epsilon_0 \quad \text{Definition} \quad \text{Permittivity} \quad (\text{B.15})$$

with  $\epsilon_r$  the dimensionless **relative permittivity** (formerly, the *dielectric constant*). This reduction in potential energy can be substantial: the relative permittivity of water at 25 °C is 80, so the reduction in potential energy for a given pair of charges at a fixed difference (with sufficient space between them for the water molecules to behave as a fluid) is by nearly two orders of magnitude.

Care should be taken to distinguish *potential energy* from *potential*. The potential energy of a charge  $Q_1$  in the presence of another charge  $Q_2$  can be expressed in terms of the **Coulomb potential**,  $\phi$  (phi):

$$V(r) = Q_1 \phi(r) \quad \phi(r) = \frac{Q_2}{4\pi\epsilon_0 r} \quad \text{Definition} \quad \text{Coulomb potential} \quad (\text{B.16})$$

The units of potential are joules per coulomb,  $\text{J C}^{-1}$ , so when  $\phi$  is multiplied by a charge in coulombs, the result is in joules. The combination joules per coulomb occurs widely and is called a volt (V):

$$1 \text{ V} = 1 \text{ J C}^{-1}$$

If there are several charges  $Q_2, Q_3, \dots$  present in the system, the total potential experienced by the charge  $Q_1$  is the sum of the potential generated by each charge:

$$\phi = \phi_2 + \phi_3 + \dots \quad (\text{B.17})$$

Just as the potential energy of a charge  $Q_1$  can be written  $V = Q_1 \phi$ , so the magnitude of the force on  $Q_1$  can be written  $F = Q_1 \mathcal{E}$ , where  $\mathcal{E}$  is the magnitude of the **electric field strength** (units: volts per metre,  $\text{V m}^{-1}$ ) arising from  $Q_2$  or from some more general charge distribution. The electric field strength (which, like the force, is actually a vector quantity) is the negative gradient of the electric potential. In one dimension, we write the magnitude of the electric field strength as

$$\mathcal{E} = -\frac{d\phi}{dx} \quad \text{Electric field strength} \quad (\text{B.18})$$

The language we have just developed inspires an important alternative energy unit, the **electronvolt** (eV): 1 eV is defined as the kinetic energy acquired when an electron is accelerated from rest through a potential difference of 1 V. The relation between electronvolts and joules is

$$1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$$

Many processes in chemistry involve energies of a few electronvolts. For example, to remove an electron from a sodium atom requires about 5 eV.

A particularly important way of supplying energy in chemistry (as in the everyday world) is by passing an electric current

through a resistance. An **electric current** ( $I$ ) is defined as the rate of supply of charge,  $I = dQ/dt$ , and is measured in *amperes* (A):

$$1 \text{ A} = 1 \text{ C s}^{-1}$$

If a charge  $Q$  is transferred from a region of potential  $\phi_i$ , where its potential energy is  $Q\phi_i$ , to where the potential is  $\phi_f$  and its potential energy is  $Q\phi_f$ , and therefore through a potential difference  $\Delta\phi = \phi_f - \phi_i$ , the change in potential energy is  $Q\Delta\phi$ . The rate at which the energy changes is  $(dQ/dt)\Delta\phi$ , or  $I\Delta\phi$ . The power is therefore

$$P = I\Delta\phi \quad \text{Electrical power} \quad (\text{B.19})$$

With current in amperes and the potential difference in volts, the power is in watts. The total energy,  $E$ , supplied in an interval  $\Delta t$  is the power (the rate of energy supply) multiplied by the duration of the interval:

$$E = P\Delta t = I\Delta\phi\Delta t \quad (\text{B.20})$$

The energy is obtained in joules with the current in amperes, the potential difference in volts, and the time in seconds.

#### (d) Thermodynamics

The systematic discussion of the transfer and transformation of energy in bulk matter is called **thermodynamics**. This subtle subject is treated in detail in the text, but it will be familiar from introductory chemistry that there are two central concepts, the **internal energy**,  $U$  (units: joules, J), and the **entropy**,  $S$  (units: joules per kelvin,  $\text{J K}^{-1}$ ).

The internal energy is the total energy of a system. The **First Law of thermodynamics** states that the internal energy is constant in a system isolated from external influences. The internal energy of a sample of matter increases as its temperature is raised, and we write

$$\Delta U = C\Delta T \quad \text{Change in internal energy} \quad (\text{B.21})$$

where  $\Delta U$  is the change in internal energy when the temperature of the sample is raised by  $\Delta T$ . The constant  $C$  is called the **heat capacity**,  $C$  (units: joules per kelvin,  $\text{J K}^{-1}$ ), of the sample. If the heat capacity is large, a small increase in temperature results in a large increase in internal energy. This remark can be expressed in a physically more significant way by inverting it: if the heat capacity is large, then even a large transfer of energy into the system leads to only a small rise in temperature. The heat capacity is an extensive property, and values for a substance are commonly reported as the **molar heat capacity**,  $C_m = C/n$  (units: joules per kelvin per mole,  $\text{J K}^{-1} \text{ mol}^{-1}$ ) or the **specific heat capacity**,  $C_s = C/m$  (units: joules per kelvin per gram,  $\text{J K}^{-1} \text{ g}^{-1}$ ), both of which are intensive properties.

Thermodynamic properties are often best discussed in terms of infinitesimal changes, in which case we would write eqn B.21 as  $dU = CdT$ . When this expression is written in the form

$$C = \frac{dU}{dT} \quad \text{Definition Heat capacity} \quad (\text{B.22})$$

we see that the heat capacity can be interpreted as the slope of the plot of the internal energy of a sample against the temperature.

As will also be familiar from introductory chemistry and will be explained in detail later, for systems maintained at constant pressure it is usually more convenient to modify the internal energy by adding to it the quantity  $pV$ , and introducing the **enthalpy**,  $H$  (units: joules, J):

$$H = U + pV \quad \text{Definition Enthalpy} \quad (\text{B.23})$$

The enthalpy, an extensive property, greatly simplifies the discussion of chemical reactions, in part because changes in enthalpy can be identified with the energy transferred as heat from a system maintained at constant pressure (as in common laboratory experiments).

#### Brief illustration B.6 The relation between $U$ and $H$

The internal energy and enthalpy of a perfect gas, for which  $pV = nRT$ , are related by

$$H = U + nRT$$

Division by  $n$  and rearrangement gives

$$H_m - U_m = RT$$

where  $H_m$  and  $U_m$  are the molar enthalpy and the molar internal energy, respectively. We see that the difference between  $H_m$  and  $U_m$  increases with temperature.

**Self-test B.6** By how much does the molar enthalpy of oxygen gas differ from its molar internal energy at 298 K?

Answer: 2.48  $\text{kJ mol}^{-1}$

The **entropy**,  $S$ , is a measure of the *quality* of the energy of a system. If the energy is distributed over many modes of motion (for example, the rotational, vibrational, and translational motions for the particles that comprise the system), then the entropy is high. If the energy is distributed over only a small number of modes of motion, then the entropy is low. The **Second Law of thermodynamics** states that any spontaneous (that is, natural) change in an isolated system is accompanied by an increase in the entropy of the system. This tendency is commonly expressed by saying that the natural direction of change is accompanied by dispersal of energy from a localized region or its conversion to a less organized form.

The entropy of a system and its surroundings is of the greatest importance in chemistry because it enables us to identify the spontaneous direction of a chemical reaction and to identify the composition at which the reaction is at **equilibrium**. In a state of *dynamic* equilibrium, which is the character of all chemical equilibria, the forward and reverse reactions are occurring at the same rate and there is no net tendency to change in either direction. However, to use the entropy to identify this state we need to consider both the system and its surroundings. This task can be simplified if the reaction is taking place at constant temperature and pressure, for then it is possible to identify the state of equilibrium as the state at which the **Gibbs energy**,  $G$  (units: joules, J), of the system has reached a minimum. The Gibbs energy is defined as

$$G = H - TS \quad \text{Definition} \quad \text{Gibbs energy} \quad (\text{B.24})$$

and is of the greatest importance in chemical thermodynamics. The Gibbs energy, which informally is called the ‘free energy’, is a measure of the energy stored in a system that is free to do useful work, such as driving electrons through a circuit or causing a reaction to be driven in its nonspontaneous (unnatural) direction.

## B.3 The relation between molecular and bulk properties

The energy of a molecule, atom, or subatomic particle that is confined to a region of space is **quantized**, or restricted to certain discrete values. These permitted energies are called **energy levels**. The values of the permitted energies depend on the characteristics of the particle (for instance, its mass) and the extent of the region to which it is confined. The quantization of energy is most important—in the sense that the allowed energies are widest apart—for particles of small mass confined to small regions of space. Consequently, quantization is very important for electrons in atoms and molecules, but usually unimportant for macroscopic bodies, for which the separation of translational energy levels of particles in containers of macroscopic dimensions is so small that for all practical purposes their translational motion is unquantized and can be varied virtually continuously.

The energy of a molecule other than its unquantized translational motion arises mostly from three modes of motion: rotation of the molecule as a whole, distortion of the molecule through vibration of its atoms, and the motion of electrons around nuclei. Quantization becomes increasingly important as we change focus from rotational to vibrational and then to electronic motion. The separation of rotational energy levels (in small molecules, about  $10^{-21}$  J or 1 zJ, corresponding to about  $0.6 \text{ kJ mol}^{-1}$ ) is smaller than that of vibrational energy levels

**Figure B.3** The energy level separations typical of four types of system. ( $1 \text{ zJ} = 10^{-21} \text{ J}$ ; in molar terms, 1 zJ is equivalent to about  $0.6 \text{ kJ mol}^{-1}$ .)

(about  $10\text{--}100 \text{ zJ}$ , or  $6\text{--}60 \text{ kJ mol}^{-1}$ ), which itself is smaller than that of electronic energy levels (about  $10^{-18} \text{ J}$  or 1 aJ, where a is another uncommon but useful SI prefix, standing for atto,  $10^{-18}$ , corresponding to about  $600 \text{ kJ mol}^{-1}$ ). Figure B.3 depicts these typical energy level separations.

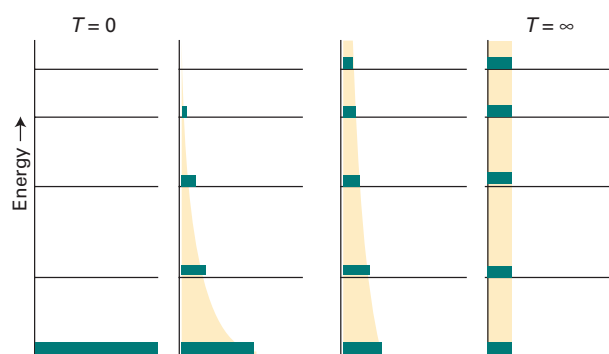

### (a) The Boltzmann distribution

The continuous thermal agitation that the molecules experience in a sample at  $T > 0$  ensures that they are distributed over the available energy levels. One particular molecule may be in a state corresponding to a low energy level at one instant, and then be excited into a high energy state a moment later. Although we cannot keep track of the state of a single molecule, we can speak of the *average* numbers of molecules in each state; even though individual molecules may be changing their states as a result of collisions, the average number in each state is constant (provided the temperature remains the same).

The average number of molecules in a state is called the **population** of the state. Only the lowest energy state is occupied at  $T = 0$ . Raising the temperature excites some molecules into higher energy states, and more and more states become accessible as the temperature is raised further (Fig. B.4). The formula for calculating the relative populations of states of various energies is called the **Boltzmann distribution** and was derived by the Austrian scientist Ludwig Boltzmann towards the end of the nineteenth century. This formula gives the ratio of the numbers of particles in states with energies  $\varepsilon_i$  and  $\varepsilon_j$  as

$$\frac{N_i}{N_j} = e^{-(\varepsilon_i - \varepsilon_j)/kT} \quad \text{Boltzmann distribution} \quad (\text{B.25a})$$

where  $k$  is **Boltzmann’s constant**, a fundamental constant with the value  $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ . In chemical applications it is common to use not the individual energies but energies per mole of molecules,  $E_i$ , with  $E_i = N_A \varepsilon_i$ , where  $N_A$  is Avogadro’s

**Figure B.4** The Boltzmann distribution of populations for a system of five energy levels as the temperature is raised from zero to infinity.

constant. When both the numerator and denominator in the exponential are multiplied by  $N_A$ , eqn B.25a becomes

$$\frac{N_i}{N_j} = e^{-(E_i - E_j)/RT} \quad \text{Alternative form} \quad \text{Boltzmann distribution} \quad (\text{B.25b})$$

where  $R = N_A k$ . We see that  $k$  is often disguised in ‘molar’ form as the gas constant. The Boltzmann distribution provides the crucial link for expressing the macroscopic properties of matter in terms of microscopic behaviour.

#### Brief illustration B.7 Relative populations

Methyl cyclohexane molecules may exist in one of two conformations, with the methyl group in either an equatorial or axial position. The equatorial form is lower in energy with the axial form being  $6.0 \text{ kJ mol}^{-1}$  higher in energy. At a temperature of  $300 \text{ K}$ , this difference in energy implies that the relative populations of molecules in the axial and equatorial states is

$$\frac{N_a}{N_e} = e^{-(E_a - E_e)/RT} = e^{-(6.0 \times 10^3 \text{ J mol}^{-1}) / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1} \times 300 \text{ K})} = 0.090$$

where  $E_a$  and  $E_e$  are molar energies. The number of molecules in an axial conformation is therefore just 9 per cent of those in the equatorial conformation.

**Self-test B.7** Determine the temperature at which the relative proportion of molecules in axial and equatorial conformations in a sample of methyl cyclohexane is 0.30 or 30 per cent.

Answer:  $600 \text{ K}$

The important features of the Boltzmann distribution to bear in mind are:

- The distribution of populations is an exponential function of energy and temperature.
- At a high temperature more energy levels are occupied than at a low temperature.

Physical interpretation

- More levels are significantly populated if they are close together in comparison with  $kT$  (like rotational and translational states), than if they are far apart (like vibrational and electronic states).

Figure B.5 summarizes the form of the Boltzmann distribution for some typical sets of energy levels. The peculiar shape of the population of rotational levels stems from the fact that eqn B.25 applies to *individual states*, and for molecular rotation quantum theory shows that the number of rotational states corresponding to a given energy level—broadly speaking, the number of planes of rotation—increases with energy; therefore, although the population of each *state* decreases with energy, the population of the *levels* goes through a maximum.

One of the simplest examples of the relation between microscopic and bulk properties is provided by **kinetic molecular theory**, a model of a perfect gas. In this model, it is assumed that the molecules, imagined as particles of negligible size, are in ceaseless, random motion and do not interact except during their brief collisions. Different speeds correspond to different energies, so the Boltzmann formula can be used to predict the proportions of molecules having a specific speed at a particular temperature. The expression giving the fraction of molecules that have a particular speed is called the **Maxwell–Boltzmann distribution** and has the features summarized in Fig. B.6. The Maxwell–Boltzmann distribution can be used to show that the average speed,  $v_{\text{mean}}$ , of the molecules depends on the temperature and their molar mass as

$$v_{\text{mean}} = \left( \frac{8RT}{\pi M} \right)^{1/2} \quad \text{Perfect gas} \quad \text{Average speed of molecules} \quad (\text{B.26})$$

Thus, the average speed is high for light molecules at high temperatures. The distribution itself gives more information. For instance, the tail towards high speeds is longer at high temperatures than at low, which indicates that at high temperatures more molecules in a sample have speeds much higher than average.

**Figure B.5** The Boltzmann distribution of populations for rotational, vibrational, and electronic energy levels at room temperature.

**Figure B.6** The (Maxwell–Boltzmann) distribution of molecular speeds with temperature and molar mass. Note that the most probable speed (corresponding to the peak of the distribution) increases with temperature and with decreasing molar mass, and simultaneously the distribution becomes broader.

### (b) Equipartition

Although the Boltzmann distribution can be used to calculate the average energy associated with each mode of motion of an atom or molecule in a sample at a given temperature, there is a much simpler shortcut. When the temperature is so high that many energy levels are occupied, we can use the **equipartition theorem**:

For a sample at thermal equilibrium the average value of each quadratic contribution to the energy is  $\frac{1}{2}kT$ .

By a ‘quadratic contribution’ we mean a term that is proportional to the square of the momentum (as in the expression for the kinetic energy,  $E_k = p^2/2m$ ) or the displacement from an

equilibrium position (as for the potential energy of a harmonic oscillator,  $E_p = \frac{1}{2}k_f x^2$ ). The theorem is strictly valid only at high temperatures or if the separation between energy levels is small because under these conditions many states are populated. The equipartition theorem is most reliable for translational and rotational modes of motion. The separation between vibrational and electronic states is typically greater than for rotation or translation, and so the equipartition theorem is unreliable for these types of motion.

#### Brief illustration B.8 Average molecular energies

An atom or molecule may move in three dimensions and its translational kinetic energy is therefore the sum of three quadratic contributions

$$E_{\text{trans}} = \frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2$$

The equipartition theorem predicts that the average energy for each of these quadratic contributions is  $\frac{1}{2}kT$ . Thus, the average kinetic energy is  $E_{\text{trans}} = 3 \times \frac{1}{2}kT = \frac{3}{2}kT$ . The molar translational energy is thus  $E_{\text{trans,m}} = \frac{3}{2}kT \times N_A = \frac{3}{2}RT$ . At 300 K

$$\begin{aligned} E_{\text{trans,m}} &= \frac{3}{2} \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (300 \text{ K}) = 3700 \text{ J mol}^{-1} \\ &= 3.7 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test B.8** A linear molecule may rotate about two axes in space, each of which counts as a quadratic contribution. Calculate the rotational contribution to the molar energy of a collection of linear molecules at 500 K.

Answer: 4.2 kJ mol<sup>-1</sup>

## Checklist of concepts

- 1. **Newton’s second law of motion** states that the rate of change of momentum is equal to the force acting on the particle.
- 2. **Work** is done in order to achieve motion against an opposing force.
- 3. **Energy** is the capacity to do work.
- 4. The **kinetic energy** of a particle is the energy it possesses as a result of its motion.
- 5. The **potential energy** of a particle is the energy it possesses as a result of its position.
- 6. The total energy of a particle is the sum of its kinetic and potential energies.
- 7. The **Coulomb potential energy** between two charges separated by a distance  $r$  varies as  $1/r$ .
- 8. The **First Law of thermodynamics** states that the internal energy is constant in a system isolated from external influences.
- 9. The **Second Law of thermodynamics** states that any spontaneous change in an isolated system is accompanied by an increase in the entropy of the system.
- 10. **Equilibrium** is the state at which the **Gibbs energy** of the system has reached a minimum.
- 11. The energy levels of confined particles are quantized.
- 12. The **Boltzmann distribution** is a formula for calculating the relative populations of states of various energies.
- 13. The **equipartition theorem** states that for a sample at thermal equilibrium the average value of each quadratic contribution to the energy is  $\frac{1}{2}kT$ .

### ► Why do you need to know this material?

Several important investigative techniques in physical chemistry, such as spectroscopy and X-ray diffraction, involve electromagnetic radiation, a wavelike electromagnetic disturbance. We shall also see that the properties of waves are central to the quantum mechanical description of electrons in atoms and molecules. To prepare for those discussions, we need to understand the mathematical description of waves.

### ► What is the key idea?

A wave is a disturbance that propagates through space with a displacement that can be expressed as a harmonic function.

### ► What do you need to know already?

You need to be familiar with the properties of harmonic (sine and cosine) functions.

A **wave** is an oscillatory disturbance that travels through space. Examples of such disturbances include the collective motion of water molecules in ocean waves and of gas particles in sound waves. A **harmonic wave** is a wave with a displacement that can be expressed as a sine or cosine function.

## C.1 Harmonic waves

A harmonic wave is characterized by a **wavelength**,  $\lambda$  (lambda), the distance between the neighbouring peaks of the wave, and its **frequency**,  $\nu$  (nu), the number of times per second at

which its displacement at a fixed point returns to its original value (Fig. C.1). The frequency is measured in *hertz*, where  $1 \text{ Hz} = 1 \text{ s}^{-1}$ . The wavelength and frequency are related by

$$\lambda\nu = v \quad \text{Relation between frequency and wavelength} \quad (\text{C.1})$$

where  $v$  is the speed of propagation of the wave.

First, consider the snapshot of a harmonic wave at  $t=0$ . The displacement  $\psi(x,t)$  varies with position  $x$  as

$$\psi(x,0) = A \cos\left\{\left(\frac{2\pi}{\lambda}\right)x + \phi\right\} \quad \text{Harmonic wave at } t=0 \quad (\text{C.2a})$$

where  $A$  is the **amplitude** of the wave, the maximum height of the wave, and  $\phi$  is the **phase** of the wave, the shift in the location of the peak from  $x=0$  and which may lie between  $-\pi$  and  $\pi$  (Fig. C.2). As time advances, the peaks migrate along the  $x$ -axis (the direction of propagation), and at any later instant the displacement is

$$\psi(x,t) = A \cos\left\{\left(\frac{2\pi}{\lambda}\right)x - 2\pi\nu t + \phi\right\} \quad \text{Harmonic wave at } t>0 \quad (\text{C.2b})$$

A given wave can also be expressed as a sine function with the same argument but with  $\phi$  replaced by  $\phi + \frac{1}{2}\pi$ .

If two waves, in the same region of space, with the same wavelength, have different phases then the resultant wave, the sum of the two, will have either enhanced or diminished amplitude. If the phases differ by  $\pm\pi$  (so the peaks of one wave coincide with the troughs of the other), then the resultant wave, the sum of the two, will have a diminished amplitude. This effect is called **destructive interference**. If the phases of the two waves

**Figure C.1** (a) The wavelength,  $\lambda$ , of a wave is the peak-to-peak distance. (b) The wave is shown travelling to the right at a speed  $v$ . At a given location, the instantaneous amplitude of the wave changes through a complete cycle (the six dots show half a cycle) as it passes a given point. The frequency,  $\nu$ , is the number of cycles per second that occur at a given point. Wavelength and frequency are related by  $\lambda\nu = v$ .

**Figure C.2** The phase  $\phi$  of a wave specifies the relative location of its peaks.

are the same (coincident peaks), the resultant has an enhanced amplitude. This effect is called **constructive interference**.

### Brief illustration C.1 Resultant waves

To gain insight into cases in which the phase difference is a value other than  $\pm\pi$ , consider the addition of the waves  $f(x) = \cos(2\pi x/\lambda)$  and  $g(x) = \cos\{2\pi x/\lambda + \phi\}$ . Figure C.3 shows plots of  $f(x)$ ,  $g(x)$ , and  $f(x) + g(x)$  against  $x/\lambda$  for  $\phi = \pi/3$ . The resultant wave has a greater amplitude than either  $f(x)$  or  $g(x)$ , and has peaks between the peaks of  $f(x)$  and  $g(x)$ .

**Figure C.3** Interference between the waves discussed in *Brief illustration C.1*.

**Self-test C.1** Consider the same waves, but with  $\phi = 3\pi/4$ . Does the resultant wave have diminished or enhanced amplitude?

Answer: Diminished amplitude

## C.2 The electromagnetic field

Light is a form of electromagnetic radiation. In classical physics, electromagnetic radiation is understood in terms of the **electromagnetic field**, an oscillating electric and magnetic disturbance that spreads as a harmonic wave through space. An **electric field** acts on charged particles (whether stationary or

moving) and a **magnetic field** acts only on moving charged particles.

The wavelength and frequency of an electromagnetic wave in a vacuum are related by

$$\lambda\nu = c \quad \begin{array}{l} \text{Electromagnetic} \\ \text{wave in a vacuum} \end{array} \quad \begin{array}{l} \text{Relation between} \\ \text{frequency and wavelength} \end{array} \quad (\text{C.3})$$

where  $c = 2.997\,924\,58 \times 10^8 \text{ m s}^{-1}$  (which we shall normally quote as  $2.998 \times 10^8 \text{ m s}^{-1}$ ) is the speed of light in a vacuum. When the wave is passing through a medium (even air), its speed is reduced to  $c'$  and, although the frequency remains unchanged, its wavelength is reduced accordingly. The reduced speed of light in a medium is normally expressed in terms of the **refractive index**,  $n_r$ , of the medium, where

$$n_r = \frac{c}{c'} \quad \begin{array}{l} \text{Refractive index} \end{array} \quad (\text{C.4})$$

The refractive index depends on the frequency of the light, and for visible light typically increases with frequency. It also depends on the physical state of the medium. For yellow light in water at  $25^\circ\text{C}$ ,  $n_r = 1.3$ , so the wavelength is reduced by 30 per cent.

The classification of the electromagnetic field according to its frequency and wavelength is summarized in Fig. C.4. It is often desirable to express the characteristics of an electromagnetic wave by giving its **wavenumber**,  $\tilde{\nu}$  (nu tilde), where

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \quad \begin{array}{l} \text{Electromagnetic radiation} \\ \text{Wavenumber} \end{array} \quad (\text{C.5})$$

A wavenumber can be interpreted as the number of complete wavelengths in a given length (of vacuum). Wavenumbers are normally reported in reciprocal centimetres ( $\text{cm}^{-1}$ ), so a wavenumber of  $5 \text{ cm}^{-1}$  indicates that there are 5 complete wavelengths in 1 cm.

### Brief illustration C.2 Wavenumbers

The wavenumber of electromagnetic radiation of wavelength 660 nm is

$$\tilde{\nu} = \frac{1}{\lambda} = \frac{1}{660 \times 10^{-9} \text{ m}} = 1.5 \times 10^6 \text{ m}^{-1} = 15\,000 \text{ cm}^{-1}$$

You can avoid errors in converting between units of  $\text{m}^{-1}$  and  $\text{cm}^{-1}$  by remembering that wavenumber represents the number of wavelengths in a given distance. Thus, a wavenumber expressed as the number of waves per centimetre and hence in units of  $\text{cm}^{-1}$  must be 100 times less than the equivalent quantity expressed per metre in units of  $\text{m}^{-1}$ .

**Self-test C.2** Calculate the wavenumber and frequency of red light, of wavelength 710 nm.

$$\text{Answer: } \tilde{\nu} = 1.41 \times 10^6 \text{ m}^{-1} = 1.41 \times 10^4 \text{ cm}^{-1}, \\ \nu = 422 \text{ THz (1 THz} = 10^{12} \text{ s}^{-1}\text{)}$$

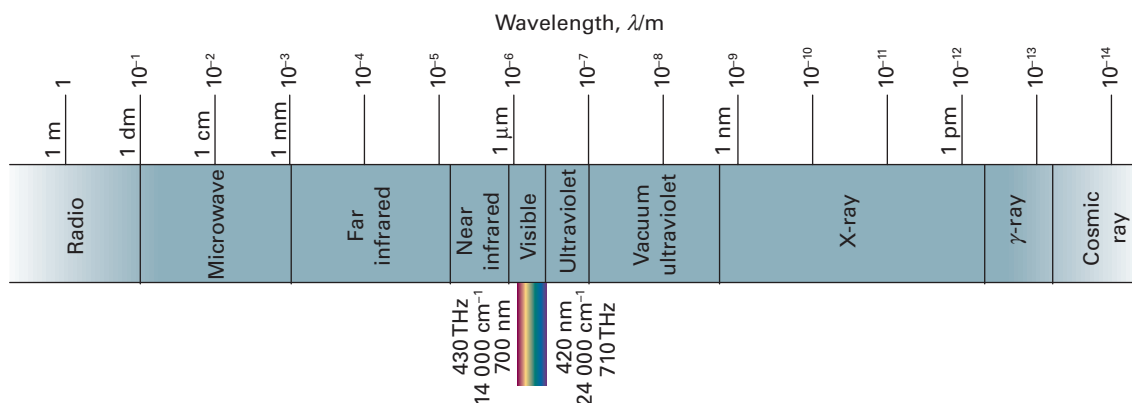

Figure C.4 The electromagnetic spectrum and its classification into regions (the boundaries are not precise).

The functions that describe the oscillating electric field,  $\mathbf{E}(x,t)$ , and magnetic field,  $\mathbf{B}(x,t)$ , travelling along the  $x$ -direction with wavelength  $\lambda$  and frequency  $\nu$  are

$$\mathbf{E}(x,t) = \mathbf{E}_0 \cos\{(2\pi/\lambda)x - 2\pi\nu t + \phi\} \quad \begin{array}{l} \text{Electro-} \\ \text{magnetic} \\ \text{radiation} \end{array} \quad \begin{array}{l} \text{Electric} \\ \text{field} \end{array} \quad (\text{C.6a})$$

$$\mathbf{B}(x,t) = \mathbf{B}_0 \cos\{(2\pi/\lambda)x - 2\pi\nu t + \phi\} \quad \begin{array}{l} \text{Electro-} \\ \text{magnetic} \\ \text{radiation} \end{array} \quad \begin{array}{l} \text{Magnetic} \\ \text{field} \end{array} \quad (\text{C.6b})$$

where  $\mathbf{E}_0$  and  $\mathbf{B}_0$  are the amplitudes of the electric and magnetic fields, respectively, and  $\phi$  is the phase of the wave. In this case the amplitude is a vector quantity, because the electric and magnetic fields have direction as well as amplitude. The magnetic field is

Figure C.5 In a plane polarized wave, the electric and magnetic fields oscillate in orthogonal planes and are perpendicular to the direction of propagation.

perpendicular to the electric field and both are perpendicular to the propagation direction (Fig. C.5). According to classical electromagnetic theory, the **intensity** of electromagnetic radiation, a measure of the energy associated with the wave, is proportional to the square of the amplitude of the wave.

Equation C.6 describes electromagnetic radiation that is **plane polarized**; it is so called because the electric and magnetic fields each oscillate in a single plane. The plane of polarization may be orientated in any direction around the direction of propagation. An alternative mode of polarization is **circular polarization**, in which the electric and magnetic fields rotate around the direction of propagation in either a clockwise or an anticlockwise sense but remain perpendicular to it and to each other (Fig. C.6).

Figure C.6 In a circularly polarized wave, the electric and magnetic fields rotate around the direction of propagation but remain perpendicular to one another. The illustration also defines 'right' and 'left-handed' polarizations ('left-handed' polarization is shown as L).

## Checklist of concepts

- 1. A **wave** is an oscillatory disturbance that travels through space.
- 2. A **harmonic wave** is a wave with a displacement that can be expressed as a sine or cosine function.

- 3. A harmonic wave is characterized by a **wavelength, frequency, phase, and amplitude**.
- 4. **Destructive interference** between two waves of the same wavelength but different phases leads to a resultant wave with diminished amplitude.
- 5. **Constructive interference** between two waves of the same wavelength and phase leads to a resultant wave with enhanced amplitude.
- 6. The **electromagnetic field** is an oscillating electric and magnetic disturbance that spreads as a harmonic wave through space.
- 7. An **electric field** acts on charged particles (whether stationary or moving).
- 8. A **magnetic field** acts only on moving charged particles.
- 9. In **plane polarized** electromagnetic radiation, the electric and magnetic fields each oscillate in a single plane and are mutually perpendicular.
- 10. In **circular polarization**, the electric and magnetic fields rotate around the direction of propagation in either a clockwise or an anticlockwise sense but remain perpendicular to it and each other.

## Checklist of equations

# FOUNDATIONS

## TOPIC A Matter

### Discussion questions

**A.1** Summarize the features of the nuclear model of the atom. Define the terms atomic number, nucleon number, and mass number.

**A.2** Where in the periodic table are metals, non-metals, transition metals, lanthanoids, and actinoids found?

**A.3** Summarize what is meant by a single bond and a multiple bond.

**A.4** Summarize the principal concepts of the VSEPR theory of molecular shape.

**A.5** Compare and contrast the properties of the solid, liquid, and gas states of matter.

### Exercises

**A.1(a)** Express the typical ground-state electron configuration of an atom of an element in (i) Group 2, (ii) Group 7, (iii) Group 15 of the periodic table.

**A.1(b)** Express the typical ground-state electron configuration of an atom of an element in (i) Group 3, (ii) Group 5, (iii) Group 13 of the periodic table.

**A.2(a)** Identify the oxidation numbers of the elements in (i)  $\text{MgCl}_2$ , (ii)  $\text{FeO}$ , (iii)  $\text{Hg}_2\text{Cl}_2$ .

**A.2(b)** Identify the oxidation numbers of the elements in (i)  $\text{CaH}_2$ , (ii)  $\text{CaC}_2$ , (iii)  $\text{LiN}_3$ .

**A.3(a)** Identify a molecule with a (i) single, (ii) double, (iii) triple bond between a carbon and a nitrogen atom.

**A.3(b)** Identify a molecule with (i) one, (ii) two, (iii) three lone pairs on the central atom.

**A.4(a)** Draw the Lewis (electron dot) structures of (i)  $\text{SO}_3^-$ , (ii)  $\text{XeF}_4$ , (iii)  $\text{P}_4$ .

**A.4(b)** Draw the Lewis (electron dot) structures of (i)  $\text{O}_3$ , (ii)  $\text{ClF}_3^+$ , (iii)  $\text{N}_3^-$ .

**A.5(a)** Identify three compounds with an incomplete octet.

**A.5(b)** Identify four hypervalent compounds.

**A.6(a)** Use VSEPR theory to predict the structures of (i)  $\text{PCl}_3$ , (ii)  $\text{PCl}_5$ , (iii)  $\text{XeF}_2$ , (iv)  $\text{XeF}_4$ .

**A.6(b)** Use VSEPR theory to predict the structures of (i)  $\text{H}_2\text{O}_2$ , (ii)  $\text{FSO}_3^-$ , (iii)  $\text{KrF}_2$ , (iv)  $\text{PCl}_4^+$ .

**A.7(a)** Identify the polarities (by attaching partial charges  $\delta^+$  and  $\delta^-$ ) of the bonds (i) C–Cl, (ii) P–H, (iii) N–O.

**A.7(b)** Identify the polarities (by attaching partial charges  $\delta^+$  and  $\delta^-$ ) of the bonds (i) C–H, (ii) P–S, (iii) N–Cl.

**A.8(a)** State whether you expect the following molecules to be polar or nonpolar: (i)  $\text{CO}_2$ , (ii)  $\text{SO}_2$ , (iii)  $\text{N}_2\text{O}$ , (iv)  $\text{SF}_4$ .

**A.8(b)** State whether you expect the following molecules to be polar or nonpolar: (i)  $\text{O}_3$ , (ii)  $\text{XeF}_2$ , (iii)  $\text{NO}_2$ , (iv)  $\text{C}_6\text{H}_{14}$ .

**A.9(a)** Arrange the molecules in Exercise A.8(a) by increasing dipole moment.

**A.9(b)** Arrange the molecules in Exercise A.8(b) by increasing dipole moment.

**A.10(a)** Classify the following properties as extensive or intensive: (i) mass, (ii) mass density, (iii) temperature, (iv) number density.

**A.10(b)** Classify the following properties as extensive or intensive: (i) pressure, (ii) specific heat capacity, (iii) weight, (iv) molality.

**A.11(a)** Calculate (i) the amount of  $\text{C}_2\text{H}_5\text{OH}$  (in moles) and (ii) the number of molecules present in 25.0 g of ethanol.

**A.11(b)** Calculate (i) the amount of  $\text{C}_6\text{H}_{12}\text{O}_6$  (in moles) and (ii) the number of molecules present in 5.0 g of glucose.

**A.12(a)** Calculate (i) the mass, (ii) the weight on the surface of the Earth (where  $g = 9.81 \text{ m s}^{-2}$ ) of 10.0 mol  $\text{H}_2\text{O}(\text{l})$ .

**A.12(b)** Calculate (i) the mass, (ii) the weight on the surface of Mars (where  $g = 3.72 \text{ m s}^{-2}$ ) of 10.0 mol  $\text{C}_6\text{H}_6(\text{l})$ .

**A.13(a)** Calculate the pressure exerted by a person of mass 65 kg standing (on the surface of the Earth) on shoes with soles of area  $150 \text{ cm}^2$ .

**A.13(b)** Calculate the pressure exerted by a person of mass 60 kg standing (on the surface of the Earth) on shoes with stiletto heels of area  $2 \text{ cm}^2$  (assume that the weight is entirely on the heels).

**A.14(a)** Express the pressure calculated in Exercise A.13(a) in atmospheres.

**A.14(b)** Express the pressure calculated in Exercise A.13(b) in atmospheres.

**A.15(a)** Express a pressure of 1.45 atm in (i) pascal, (ii) bar.

**A.15(b)** Express a pressure of 222 atm in (i) pascal, (ii) bar.

**A.16(a)** Convert blood temperature,  $37.0^\circ\text{C}$ , to the Kelvin scale.

**A.16(b)** Convert the boiling point of oxygen,  $90.18 \text{ K}$ , to the Celsius scale.

**A.17(a)** Equation A.4 is a relation between the Kelvin and Celsius scales. Devise the corresponding equation relating the Fahrenheit and Celsius scales and use it to express the boiling point of ethanol ( $78.5^\circ\text{C}$ ) in degrees Fahrenheit.

**A.17(b)** The Rankine scale is a version of the thermodynamic temperature scale in which the degrees ( $^\circ\text{R}$ ) are the same size as degrees Fahrenheit. Derive an expression relating the Rankine and Kelvin scales and express the freezing point of water in degrees Rankine.

**A.18(a)** A sample of hydrogen gas was found to have a pressure of 110 kPa when the temperature was  $20.0^\circ\text{C}$ . What can its pressure be expected to be when the temperature is  $7.0^\circ\text{C}$ ?

**A.18(b)** A sample of 325 mg of neon occupies  $2.00 \text{ dm}^3$  at  $20.0^\circ\text{C}$ . Use the perfect gas law to calculate the pressure of the gas.

**A.19(a)** At  $500^\circ\text{C}$  and 93.2 kPa, the mass density of sulfur vapour is  $3.710 \text{ kg m}^{-3}$ . What is the molecular formula of sulfur under these conditions?

**A.19(b)** At  $100^\circ\text{C}$  and 16.0 kPa, the mass density of phosphorus vapour is  $0.6388 \text{ kg m}^{-3}$ . What is the molecular formula of phosphorus under these conditions?

**A.20(a)** Calculate the pressure exerted by 22 g of ethane behaving as a perfect gas when confined to  $1000 \text{ cm}^3$  at  $25.0^\circ\text{C}$ .

**A.20(b)** Calculate the pressure exerted by 7.05 g of oxygen behaving as a perfect gas when confined to  $100 \text{ cm}^3$  at  $100.0^\circ\text{C}$ .

**A.21(a)** A vessel of volume  $10.0 \text{ dm}^3$  contains 2.0 mol  $\text{H}_2$  and 1.0 mol  $\text{N}_2$  at  $5.0^\circ\text{C}$ . Calculate the partial pressure of each component and their total pressure.

**A.21(b)** A vessel of volume  $100 \text{ cm}^3$  contains 0.25 mol  $\text{O}_2$  and 0.034 mol  $\text{CO}_2$  at  $10.0^\circ\text{C}$ . Calculate the partial pressure of each component and their total pressure.

## TOPIC B Energy

### Discussion questions

- B.1** What is energy?
- B.2** Distinguish between kinetic and potential energy.
- B.3** State the Second Law of thermodynamics. Can the entropy of the system that is not isolated from its surroundings decrease during a spontaneous process?

### Exercises

- B.1(a)** A particle of mass 1.0 g is released near the surface of the Earth, where the acceleration of free fall is  $g=9.81 \text{ m s}^{-2}$ . What will be its speed and kinetic energy after (i) 1.0 s, (ii) 3.0 s. Ignore air resistance.
- B.1(b)** The same particle in Exercise B.1(a) is released near the surface of Mars, where the acceleration of free fall is  $g=3.72 \text{ m s}^{-2}$ . What will be its speed and kinetic energy after (i) 1.0 s, (ii) 3.0 s. Ignore air resistance.
- B.2(a)** An ion of charge  $ze$  moving through water is subject to an electric field of strength  $\mathcal{E}$  which exerts a force  $ze\mathcal{E}$ , but it also experiences a frictional drag proportional to its speed  $s$  and equal to  $6\pi\eta R s$ , where  $R$  is its radius and  $\eta$  (eta) is the viscosity of the medium. What will be its terminal velocity?
- B.2(b)** A particle descending through a viscous medium experiences a frictional drag proportional to its speed  $s$  and equal to  $6\pi\eta R s$ , where  $R$  is its radius and  $\eta$  (eta) is the viscosity of the medium. If the acceleration of free fall is denoted  $g$ , what will be the terminal velocity of a sphere of radius  $R$  and mass density  $\rho$ ?
- B.3(a)** Confirm that the general solution of the harmonic oscillator equation of motion ( $m d^2x/dt^2 = -k_s x$ ) is  $x(t) = A \sin \omega t + B \cos \omega t$  with  $\omega = (k_s/m)^{1/2}$ .
- B.3(b)** Consider a harmonic oscillator with  $B=0$  (in the notation of Exercise B.3(a)); relate the total energy at any instant to its maximum displacement amplitude.
- B.4(a)** The force constant of a C–H bond is about  $450 \text{ N m}^{-1}$ . How much work is needed to stretch the bond by (i) 10 pm, (ii) 20 pm?
- B.4(b)** The force constant of the H–H bond is about  $510 \text{ N m}^{-1}$ . How much work is needed to stretch the bond by 20 pm?
- B.5(a)** An electron is accelerated in an electron microscope from rest through a potential difference  $\Delta\phi = 100 \text{ kV}$  and acquires an energy of  $e\Delta\phi$ . What is its final speed? What is its energy in electronvolts (eV)?
- B.5(b)** A  $\text{C}_6\text{H}_4^{2+}$  ion is accelerated in a mass spectrometer from rest through a potential difference  $\Delta\phi = 20 \text{ kV}$  and acquires an energy of  $e\Delta\phi$ . What is its final speed? What is its energy in electronvolts (eV)?
- B.6(a)** Calculate the work that must be done in order to remove a  $\text{Na}^+$  ion from 200 pm away from a  $\text{Cl}^-$  ion to infinity (in a vacuum). What work would be needed if the separation took place in water?
- B.6(b)** Calculate the work that must be done in order to remove an  $\text{Mg}^{2+}$  ion from 250 pm away from an  $\text{O}^{2-}$  ion to infinity (in a vacuum). What work would be needed if the separation took place in water?
- B.7(a)** Calculate the electric potential due to the nuclei at a point in a LiH molecule located at 200 pm from the Li nucleus and 150 pm from the H nucleus.
- B.7(b)** Plot the electric potential due to the nuclei at a point in a  $\text{Na}^+\text{Cl}^-$  ion pair located on a line half way between the nuclei (the internuclear separation is 283 pm) as the point approaches from infinity and ends at the mid-point between the nuclei.
- B.8(a)** An electric heater is immersed in a flask containing 200 g of water, and a current of 2.23 A from a 15.0 V supply is passed for 12.0 minutes. How much energy is supplied to the water? Estimate the rise in temperature (for water,  $C = 75.3 \text{ J K}^{-1} \text{ mol}^{-1}$ ).

- B.4** What is meant by quantization of energy? In what circumstances are the effects of quantization most important for microscopic systems?
- B.5** What are the assumptions of the kinetic molecular theory?
- B.6** What are the main features of the Maxwell–Boltzmann distribution of speeds?
- B.8(b)** An electric heater is immersed in a flask containing 150 g of ethanol, and a current of 1.12 A from a 12.5 V supply is passed for 172 s. How much energy is supplied to the ethanol? Estimate the rise in temperature (for ethanol,  $C = 111.5 \text{ J K}^{-1} \text{ mol}^{-1}$ ).
- B.9(a)** The heat capacity of a sample of iron was  $3.67 \text{ J K}^{-1}$ . By how much would its temperature rise if 100 J of energy were transferred to it as heat?
- B.9(b)** The heat capacity of a sample of water was  $5.77 \text{ J K}^{-1}$ . By how much would its temperature rise if 50.0 kJ of energy were transferred to it as heat?
- B.10(a)** The molar heat capacity of lead is  $26.44 \text{ J K}^{-1} \text{ mol}^{-1}$ . How much energy must be supplied (by heating) to 100 g of lead to increase its temperature by  $10.0^\circ\text{C}$ ?
- B.10(b)** The molar heat capacity of water is  $75.2 \text{ J K}^{-1} \text{ mol}^{-1}$ . How much energy must be supplied by heating to 10.0 g of water to increase its temperature by  $10.0^\circ\text{C}$ ?
- B.11(a)** The molar heat capacity of ethanol is  $111.46 \text{ J K}^{-1} \text{ mol}^{-1}$ . What is its specific heat capacity?
- B.11(b)** The molar heat capacity of sodium is  $28.24 \text{ J K}^{-1} \text{ mol}^{-1}$ . What is its specific heat capacity?
- B.12(a)** The specific heat capacity of water is  $4.18 \text{ J K}^{-1} \text{ g}^{-1}$ . What is its molar heat capacity?
- B.12(b)** The specific heat capacity of copper is  $0.384 \text{ J K}^{-1} \text{ g}^{-1}$ . What is its molar heat capacity?
- B.13(a)** By how much does the molar enthalpy of hydrogen gas differ from its molar internal energy at  $1000^\circ\text{C}$ ? Assume perfect gas behaviour.
- B.13(b)** The mass density of water is  $0.997 \text{ g cm}^{-3}$ . By how much does the molar enthalpy of water differ from its molar internal energy at  $298 \text{ K}$ ?
- B.14(a)** Which do you expect to have the greater entropy at  $298 \text{ K}$  and 1 bar, liquid water or water vapour?
- B.14(b)** Which do you expect to have the greater entropy at  $0^\circ\text{C}$  and 1 atm, liquid water or ice?
- B.15(a)** Which do you expect to have the greater entropy, 100 g of iron at  $300 \text{ K}$  or  $3000 \text{ K}$ ?
- B.15(b)** Which do you expect to have the greater entropy, 100 g of water at  $0^\circ\text{C}$  or  $100^\circ\text{C}$ ?
- B.16(a)** Give three examples of a system that is in dynamic equilibrium.
- B.16(b)** Give three examples of a system that is in static equilibrium.
- B.17(a)** Suppose two states differ in energy by 1.0 eV (electronvolts, see inside the front cover); what is the ratio of their populations at (a)  $300 \text{ K}$ , (b)  $3000 \text{ K}$ ?
- B.17(b)** Suppose two states differ in energy by 2.0 eV (electronvolts, see inside the front cover); what is the ratio of their populations at (a)  $200 \text{ K}$ , (b)  $2000 \text{ K}$ ?
- B.18(a)** Suppose two states differ in energy by 1.0 eV, what can be said about their populations when  $T=0$ ?
- B.18(b)** Suppose two states differ in energy by 1.0 eV, what can be said about their populations when the temperature is infinite?

**B.19(a)** A typical vibrational excitation energy of a molecule corresponds to a wavenumber of  $2500\text{ cm}^{-1}$  (convert to an energy separation by multiplying by  $hc$ ; see *Foundations C*). Would you expect to find molecules in excited vibrational states at room temperature ( $20^\circ\text{C}$ )?

**B.19(b)** A typical rotational excitation energy of a molecule corresponds to a frequency of about  $10\text{ GHz}$  (convert to an energy separation by multiplying by  $h$ ; see *Foundations C*). Would you expect to find gas-phase molecules in excited rotational states at room temperature ( $20^\circ\text{C}$ )?

**B.20(a)** Suggest a reason why most molecules survive for long periods at room temperature.

**B.20(b)** Suggest a reason why the rates of chemical reactions typically increase with increasing temperature.

**B.21(a)** Calculate the relative mean speeds of  $\text{N}_2$  molecules in air at  $0^\circ\text{C}$  and  $40^\circ\text{C}$ .

**B.21(b)** Calculate the relative mean speeds of  $\text{CO}_2$  molecules in air at  $20^\circ\text{C}$  and  $30^\circ\text{C}$ .

**B.22(a)** Calculate the relative mean speeds of  $\text{N}_2$  and  $\text{CO}_2$  molecules in air.

**B.22(b)** Calculate the relative mean speeds of  $\text{Hg}_2$  and  $\text{H}_2$  molecules in a gaseous mixture.

**B.23(a)** Use the equipartition theorem to calculate the contribution of translational motion to the internal energy of  $5.0\text{ g}$  of argon at  $25^\circ\text{C}$ .

**B.23(b)** Use the equipartition theorem to calculate the contribution of translational motion to the internal energy of  $10.0\text{ g}$  of helium at  $30^\circ\text{C}$ .

**B.24(a)** Use the equipartition theorem to calculate the contribution to the total internal energy of a sample of  $10.0\text{ g}$  of (i) carbon dioxide, (ii) methane at  $20^\circ\text{C}$ ; take into account translation and rotation but not vibration.

**B.24(b)** Use the equipartition theorem to calculate the contribution to the total internal energy of a sample of  $10.0\text{ g}$  of lead at  $20^\circ\text{C}$ , taking into account the vibrations of the atoms.

**B.25(a)** Use the equipartition theorem to compute the molar heat capacity of argon.

**B.25(b)** Use the equipartition theorem to compute the molar heat capacity of helium.

**B.26(a)** Use the equipartition theorem to estimate the heat capacity of (i) carbon dioxide, (ii) methane.

**B.26(b)** Use the equipartition theorem to estimate the heat capacity of (i) water vapour, (ii) lead.

## TOPIC C Waves

### Discussion questions

**C.1** How many types of wave motion can you identify?

**C.2** What is the wave nature of the sound of a sudden 'bang'?

### Exercises

**C.1(a)** What is the speed of light in water if the refractive index of the latter is  $1.33$ ?

**C.1(b)** What is the speed of light in benzene if the refractive index of the latter is  $1.52$ ?

**C.2(a)** The wavenumber of a typical vibrational transition of a hydrocarbon is  $2500\text{ cm}^{-1}$ . Calculate the corresponding wavelength and frequency.

**C.2(b)** The wavenumber of a typical vibrational transition of an O–H bond is  $3600\text{ cm}^{-1}$ . Calculate the corresponding wavelength and frequency.

## Integrated activities

**F.1** In Topic 1B we show that for a perfect gas the fraction of molecules that have a speed in the range  $v$  to  $v + dv$  is  $f(v)dv$ , where

$$f(v) = 4\pi \left( \frac{M}{2\pi RT} \right)^{3/2} v^2 e^{-Mv^2/2RT}$$

is the Maxwell–Boltzmann distribution (eqn 1B.4). Use this expression and mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book for the following exercises:

(a) Refer to the graph in Fig. B.6. Plot different distributions by keeping the molar mass constant at  $100\text{ g mol}^{-1}$  and varying the temperature of the sample between  $200\text{ K}$  and  $2000\text{ K}$ .

(b) Evaluate numerically the fraction of molecules with speeds in the range  $100\text{ m s}^{-1}$  to  $200\text{ m s}^{-1}$  at  $300\text{ K}$  and  $1000\text{ K}$ .

**F.2** Based on your observations from Problem F.1, provide a molecular interpretation of temperature.

# PART ONE

# Thermodynamics

Part 1 of the text develops the concepts of thermodynamics, the science of the transformations of energy. Thermodynamics provides a powerful way to discuss equilibria and the direction of natural change in chemistry. Its concepts apply to both physical change, such as fusion and vaporization, and chemical change, including electrochemistry. We see that through the concepts of energy, enthalpy, entropy, Gibbs energy, and the chemical potential it is possible to obtain a unified view of these core features of chemistry and to treat equilibria quantitatively.

The chapters in Part 1 deal with the bulk properties of matter; those of Part 2 show how these properties stem from the behaviour of individual atoms.

## 1 The properties of gases

## 6 Chemical equilibrium

# CHAPTER 1

## The properties of gases

A **gas** is a form of matter that fills whatever container it occupies. This chapter establishes the properties of gases that will be used throughout the text.

### 1A The perfect gas

The chapter begins with an account of an idealized version of a gas, a ‘perfect gas’, and shows how its equation of state may be assembled from the experimental observations summarized by Boyle’s law, Charles’s law, and Avogadro’s principle.

### 1B The kinetic model

One central feature of physical chemistry is its role in building models of molecular behaviour that seek to explain observed phenomena. A prime example of this procedure is the development of a molecular model of a perfect gas in terms of a collection of molecules (or atoms) in ceaseless, essentially random motion. This model is the basis of ‘kinetic molecular theory’. As well as accounting for the gas laws, this theory can be used to predict the average speed at which molecules move in a gas, and that speed’s dependence on temperature. In combination with the Boltzmann distribution (*Foundations B*), the kinetic theory can also be used to predict the spread of molecular speeds and its dependence on molecular mass and temperature.

### 1C Real gases

The perfect gas is an excellent starting point for the discussion of properties of all gases, and its properties are invoked throughout the chapters on thermodynamics that follow this chapter. However, actual gases, ‘real gases’, have properties that differ from those of perfect gases, and we need to be able to interpret these deviations and build the effects of molecular attractions and repulsions into our model. The discussion of real gases is another example of how initially primitive models in physical chemistry are elaborated to take into account more detailed observations.

### What is the impact of this material?

The perfect gas law and the kinetic theory can be applied to the study of phenomena confined to a reaction vessel or encompassing an entire planet or star. We have identified two applications. In *Impact I1.1* we see how the gas laws are used in the discussion of meteorological phenomena—the weather. In *Impact I1.2* we examine how the kinetic model of gases has a surprising application: to the discussion of dense stellar media, such as the interior of the Sun.

### ► Why do you need to know this material?

Equations related to perfect gases provide the basis for the development of many equations in thermodynamics. The perfect gas law is also a good first approximation for accounting for the properties of real gases.

### ► What is the key idea?

The perfect gas law, which is based on a series of empirical observations, is a limiting law that is obeyed increasingly well as the pressure of a gas tends to zero.

### ► What do you need to know already?

You need to be aware of the concepts of pressure and temperature introduced in *Foundations A*.

In molecular terms, a gas consists of a collection of molecules that are in ceaseless motion and which interact significantly with one another only when they collide. The properties of gases were among the first to be established quantitatively (largely during the seventeenth and eighteenth centuries) when the technological requirements of travel in balloons stimulated their investigation.

## 1A.1 Variables of state

The **physical state** of a sample of a substance, its physical condition, is defined by its physical properties. Two samples of the same substance that have the same physical properties are in the same state. The variables needed to specify the state of a system are the amount of substance it contains,  $n$ , the volume it occupies,  $V$ , the pressure,  $p$ , and the temperature,  $T$ .

### (a) Pressure

The origin of the force exerted by a gas is the incessant battering of the molecules on the walls of its container. The collisions are so numerous that they exert an effectively steady force, which is experienced as a steady pressure. The SI unit of pressure, the *pascal* (Pa,  $1 \text{ Pa} = 1 \text{ N m}^{-2}$ ) is introduced in *Foundations A*. As discussed there, several other units are still widely used (Table 1A.1). A pressure of 1 bar is the **standard pressure** for reporting data; we denote it  $p^\ominus$ .

If two gases are in separate containers that share a common movable wall (a ‘piston’, Fig. 1A.1), the gas that has the higher pressure will tend to compress (reduce the volume of) the gas that has lower pressure. The pressure of the high-pressure gas will fall as it expands and that of the low-pressure gas will rise as it is compressed. There will come a stage when the two pressures are equal and the wall has no further tendency to move. This condition of equality of pressure on either side of a movable wall is a state of **mechanical equilibrium** between the two gases. The pressure of a gas is therefore an indication of whether a container that contains the gas will be in mechanical equilibrium with another gas with which it shares a movable wall.

Table 1A.1 Pressure units\*

Name	Symbol	Value
pascal	1 Pa	<b>1 N m<sup>-2</sup>, 1 kg m<sup>-1</sup> s<sup>-2</sup></b>
bar	1 bar	<b>10<sup>5</sup> Pa</b>
atmosphere	1 atm	<b>101.325 kPa</b>
torr	1 Torr	<b>(101 325/760) Pa=133.32... Pa</b>
millimetres of mercury	1 mmHg	133.322... Pa
pounds per square inch	1 psi	6.894 757... kPa

\* Values in bold are exact.

**Figure 1A.1** When a region of high pressure is separated from a region of low pressure by a movable wall, the wall will be pushed into one region or the other, as in (a) and (c). However, if the two pressures are identical, the wall will not move (b). The latter condition is one of mechanical equilibrium between the two regions.

The pressure exerted by the atmosphere is measured with a *barometer*. The original version of a barometer (which was invented by Torricelli, a student of Galileo) was an inverted tube of mercury sealed at the upper end. When the column of mercury is in mechanical equilibrium with the atmosphere, the pressure at its base is equal to that exerted by the atmosphere. It follows that the height of the mercury column is proportional to the external pressure.

### Example 1A.1 Calculating the pressure exerted by a column of liquid

Derive an equation for the pressure at the base of a column of liquid of mass density  $\rho$  (rho) and height  $h$  at the surface of the Earth. The pressure exerted by a column of liquid is commonly called the ‘hydrostatic pressure’.

**Method** According to *Foundations A*, the pressure is the force,  $F$ , divided by the area,  $A$ , to which the force is applied:  $p = F/A$ . For a mass  $m$  subject to a gravitational field at the surface of the earth,  $F = mg$ , where  $g$  is the acceleration of free fall. To calculate  $F$  we need to know the mass  $m$  of the column of liquid, which is its mass density,  $\rho$ , multiplied by its volume,  $V$ :  $m = \rho V$ . The first step, therefore, is to calculate the volume of a cylindrical column of liquid.

**Answer** Let the column have cross-sectional area  $A$ , then its volume is  $Ah$  and its mass is  $m = \rho Ah$ . The force the column of this mass exerts at its base is

$$F = mg = \rho Ahg$$

The pressure at the base of the column is therefore

$$p = \frac{F}{A} = \frac{\rho Ahg}{A} = \rho gh \quad \text{Hydrostatic pressure} \quad (1A.1)$$

Note that the hydrostatic pressure is independent of the shape and cross-sectional area of the column. The mass of the column of a given height increases as the area, but so does the area on which the force acts, so the two cancel.

**Self-test 1A.1** Derive an expression for the pressure at the base of a column of liquid of length  $l$  held at an angle  $\theta$  (theta) to the vertical (1).

Answer:  $p = \rho gl \cos \theta$

The pressure of a sample of gas inside a container is measured by using a pressure gauge, which is a device with properties that respond to the pressure. For instance, a *Bayard–Alpert pressure gauge* is based on the ionization of the molecules present in the gas and the resulting current of ions is interpreted in terms of the pressure. In a *capacitance manometer*, the deflection of a diaphragm relative to a fixed electrode is monitored through its effect on the capacitance of the arrangement. Certain semiconductors also respond to pressure and are used as transducers in solid-state pressure gauges.

### (b) Temperature

The concept of temperature is introduced in *Foundations A*. In the early days of thermometry (and still in laboratory practice today), temperatures were related to the length of a column of liquid, and the difference in lengths shown when the thermometer was first in contact with melting ice and then with boiling water was divided into 100 steps called ‘degrees’, the lower point being labelled 0. This procedure led to the **Celsius scale** of temperature. In this text, temperatures on the Celsius scale are denoted  $\theta$  (theta) and expressed in *degrees Celsius* ( $^{\circ}\text{C}$ ). However, because different liquids expand to different extents, and do not always expand uniformly over a given range, thermometers constructed from different materials showed different numerical values of the temperature between their fixed points. The pressure of a gas, however, can be used to construct a **perfect-gas temperature scale** that is independent of the identity of the gas. The perfect-gas scale turns out to be identical to the **thermodynamic temperature scale** introduced in Topic 3A, so we shall use the latter term from now on to avoid a proliferation of names.

On the thermodynamic temperature scale, temperatures are denoted  $T$  and are normally reported in *kelvins* (K; not  $^{\circ}\text{K}$ ). Thermodynamic and Celsius temperatures are related by the exact expression

$$T/\text{K} = \theta/^{\circ}\text{C} + 273.15 \quad \text{Definition of Celsius scale} \quad (1\text{A.2})$$

This relation is the current definition of the Celsius scale in terms of the more fundamental Kelvin scale. It implies that a difference in temperature of  $1^{\circ}\text{C}$  is equivalent to a difference of 1 K.

*A note on good practice* We write  $T=0$ , not  $T=0\text{K}$  for the zero temperature on the thermodynamic temperature scale. This scale is absolute, and the lowest temperature is 0 regardless of the size of the divisions on the scale (just as we write  $p=0$  for zero pressure, regardless of the size of the units we adopt, such as bar or pascal). However, we write  $0^{\circ}\text{C}$  because the Celsius scale is not absolute.

### Brief illustration 1A.1 Temperature conversion

To express  $25.00^{\circ}\text{C}$  as a temperature in kelvins, we use eqn 1A.4 to write

$$T/\text{K} = (25.00^{\circ}\text{C})/^{\circ}\text{C} + 273.15 = 25.00 + 273.15 = 298.15$$

Note how the units (in this case,  $^{\circ}\text{C}$ ) are cancelled like numbers. This is the procedure called ‘quantity calculus’ in which a physical quantity (such as the temperature) is the product of a numerical value (25.00) and a unit ( $1^{\circ}\text{C}$ ); see *The chemist’s toolkit A.1 of Foundations*. Multiplication of both sides by the unit K then gives  $T=298.15\text{K}$ .

*A note on good practice* When the units need to be specified in an equation, the approved procedure, which avoids any ambiguity, is to write (physical quantity)/units, which is a dimensionless number, just as  $(25.00^{\circ}\text{C})/^{\circ}\text{C} = 25.00$  in this illustration. Units may be multiplied and cancelled just like numbers.

## 1A.2 Equations of state

Although in principle the state of a pure substance is specified by giving the values of  $n$ ,  $V$ ,  $p$ , and  $T$ , it has been established experimentally that it is sufficient to specify only three of these variables, for then the fourth variable is fixed. That is, it is an experimental fact that each substance is described by an **equation of state**, an equation that interrelates these four variables.

The general form of an equation of state is

$$p = f(T, V, n) \quad \text{General form of an equation of state} \quad (1\text{A.3})$$

This equation tells us that if we know the values of  $n$ ,  $T$ , and  $V$  for a particular substance, then the pressure has a fixed value. Each substance is described by its own equation of state, but

we know the explicit form of the equation in only a few special cases. One very important example is the equation of state of a ‘perfect gas’, which has the form  $p = nRT/V$ , where  $R$  is a constant independent of the identity of the gas.

The equation of state of a perfect gas was established by combining a series of empirical laws.

### (a) The empirical basis

We assume that the following individual gas laws are familiar:

$$\text{Boyle’s law: } pV = \text{constant, at constant } n, T \quad (1\text{A.4a})$$

$$\text{Charles’s law: } V = \text{constant} \times T, \text{ at constant } n, p \quad (1\text{A.4b})$$

$$p = \text{constant} \times T, \text{ at constant } n, V \quad (1\text{A.4c})$$

**Avogadro’s principle:**

$$V = \text{constant} \times n \text{ at constant } p, T \quad (1\text{A.4d})$$

Boyle’s and Charles’s laws are examples of a **limiting law**, a law that is strictly true only in a certain limit, in this case  $p \rightarrow 0$ . For example, if it is found empirically that the volume of a substance fits an expression  $V = aT + bp + cp^2$ , then in the limit of  $p \rightarrow 0$ ,  $V = aT$ . Throughout this text, equations valid in this limiting sense are labelled with a blue equation number, as in these expressions. Although these relations are strictly true only at  $p=0$ , they are reasonably reliable at normal pressures ( $p \approx 1\text{bar}$ ) and are used widely throughout chemistry.

Avogadro’s principle is commonly expressed in the form ‘equal volumes of gases at the same temperature and pressure contain the same numbers of molecules’. It is a principle rather than a law (a summary of experience) because it depends on the validity of a model, in this case the existence of molecules. Despite there now being no doubt about the existence of molecules, it is still a model-based principle rather than a law.

Figure 1A.2 depicts the variation of the pressure of a sample of gas as the volume is changed. Each of the curves in the

Figure 1A.2 The pressure–volume dependence of a fixed amount of perfect gas at different temperatures. Each curve is a hyperbola ( $pV = \text{constant}$ ) and is called an isotherm.

Figure 1A.3 Straight lines are obtained when the pressure is plotted against  $1/V$  at constant temperature.

graph corresponds to a single temperature and hence is called an **isotherm**. According to Boyle's law, the isotherms of gases are hyperbolas (a curve obtained by plotting  $y$  against  $x$  with  $xy = \text{constant}$ , or  $y = \text{constant}/x$ ). An alternative depiction, a plot of pressure against  $1/\text{volume}$ , is shown in Fig. 1A.3. The linear variation of volume with temperature summarized by Charles's law is illustrated in Fig. 1A.4. The lines in this illustration are examples of **isobars**, or lines showing the variation of properties at constant pressure. Figure 1A.5 illustrates the linear variation of pressure with temperature. The lines in this diagram are **isochores**, or lines showing the variation of properties at constant volume.

*A note on good practice* To test the validity of a relation between two quantities, it is best to plot them in such a way that they should give a straight line, for deviations from a straight line are much easier to detect than deviations from a curve. The development of expressions that, when plotted, give a straight line is a very important and common procedure in physical chemistry.

Figure 1A.4 The variation of the volume of a fixed amount of gas with the temperature at constant pressure. Note that in each case the isobars extrapolate to zero volume at  $T=0$ , or  $\theta = -273^\circ\text{C}$ .

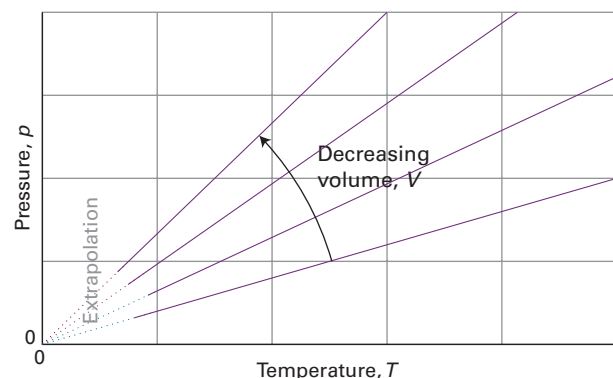

Figure 1A.5 The pressure also varies linearly with the temperature at constant volume, and extrapolates to zero at  $T=0$  ( $-273^\circ\text{C}$ ).

The empirical observations summarized by eqn 1A.5 can be combined into a single expression:

$$pV = \text{constant} \times nT$$

This expression is consistent with Boyle's law ( $pV = \text{constant}$ ) when  $n$  and  $T$  are constant, with both forms of Charles's law ( $p \propto T$ ,  $V \propto T$ ) when  $n$  and either  $V$  or  $p$  are held constant, and with Avogadro's principle ( $V \propto n$ ) when  $p$  and  $T$  are constant. The constant of proportionality, which is found experimentally to be the same for all gases, is denoted  $R$  and called the (molar) **gas constant**. The resulting expression

$$pV = nRT \quad \text{Perfect gas law} \quad (1A.5)$$

is the **perfect gas law** (or *perfect gas equation of state*). It is the approximate equation of state of any gas, and becomes increasingly exact as the pressure of the gas approaches zero. A gas that obeys eqn 1A.5 exactly under all conditions is called a **perfect gas** (or *ideal gas*). A **real gas**, an actual gas, behaves more like a perfect gas the lower the pressure, and is described exactly by eqn 1A.5 in the limit of  $p \rightarrow 0$ . The gas constant  $R$  can be determined by evaluating  $R = pV/nT$  for a gas in the limit of zero pressure (to guarantee that it is behaving perfectly). However, a more accurate value can be obtained by measuring the speed of sound in a low-pressure gas (argon is used in practice), for the speed of sound depends on the value of  $R$  and extrapolating its value to zero pressure. Another route to its value is to recognize (as explained in *Foundations B*) that it is related to Boltzmann's constant,  $k$ , by

$$R = N_A k \quad \text{The (molar) gas constant} \quad (1A.6)$$

where  $N_A$  is Avogadro's constant. There are currently (in 2014) plans to use this relation as the sole route to  $R$ , with defined values of  $N_A$  and  $k$ . Table 1A.2 lists the values of  $R$  in a variety of units.

*A note on good practice* Despite 'ideal gas' being the more common term, we prefer 'perfect gas'. As explained in Topic 5A, in an 'ideal mixture' of A and B, the AA, BB, and AB

Table 1A.2 The gas constant ( $R=N_A k$ )

R	
8.314 47	J K <sup>-1</sup> mol <sup>-1</sup>

interactions are all the same but not necessarily zero. In a perfect gas, not only are the interactions all the same, they are also zero.

The surface in Fig. 1A.6 is a plot of the pressure of a fixed amount of perfect gas against its volume and thermodynamic temperature as given by eqn 1A.5. The surface depicts the only possible states of a perfect gas: the gas cannot exist in states that do not correspond to points on the surface. The graphs in Figs. 1A.2 and 1A.4 correspond to the sections through the surface (Fig. 1A.7).

Figure 1A.6 A region of the  $p, V, T$  surface of a fixed amount of perfect gas. The points forming the surface represent the only states of the gas that can exist.

Figure 1A.7 Sections through the surface shown in Fig. 1A.6 at constant temperature give the isotherms shown in Fig. 1A.2, the isobars shown in Fig. 1A.4, and the isochores shown in Fig. 1A.5.

### Example 1A.2 Using the perfect gas law

In an industrial process, nitrogen is heated to 500 K in a vessel of constant volume. If it enters the vessel at 100 atm and 300 K, what pressure would it exert at the working temperature if it behaved as a perfect gas?

**Method** We expect the pressure to be greater on account of the increase in temperature. The perfect gas law in the form  $pV/nT=R$  implies that if the conditions are changed from one set of values to another, then because  $pV/nT$  is equal to a constant, the two sets of values are related by the ‘combined gas law’

$$\frac{p_1 V_1}{n_1 T_1} = \frac{p_2 V_2}{n_2 T_2} \quad \text{Combined gas law (1A.7)}$$

This expression is easily rearranged to give the unknown quantity (in this case  $p_2$ ) in terms of the known. The known and unknown data are summarized as follows:

	$n$	$p$	$V$	$T$
Initial	Same	100	Same	300
Final	Same	?	Same	500

**Answer** Cancellation of the volumes (because  $V_1 = V_2$ ) and amounts (because  $n_1 = n_2$ ) on each side of the combined gas law results in

$$\frac{p_1}{T_1} = \frac{p_2}{T_2}$$

which can be rearranged into

$$p_2 = \frac{T_2}{T_1} \times p_1$$

Substitution of the data then gives

$$p_2 = \frac{500\text{ K}}{300\text{ K}} \times (100\text{ atm}) = 167\text{ atm}$$

Experiment shows that the pressure is actually 183 atm under these conditions, so the assumption that the gas is perfect leads to a 10 per cent error.

**Self-test 1A.2** What temperature would result in the same sample exerting a pressure of 300 atm?

Answer: 900 K

The perfect gas law is of the greatest importance in physical chemistry because it is used to derive a wide range of relations that are used throughout thermodynamics. However, it is also of considerable practical utility for calculating the properties of a gas under a variety of conditions. For instance, the molar volume,  $V_m = V/n$ , of a perfect gas under the conditions called **standard ambient temperature and pressure (SATP)**, which means

298.15 K and 1 bar (that is, exactly  $10^5$  Pa), is easily calculated from  $V_m = RT/p$  to be  $24.789 \text{ dm}^3 \text{ mol}^{-1}$ . An earlier definition, **standard temperature and pressure (STP)**, was  $0^\circ\text{C}$  and 1 atm; at STP, the molar volume of a perfect gas is  $22.414 \text{ dm}^3 \text{ mol}^{-1}$ .

The molecular explanation of Boyle's law is that if a sample of gas is compressed to half its volume, then twice as many molecules strike the walls in a given period of time than before it was compressed. As a result, the average force exerted on the walls is doubled. Hence, when the volume is halved the pressure of the gas is doubled, and  $pV$  is a constant. Boyle's law applies to all gases regardless of their chemical identity (provided the pressure is low) because at low pressures the average separation of molecules is so great that they exert no influence on one another and hence travel independently. The molecular explanation of Charles's law lies in the fact that raising the temperature of a gas increases the average speed of its molecules. The molecules collide with the walls more frequently and with greater impact. Therefore they exert a greater pressure on the walls of the container. For a quantitative account of these relations, see Topic 1B.

## (b) Mixtures of gases

When dealing with gaseous mixtures, we often need to know the contribution that each component makes to the total pressure of the sample. The **partial pressure**,  $p_J$ , of a gas J in a mixture (any gas, not just a perfect gas), is defined as

$$p_J = x_J p \quad \text{Definition} \quad \text{Partial pressure} \quad (1A.8)$$

where  $x_J$  is the **mole fraction** of the component J, the amount of J expressed as a fraction of the total amount of molecules,  $n$ , in the sample:

$$x_J = \frac{n_J}{n} \quad n = n_A + n_B + \dots \quad \text{Definition} \quad \text{Mole fraction} \quad (1A.9)$$

When no J molecules are present,  $x_J = 0$ ; when only J molecules are present,  $x_J = 1$ . It follows from the definition of  $x_J$  that, whatever the composition of the mixture,  $x_A + x_B + \dots = 1$  and therefore that the sum of the partial pressures is equal to the total pressure:

$$p_A + p_B + \dots = (x_A + x_B + \dots)p = p \quad (1A.10)$$

This relation is true for both real and perfect gases.

When all the gases are perfect, the partial pressure as defined in eqn 1A.9 is also the pressure that each gas would exert if it occupied the same container alone at the same temperature. The latter is the original meaning of 'partial pressure'. That identification was the basis of the original formulation of **Dalton's law**:

The pressure exerted by a mixture of gases is the sum of the pressures that each one would exert if it occupied the container alone.

Dalton's law

Now, however, the relation between partial pressure (as defined in eqn 1A.8) and total pressure (as given by eqn 1A.10) is true for all gases and the identification of partial pressure with the pressure that the gas would exert on its own is valid only for a perfect gas.

### Example 1A.3 Calculating partial pressures

The mass percentage composition of dry air at sea level is approximately  $\text{N}_2$ : 75.5;  $\text{O}_2$ : 23.2; Ar: 1.3. What is the partial pressure of each component when the total pressure is 1.20 atm?

**Method** We expect species with a high mole fraction to have a proportionally high partial pressure. Partial pressures are defined by eqn 1A.8. To use the equation, we need the mole fractions of the components. To calculate mole fractions, which are defined by eqn 1A.9, we use the fact that the amount of molecules J of molar mass  $M_J$  in a sample of mass  $m_J$  is  $n_J = m_J/M_J$ . The mole fractions are independent of the total mass of the sample, so we can choose the latter to be exactly 100 g (which makes the conversion from mass percentages very easy). Thus, the mass of  $\text{N}_2$  present is 75.5 per cent of 100 g, which is 75.5 g.

**Answer** The amounts of each type of molecule present in 100 g of air, in which the masses of  $\text{N}_2$ ,  $\text{O}_2$ , and Ar are 75.5 g, 23.2 g, and 1.3 g, respectively, are

$$\begin{aligned} n(\text{N}_2) &= \frac{75.5 \text{ g}}{28.02 \text{ g mol}^{-1}} = \frac{75.5}{28.02} \text{ mol} = 2.69 \text{ mol} \\ n(\text{O}_2) &= \frac{23.2 \text{ g}}{32.00 \text{ g mol}^{-1}} = \frac{23.2}{32.00} \text{ mol} = 0.725 \text{ mol} \\ n(\text{Ar}) &= \frac{1.3 \text{ g}}{39.95 \text{ g mol}^{-1}} = \frac{1.3}{39.95} \text{ mol} = 0.033 \text{ mol} \end{aligned}$$

The total is 3.45 mol. The mole fractions are obtained by dividing each of the above amounts by 3.45 mol and the partial pressures are then obtained by multiplying the mole fraction by the total pressure (1.20 atm):

	$\text{N}_2$	$\text{O}_2$	Ar
Mole fraction:	0.780	0.210	0.0096
Partial pressure/atm:	0.936	0.252	0.012

We have not had to assume that the gases are perfect: partial pressures are defined as  $p_J = x_J p$  for any kind of gas.

**Self-test 1A.3** When carbon dioxide is taken into account, the mass percentages are 75.52 ( $\text{N}_2$ ), 23.15 ( $\text{O}_2$ ), 1.28 (Ar), and 0.046 ( $\text{CO}_2$ ). What are the partial pressures when the total pressure is 0.900 atm?

Answer: 0.703, 0.189, 0.0084, 0.00027 atm

## Checklist of concepts

- 1. The **physical state** of a sample of a substance, its physical condition, is defined by its physical properties.
- 2. **Mechanical equilibrium** is the condition of equality of pressure on either side of a shared movable wall.
- 3. An **equation of state** is an equation that interrelates the variables that define the state of a substance.
- 4. Boyle's and Charles's laws are examples of a **limiting law**, a law that is strictly true only in a certain limit, in this case  $p \rightarrow 0$ .
- 5. An **isotherm** is a line in a graph that corresponds to a single temperature.
- 6. An **isobar** is a line in a graph that corresponds to a single pressure.
- 7. An **isochore** is a line in a graph that corresponds to a single volume.
- 8. A **perfect gas** is a gas that obeys the perfect gas law under all conditions.
- 9. **Dalton's law** states that the pressure exerted by a mixture of (perfect) gases is the sum of the pressures that each one would exert if it occupied the container alone.

### ► Why do you need to know this material?

This material illustrates an important skill in science: the ability to extract quantitative information from a qualitative model. Moreover, the model is used in the discussion of the transport properties of gases (Topic 19A), reaction rates in gases (Topic 20F), and catalysis (Topic 22C).

### ► What is the key idea?

A gas consists of molecules of negligible size in ceaseless random motion and obeying the laws of classical mechanics in their collisions.

### ► What do you need to know already?

You need to be aware of Newton's second law of motion, that the acceleration of a body is proportional to the force acting on it, and the conservation of linear momentum.

In the **kinetic theory** of gases (which is sometimes called the *kinetic-molecular theory*, KMT) it is assumed that the only contribution to the energy of the gas is from the kinetic energies of the molecules. The kinetic model is one of the most remarkable—and arguably most beautiful—models in physical

chemistry, for from a set of very slender assumptions, powerful quantitative conclusions can be reached.

## 1B.1 The model

The kinetic model is based on three assumptions:

1. The gas consists of molecules of mass  $m$  in ceaseless random motion obeying the laws of classical mechanics.
2. The size of the molecules is negligible, in the sense that their diameters are much smaller than the average distance travelled between collisions.
3. The molecules interact only through brief elastic collisions.

An **elastic collision** is a collision in which the total translational kinetic energy of the molecules is conserved.

### (a) Pressure and molecular speeds

From the very economical assumptions of the kinetic model, we show in the following *Justification* that the pressure and volume of the gas are related by

$$pV = \frac{1}{3}nMv_{\text{rms}}^2 \quad \text{Perfect gas Pressure (1B.1)}$$

where  $M = mN_A$ , the molar mass of the molecules of mass  $m$ , and  $v_{\text{rms}}$  is the square root of the mean of the squares of the speeds,  $v$ , of the molecules:

$$v_{\text{rms}} = \langle v^2 \rangle^{1/2} \quad \text{Definition Root-mean-square speed (1B.2)}$$

#### Justification 1.1B The pressure of a gas according to the kinetic model

Consider the arrangement in Fig. 1B.1. When a particle of mass  $m$  that is travelling with a component of velocity  $v_x$  parallel to the  $x$ -axis collides with the wall on the right and is reflected, its linear momentum changes from  $mv_x$  before the collision to  $-mv_x$  after the collision (when it is travelling in the opposite direction). The  $x$ -component of momentum therefore changes by  $2mv_x$  on each collision (the  $y$ - and  $z$ -components are unchanged). Many molecules collide with the wall in an interval  $\Delta t$ , and the total change of momentum is the product of the change in momentum of each molecule multiplied

**Figure 1B.1** The pressure of a gas arises from the impact of its molecules on the walls. In an elastic collision of a molecule with a wall perpendicular to the  $x$ -axis, the  $x$ -component of velocity is reversed but the  $y$ - and  $z$ -components are unchanged.

by the number of molecules that reach the wall during the interval.

Because a molecule with velocity component  $v_x$  can travel a distance  $v_x \Delta t$  along the  $x$ -axis in an interval  $\Delta t$ , all the molecules within a distance  $v_x \Delta t$  of the wall will strike it if they are travelling towards it (Fig. 1B.2). It follows that if the wall has area  $A$ , then all the particles in a volume  $A \times v_x \Delta t$  will reach the wall (if they are travelling towards it). The number density of particles is  $nN_A/V$ , where  $n$  is the total amount of molecules in the container of volume  $V$  and  $N_A$  is Avogadro's constant, so the number of molecules in the volume  $A v_x \Delta t$  is  $(nN_A/V) \times A v_x \Delta t$ .

At any instant, half the particles are moving to the right and half are moving to the left. Therefore, the average number of collisions with the wall during the interval  $\Delta t$  is  $\frac{1}{2} nN_A A v_x \Delta t / V$ . The total momentum change in that interval is the product of this number and the change  $2mv_x$ :

$$\begin{aligned} \text{Momentum change} &= \frac{nN_A A v_x \Delta t}{2V} \times 2mv_x \\ &= \frac{\overbrace{nmN_A}^M A v_x^2 \Delta t}{V} = \frac{nMAv_x^2 \Delta t}{V} \end{aligned}$$

**Figure 1B.2** A molecule will reach the wall on the right within an interval  $\Delta t$  if it is within a distance  $v_x \Delta t$  of the wall and travelling to the right.

Next, to find the force, we calculate the rate of change of momentum, which is this change of momentum divided by the interval  $\Delta t$  during which it occurs:

$$\text{Rate of change of momentum} = \frac{nMAv_x^2}{V}$$

This rate of change of momentum is equal to the force (by Newton's second law of motion). It follows that the pressure, the force divided by the area, is

$$\text{Pressure} = \frac{nMv_x^2}{V}$$

Not all the molecules travel with the same velocity, so the detected pressure,  $p$ , is the average (denoted  $\langle \dots \rangle$ ) of the quantity just calculated:

$$p = \frac{nM \langle v_x^2 \rangle}{V}$$

This expression already resembles the perfect gas equation of state.

To write an expression for the pressure in terms of the root-mean-square speed,  $v_{\text{rms}}$ , we begin by writing the speed of a single molecule,  $v$ , as  $v^2 = v_x^2 + v_y^2 + v_z^2$ . Because the root-mean-square speed is defined as  $v_{\text{rms}} = \langle v^2 \rangle^{1/2}$ , it follows that

$$v_{\text{rms}}^2 = \langle v^2 \rangle = \langle v_x^2 \rangle + \langle v_y^2 \rangle + \langle v_z^2 \rangle$$

However, because the molecules are moving randomly, all three averages are the same. It follows that  $v_{\text{rms}}^2 = \langle 3v_x^2 \rangle$ . Equation 1B.1 follows immediately by substituting  $\langle v_x^2 \rangle = \frac{1}{3} \langle v_{\text{rms}}^2 \rangle$  into  $p = nM \langle v_x^2 \rangle / V$ .

Equation 1B.1 is one of the key results of the kinetic model. We see that, if the root-mean-square speed of the molecules depends only on the temperature, then at constant temperature

$$pV = \text{constant}$$

which is the content of Boyle's law. Moreover, for eqn 1B.1 to be the equation of state of a perfect gas, its right-hand side must be equal to  $nRT$ . It follows that the root-mean-square speed of the molecules in a gas at a temperature  $T$  must be

$$v_{\text{rms}} = \left( \frac{3RT}{M} \right)^{1/2} \quad \text{Perfect gas RMS speed} \quad (1B.3)$$

#### Brief illustration 1B.1 Molecular speeds

For  $N_2$  molecules at  $25^\circ\text{C}$ , we use  $M = 28.02 \text{ g mol}^{-1}$ , then

$$v_{\text{rms}} = \left\{ \frac{3 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{0.02802 \text{ kg mol}^{-1}} \right\}^{1/2} = 515 \text{ m s}^{-1}$$

Shortly we shall encounter the mean speed,  $v_{\text{mean}}$ , and the most probable speed  $v_{\text{mp}}$ ; they are, respectively,

$$v_{\text{mean}} = \left(\frac{8}{3\pi}\right)^{1/2} v_{\text{rms}} = 0.921\dots \times (515 \text{ m s}^{-1}) = 475 \text{ m s}^{-1}$$

$$v_{\text{mp}} = \left(\frac{2}{3}\right)^{1/2} v_{\text{rms}} = 0.816\dots \times (515 \text{ m s}^{-1}) = 420 \text{ m s}^{-1}$$

**Self-test 1B.1** Evaluate the root-mean-square speed of  $\text{H}_2$  molecules at  $25^\circ\text{C}$ .

Answer:  $1.92 \text{ km s}^{-1}$

## (b) The Maxwell–Boltzmann distribution of speeds

Equation 1B.2 is an expression for the mean square speed of molecules. However, in an actual gas the speeds of individual molecules span a wide range, and the collisions in the gas continually redistribute the speeds among the molecules. Before a collision, a molecule may be travelling rapidly, but after a collision it may be accelerated to a very high speed, only to be slowed again by the next collision. The fraction of molecules that have speeds in the range  $v$  to  $v + dv$  is proportional to the width of the range, and is written  $f(v)dv$ , where  $f(v)$  is called the **distribution of speeds**. Note that, in common with other distribution functions,  $f(v)$  acquires physical significance only after it is multiplied by the range of speeds of interest. In the following *Justification* we show that the fraction of molecules that have a speed in the range  $v$  to  $v + dv$  is  $f(v)dv$ , where

$$f(v) = 4\pi \left(\frac{M}{2\pi RT}\right)^{3/2} v^2 e^{-Mv^2/2RT} \quad \text{Perfect gas} \quad \text{Maxwell–Boltzmann distribution} \quad (1B.4)$$

The function  $f(v)$  is called the **Maxwell–Boltzmann distribution of speeds**.

### Justification 1B.2 The Maxwell–Boltzmann distribution of speeds

The Boltzmann distribution (*Foundations B*) implies that the fraction of molecules with velocity components  $v_x$ ,  $v_y$ , and  $v_z$  is proportional to an exponential function of their kinetic energy:  $f(v) = Ke^{-\epsilon/kT}$ , where  $K$  is a constant of proportionality. The kinetic energy is

$$\epsilon = \frac{1}{2}mv_x^2 + \frac{1}{2}mv_y^2 + \frac{1}{2}mv_z^2$$

Therefore, we can use the relation  $a^{x+y+z} = a^x a^y a^z$  to write

$$f(v) = Ke^{-(mv_x^2 + mv_y^2 + mv_z^2)/2kT} = Ke^{-mv_x^2/2kT} e^{-mv_y^2/2kT} e^{-mv_z^2/2kT}$$

The distribution factorizes into three terms, and we can write  $f(v) = f(v_x)f(v_y)f(v_z)$  and  $K = K_x K_y K_z$ , with

$$f(v_x) = K_x e^{-mv_x^2/2kT}$$

and likewise for the other two axes.

To determine the constant  $K_x$ , we note that a molecule must have a velocity component somewhere in the range  $-\infty < v_x < \infty$ , so

$$\int_{-\infty}^{\infty} f(v_x) dv_x = 1$$

Substitution of the expression for  $f(v_x)$  then gives

$$1 = K_x \int_{-\infty}^{\infty} e^{-mv_x^2/2kT} dv_x \stackrel{\text{Integral G.1}}{=} K_x \left(\frac{2\pi kT}{m}\right)^{1/2}$$

Therefore,  $K_x = (m/2\pi kT)^{1/2}$  and at this stage we can write

$$f(v_x) = \left(\frac{m}{2\pi kT}\right)^{1/2} e^{-mv_x^2/2kT} \quad (1B.5)$$

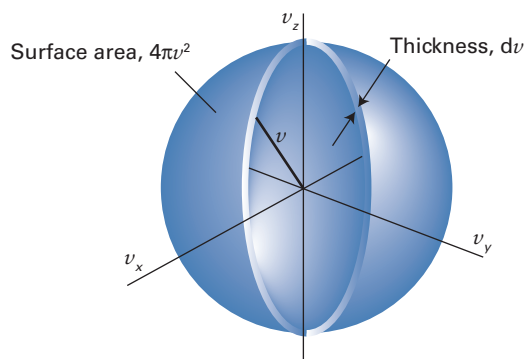

The probability that a molecule has a velocity in the range  $v_x$  to  $v_x + dv_x$ ,  $v_y$  to  $v_y + dv_y$ ,  $v_z$  to  $v_z + dv_z$ , is therefore

$$f(v_x)f(v_y)f(v_z) = \left(\frac{m}{2\pi kT}\right)^{3/2} e^{-mv_x^2/2kT} e^{-mv_y^2/2kT} e^{-mv_z^2/2kT} \times dv_x dv_y dv_z$$

$$= \left(\frac{m}{2\pi kT}\right)^{3/2} e^{-mv^2/2kT} dv_x dv_y dv_z$$

where  $v^2 = v_x^2 + v_y^2 + v_z^2$ .

To evaluate the probability that the molecules have a speed in the range  $v$  to  $v + dv$  regardless of direction we think of the three velocity components as defining three coordinates in ‘velocity space’, with the same properties as ordinary space except that the coordinates are labelled  $(v_x, v_y, v_z)$  instead of  $(x, y, z)$ . Just as the volume element in ordinary space is  $dx dy dz$ , so the volume element in velocity space is  $dv_x dv_y dv_z$ . The sum of all the volume elements in ordinary space that lie at a distance  $r$  from the centre is the volume of a spherical shell of radius  $r$  and thickness  $dr$ . That volume is the product of its surface area,  $4\pi r^2$ , and its thickness  $dr$ , and is therefore  $4\pi r^2 dr$ . Similarly, the analogous volume in velocity space is the volume of a shell of radius  $v$  and thickness  $dv$ , namely  $4\pi v^2 dv$  (Fig. 1B.3). Now, because  $f(v_x)f(v_y)f(v_z)$ , the term in blue in the last equation, depends only on  $v^2$ , and has the same value everywhere in a shell of radius  $v$ , the total probability of the molecules possessing a speed in the range  $v$  to  $v + dv$  is the product of the term in blue and the volume of the

**Figure 1B.3** To evaluate the probability that a molecule has a speed in the range  $v$  to  $v + dv$ , we evaluate the total probability that the molecule will have a speed that is anywhere on the surface of a sphere of radius  $v = (v_x^2 + v_y^2 + v_z^2)^{1/2}$  by summing the probabilities that it is in a volume element  $dv_x dv_y dv_z$  at a distance  $v$  from the origin.

shell of radius  $v$  and thickness  $dv$ . If this probability is written  $f(v)dv$ , it follows that

$$f(v)dv = 4\pi v^2 dv \left( \frac{m}{2\pi kT} \right)^{3/2} e^{-mv^2/2kT}$$

and  $f(v)$  itself, after minor rearrangement, is

$$f(v) = 4\pi \left( \frac{m}{2\pi kT} \right)^{3/2} v^2 e^{-mv^2/2kT}$$

Because  $m/k = M/R$ , this expression is eqn 1B.4.

The important features of the Maxwell–Boltzmann distribution are as follows (and are shown pictorially in Fig. 1B.4):

- Equation 1B.4 includes a decaying exponential function (more specifically, a Gaussian function). Its presence implies that the fraction of molecules with very high speeds will be very small because  $e^{-x^2}$  becomes very small when  $x$  is large.
- The factor  $M/2RT$  multiplying  $v^2$  in the exponent is large when the molar mass,  $M$ , is large, so the exponential factor goes most rapidly towards zero when  $M$  is large. That is, heavy molecules are unlikely to be found with very high speeds.
- The opposite is true when the temperature,  $T$ , is high: then the factor  $M/2RT$  in the exponent is small, so the exponential factor falls towards zero relatively slowly as  $v$  increases. In other words, a greater fraction of the molecules can be expected to have high speeds at high temperatures than at low temperatures.

Physical interpretation

**Figure 1B.4** The distribution of molecular speeds with temperature and molar mass. Note that the most probable speed (corresponding to the peak of the distribution) increases with temperature and with decreasing molar mass, and simultaneously the distribution becomes broader.

- A factor  $v^2$  (the term before the  $e$ ) multiplies the exponential. This factor goes to zero as  $v$  goes to zero, so the fraction of molecules with very low speeds will also be very small whatever their mass.
- The remaining factors (the term in parentheses in eqn 1B.4 and the  $4\pi$ ) simply ensure that, when we sum the fractions over the entire range of speeds from zero to infinity, then we get 1.

The Maxwell distribution has been verified experimentally. For example, molecular speeds can be measured directly with a velocity selector (Fig. 1B.5). The spinning discs have slits that permit the passage of only those molecules moving through them at the appropriate speed, and the number of molecules can be determined by collecting them at a detector.

### (c) Mean values

Once we have the Maxwell–Boltzmann distribution, we can calculate the mean value of any power of the speed by evaluating the appropriate integral. For instance, to evaluate the

**Figure 1B.5** A velocity selector. Only molecules travelling at speeds within a narrow range pass through the succession of slits as they rotate into position.

**Figure 1B.6** To calculate the probability that a molecule will have a speed in the range  $v_1$  to  $v_2$ , we integrate the distribution between those two limits; the integral is equal to the area of the curve between the limits, as shown shaded here.

fraction of molecules in the range  $v_1$  to  $v_2$  we evaluate the integral:

$$F(v_1, v_2) = \int_{v_1}^{v_2} f(v) dv \quad (1B.6)$$

This integral is the area under the graph of  $f$  as a function of  $v$  and, except in special cases, has to be evaluated numerically by using mathematical software (Fig. 1B.6). To evaluate the average value of  $v^n$  we calculate

$$\langle v^n \rangle = \int_0^{\infty} v^n f(v) dv \quad (1B.7)$$

In particular, integration with  $n=2$  results in eqn 1B.3 for the mean square speed ( $v^2$ ) of the molecules at a temperature  $T$ . We can conclude that the root-mean-square speed of the molecules of a gas is proportional to the square root of the temperature and inversely proportional to the square root of the molar mass. That is, the higher the temperature, the higher the root-mean-square speed of the molecules, and, at a given temperature, heavy molecules travel more slowly than light molecules. Sound waves are pressure waves, and for them to propagate the molecules of the gas must move to form regions of high and low pressure. Therefore, we should expect the root-mean-square speeds of molecules to be comparable to the speed of sound in air ( $340 \text{ m s}^{-1}$ ). As we have seen, the root-mean-square speed of  $\text{N}_2$  molecules, for instance, is  $515 \text{ m s}^{-1}$  at  $298 \text{ K}$ .

### Example 1B.1 Calculating the mean speed of molecules in a gas

Calculate the mean speed,  $v_{\text{mean}}$ , of  $\text{N}_2$  molecules in air at  $25^\circ\text{C}$ .

**Method** The mean speed is obtained by evaluating the integral

$$v_{\text{mean}} = \int_0^{\infty} v f(v) dv$$

with  $f(v)$  given in eqn 1B.4. Either use mathematical software or use the standard integrals in the *Resource section*.

**Answer** The integral required is

$$v_{\text{mean}} = 4\pi \left( \frac{M}{2\pi RT} \right)^{3/2} \int_0^{\infty} v^3 e^{-mv^2/2kT} dv$$

**Integral G.4**

$$\stackrel{\text{Integral G.4}}{=} 4\pi \left( \frac{M}{2\pi RT} \right)^{3/2} \times \frac{1}{2} \left( \frac{2RT}{M} \right)^{1/2} = \left( \frac{8RT}{\pi M} \right)^{1/2}$$

Substitution of the data then gives

$$v_{\text{mean}} = \left( \frac{8 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{\pi \times (28.02 \times 10^{-3} \text{ kg mol}^{-1})} \right)^{1/2} = 475 \text{ m s}^{-1}$$

We have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$  (the difference from the earlier value of 474 is due to rounding effects in that calculation; this value is more accurate).

**Self-test 1B.2** Evaluate the root-mean-square speed of the molecules by integration. Use mathematical software or use a standard integral in the *Resource section*.

$$\text{Answer: } v_{\text{rms}} = (3RT/M)^{1/2} = 515 \text{ m s}^{-1}$$

As shown in *Example 1B.1*, we can use the Maxwell-Boltzmann distribution to evaluate the **mean speed**,  $v_{\text{mean}}$ , of the molecules in a gas:

$$v_{\text{mean}} = \left( \frac{8RT}{\pi M} \right)^{1/2} = \left( \frac{8}{3\pi} \right)^{1/2} v_{\text{rms}} \quad \text{Perfect gas} \quad \text{Mean speed} \quad (1B.8)$$

We can identify the **most probable speed**,  $v_{\text{mp}}$ , from the location of the peak of the distribution:

$$v_{\text{mp}} = \left( \frac{2RT}{M} \right)^{1/2} = \left( \frac{2}{3} \right)^{1/2} v_{\text{rms}} \quad \text{Perfect gas} \quad \text{Most probable speed} \quad (1B.9)$$

The location of the peak of the distribution is found by differentiating  $f(v)$  with respect to  $v$  and looking for the value of  $v$  at which the derivative is zero (other than at  $v=0$  and  $v=\infty$ ); see Problem 1B.3. Figure 1B.7 summarizes these results and some numerical values were calculated in *Brief illustration 1B.1*.

The **mean relative speed**,  $v_{\text{rel}}$ , the mean speed with which one molecule approaches another of the same kind, can also be calculated from the distribution:

$$v_{\text{rel}} = 2^{1/2} v_{\text{mean}} \quad \text{Perfect gas, identical molecules} \quad \text{Mean relative speed} \quad (1B.10a)$$

**Figure 1B.7** A summary of the conclusions that can be deduced from the Maxwell distribution for molecules of molar mass  $M$  at a temperature  $T$ :  $v_{\text{mp}}$  is the most probable speed,  $v_{\text{mean}}$  is the mean speed, and  $v_{\text{rms}}$  is the root-mean-square speed.

This result is much harder to derive, but the diagram in Fig. 1B.8 should help to show that it is plausible. For the relative mean speed of two dissimilar molecules of masses  $m_A$  and  $m_B$ :

$$v_{\text{rel}} = \left( \frac{8kT}{\pi\mu} \right)^{1/2} \quad \mu = \frac{m_A m_B}{m_A + m_B} \quad \text{Perfect gas} \quad \text{Mean relative speed} \quad (1B.10b)$$

**Figure 1B.8** A simplified version of the argument to show that the mean relative speed of molecules in a gas is related to the mean speed. When the molecules are moving in the same direction, the mean relative speed is zero; it is  $2v$  when the molecules are approaching each other. A typical mean direction of approach is from the side, and the mean speed of approach is then  $2^{1/2}v$ . The last direction of approach is the most characteristic, so the mean speed of approach can be expected to be about  $2^{1/2}v$ . This value is confirmed by more detailed calculation.

### Brief illustration 1B.2 Relative molecular speeds

We have already seen (in *Brief illustration 1B.1*) that the rms speed of  $\text{N}_2$  molecules at  $25^\circ\text{C}$  is  $515 \text{ m s}^{-1}$ . It follows from eqn 1B.10a that their relative mean speed is

$$v_{\text{rel}} = 2^{1/2} \times (515 \text{ m s}^{-1}) = 728 \text{ m s}^{-1}$$

**Self-test 1B.3** What is the relative mean speed of  $\text{N}_2$  and  $\text{H}_2$  molecules in a gas at  $25^\circ\text{C}$ ?

Answer:  $1.83 \text{ km s}^{-1}$

## 1B.2 Collisions

The kinetic model enables us to make the qualitative picture of a gas as a collection of ceaselessly moving, colliding molecules more quantitative. In particular, it enables us to calculate the frequency with which molecular collisions occur and the distance a molecule travels on average between collisions.

### (a) The collision frequency

Although the kinetic-molecular theory assumes that the molecules are point-like, we can count a ‘hit’ whenever the centres of two molecules come within a distance  $d$  of each other, where  $d$ , the collision diameter, is of the order of the actual diameters of the molecules (for impenetrable hard spheres  $d$  is the diameter). As we show in the following *Justification*, we can use the kinetic model to deduce that the **collision frequency**,  $z$ , the number of collisions made by one molecule divided by the time interval during which the collisions are counted, when there are  $N$  molecules in a volume  $V$  is

$$z = \sigma v_{\text{rel}} \mathcal{N} \quad \text{Perfect gas} \quad \text{Collision frequency} \quad (1B.11a)$$

with  $\mathcal{N} = N/V$ , the number density, and  $v_{\text{rel}}$  given by eqn 1B.10. The area  $\sigma = \pi d^2$  is called the **collision cross-section** of the molecules. Some typical collision cross-sections are given in Table 1B.1. In terms of the pressure (as is also shown in the following *Justification*),

$$z = \frac{\sigma v_{\text{rel}} p}{kT} \quad \text{Perfect gas} \quad \text{Collision frequency} \quad (1B.11b)$$

**Table 1B.1\*** Collision cross-sections,  $\sigma/\text{nm}^2$

	$\sigma/\text{nm}^2$
$\text{C}_6\text{H}_6$	0.88
$\text{CO}_2$	0.52
He	0.21
$\text{N}_2$	0.43

\* More values are given in the *Resource section*.

### Justification 1B.3 The collision frequency according to the kinetic model

Consider the positions of all the molecules except one to be frozen. Then note what happens as one mobile molecule travels through the gas with a mean relative speed  $v_{\text{rel}}$  for a

**Figure 1B.9** The calculation of the collision frequency and the mean free path in the kinetic theory of gases.

time  $\Delta t$ . In doing so it sweeps out a 'collision tube' of cross-sectional area  $\sigma = \pi d^2$  and length  $v_{\text{rel}}\Delta t$  and therefore of volume  $\sigma v_{\text{rel}}\Delta t$  (Fig. 1B.9). The number of stationary molecules with centres inside the collision tube is given by the volume of the tube multiplied by the number density  $\mathcal{N} = N/V$ , and is  $\mathcal{N}\sigma v_{\text{rel}}\Delta t$ . The number of hits scored in the interval  $\Delta t$  is equal to this number, so the number of collisions divided by the time interval is  $\mathcal{N}\sigma v_{\text{rel}}$ , which is eqn 1B.11a. The expression in terms of the pressure of the gas is obtained by using the perfect gas equation to write

$$\mathcal{N} = \frac{N}{V} = \frac{nN_A}{V} = \frac{nN_A}{nRT/p} = \frac{p}{kT}$$

Equation 1B.11a shows that, at constant volume, the collision frequency increases with increasing temperature. Equation 1B.11b shows that, at constant temperature, the collision frequency is proportional to the pressure. Such a proportionality is plausible because the greater the pressure, the greater the number density of molecules in the sample, and the rate at which they encounter one another is greater even though their average speed remains the same.

#### Brief illustration 1B.3 Molecular collisions

For an  $\text{N}_2$  molecule in a sample at 1.00 atm (101 kPa) and 25 °C, from *Brief illustration 1B.2* we know that  $v_{\text{rel}} = 728 \text{ m s}^{-1}$ . Therefore, from eqn 1B.11b, and taking  $\sigma = 0.45 \text{ nm}^2$  (corresponding to  $0.45 \times 10^{-18} \text{ m}^2$ ) from Table 1B.1,

$$z = \frac{(0.43 \times 10^{-18} \text{ m}^2) \times (728 \text{ m s}^{-1}) \times (1.01 \times 10^5 \text{ Pa})}{(1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} \\ = 7.7 \times 10^9 \text{ s}^{-1}$$

so a given molecule collides about  $8 \times 10^9$  times each second. We are beginning to appreciate the timescale of events in gases.

**Self-test 1B.4** Evaluate the collision frequency between  $\text{H}_2$  molecules in a gas under the same conditions.

Answer:  $4.1 \times 10^9 \text{ s}^{-1}$

#### (b) The mean free path

Once we have the collision frequency, we can calculate the **mean free path**,  $\lambda$  (lambda), the average distance a molecule travels between collisions. If a molecule collides with a frequency  $z$ , it spends a time  $1/z$  in free flight between collisions, and therefore travels a distance  $(1/z)v_{\text{rel}}$ . It follows that the mean free path is

$$\lambda = \frac{v_{\text{rel}}}{z} \quad \text{Perfect gas} \quad \text{Mean free path} \quad (1B.12)$$

Substitution of the expression for  $z$  in eqn 1B.11b gives

$$\lambda = \frac{kT}{\sigma p} \quad \text{Perfect gas} \quad \text{Mean free path} \quad (1B.13)$$

Doubling the pressure reduces the mean free path by half.

#### Brief illustration 1B.4 The mean free path

In *Brief illustration 1B.2* we noted that  $v_{\text{rel}} = 728 \text{ m s}^{-1}$  for  $\text{N}_2$  molecules at 25 °C, and in *Brief illustration 1B.3* that  $z = 7.7 \times 10^9 \text{ s}^{-1}$  when the pressure is 1.00 atm. Under these circumstances, the mean free path of  $\text{N}_2$  molecules is

$$\lambda = \frac{728 \text{ m s}^{-1}}{7.7 \times 10^9 \text{ s}^{-1}} = 9.5 \times 10^{-8} \text{ m}$$

or 95 nm, about  $10^3$  molecular diameters.

**Self-test 1B.5** Evaluate the mean free path of benzene molecules at 25 °C in a sample where the pressure is 0.10 atm.

Answer: 460 nm

Although the temperature appears in eqn 1B.13, in a sample of constant volume, the pressure is proportional to  $T$ , so  $T/p$  remains constant when the temperature is increased. Therefore, the mean free path is independent of the temperature in a sample of gas in a container of fixed volume: the distance between collisions is determined by the number of molecules present in the given volume, not by the speed at which they travel.

In summary, a typical gas ( $\text{N}_2$  or  $\text{O}_2$ ) at 1 atm and 25 °C can be thought of as a collection of molecules travelling with a mean speed of about  $500 \text{ m s}^{-1}$ . Each molecule makes a collision within about 1 ns, and between collisions it travels about  $10^3$  molecular diameters. The kinetic model of gases is valid and the gas behaves nearly perfectly if the diameter of the molecules is much smaller than the mean free path ( $d \ll \lambda$ ), for then the molecules spend most of their time far from one another.

## Checklist of concepts

- 1. The **kinetic model** of a gas considers only the contribution to the energy from the kinetic energies of the molecules.
- 2. Important results from the model include expressions for the pressure and the **root-mean-square speed**.
- 3. The **Maxwell–Boltzmann distribution of speeds** gives the fraction of molecules that have speeds in a specified range.
- 4. The **collision frequency** is the number of collisions made by a molecule in an interval divided by the length of the interval.
- 5. The **mean free path** is the average distance a molecule travels between collisions.

### ► Why do you need to know this material?

Actual gases, so-called 'real gases', differ from perfect gases and it is important to be able to discuss their properties. Moreover, the deviations from perfect behaviour give insight into the nature of the interactions between molecules. Accounting for these interactions is also an introduction to the technique of model building in physical chemistry.

### ► What is the key idea?

Attractions and repulsions between gas molecules account for modifications to the isotherms of a gas and account for critical behaviour.

### ► What do you need to know already?

This Topic builds on and extends the discussion of perfect gases in Topic 1A. The principal mathematical technique employed is differentiation to identify a point of inflexion of a curve.

Real gases do not obey the perfect gas law exactly except in the limit of  $p \rightarrow 0$ . Deviations from the law are particularly important at high pressures and low temperatures, especially when a gas is on the point of condensing to liquid.

## 1C.1 Deviations from perfect behaviour

Real gases show deviations from the perfect gas law because molecules interact with one another. A point to keep in mind is that repulsive forces between molecules assist expansion and attractive forces assist compression.

Repulsive forces are significant only when molecules are almost in contact: they are short-range interactions, even on a scale measured in molecular diameters (Fig. 1C.1). Because they are short-range interactions, repulsions can be expected to be important only when the average separation of the molecules is small. This is the case at high pressure, when many molecules occupy a small volume. On the other hand, attractive intermolecular forces have a relatively long range and are effective over several molecular diameters. They are important when the molecules are fairly close together but not necessarily touching (at the intermediate separations in Fig. 1C.1).

**Figure 1C.1** The variation of the potential energy of two molecules on their separation. High positive potential energy (at very small separations) indicates that the interactions between them are strongly repulsive at these distances. At intermediate separations, where the potential energy is negative, the attractive interactions dominate. At large separations (on the right) the potential energy is zero and there is no interaction between the molecules.

Attractive forces are ineffective when the molecules are far apart (well to the right in Fig. 1C.1). Intermolecular forces are also important when the temperature is so low that the molecules travel with such low mean speeds that they can be captured by one another.

The consequences of these interactions are shown by shapes of experimental isotherms (Fig. 1C.2). At low pressures, when the sample occupies a large volume, the molecules are so far apart for most of the time that the intermolecular forces play no significant role, and the gas behaves virtually perfectly. At moderate pressures, when the average separation of the molecules is only a few molecular diameters, the attractive forces dominate the repulsive forces. In this case, the gas can be expected to be more compressible than a perfect gas because the forces help to draw the molecules together. At high pressures, when the average separation of the molecules is small, the repulsive forces dominate and the gas can be expected to be less compressible because now the forces help to drive the molecules apart.

Consider what happens when we compress (reduce the volume of) a sample of gas initially in the state marked A in Fig. 1C.2 at constant temperature by pushing in a piston. Near A, the pressure of the gas rises in approximate agreement with Boyle's law. Serious deviations from that law begin to appear when the volume has been reduced to B.

At C (which corresponds to about 60 atm for carbon dioxide), all similarity to perfect behaviour is lost, for suddenly the piston slides in without any further rise in pressure: this stage is represented by the horizontal line CDE. Examination of the contents of the vessel shows that just to the left of C a liquid appears, and there are two phases separated by a sharply defined surface. As the volume is decreased from C through D to E, the amount of liquid increases. There is no additional resistance to the piston because the gas can respond

**Figure 1C.2** Experimental isotherms of carbon dioxide at several temperatures. The 'critical isotherm', the isotherm at the critical temperature, is at 31.1 °C.

by condensing. The pressure corresponding to the line CDE, when both liquid and vapour are present in equilibrium, is called the **vapour pressure** of the liquid at the temperature of the experiment.

At E, the sample is entirely liquid and the piston rests on its surface. Any further reduction of volume requires the exertion of considerable pressure, as is indicated by the sharply rising line to the left of E. Even a small reduction of volume from E to F requires a great increase in pressure.

### (a) The compression factor

As a first step in making these observations quantitative we introduce the **compression factor**,  $Z$ , the ratio of the measured molar volume of a gas,  $V_m = V/n$ , to the molar volume of a perfect gas,  $V_m^\circ$ , at the same pressure and temperature:

$$Z = \frac{V_m}{V_m^\circ} \quad \text{Definition} \quad \text{Compression factor} \quad (1C.1)$$

Because the molar volume of a perfect gas is equal to  $RT/p$ , an equivalent expression is  $Z = RT/pV_m^\circ$ , which we can write as

$$pV_m = RTZ \quad (1C.2)$$

Because for a perfect gas  $Z=1$  under all conditions, deviation of  $Z$  from 1 is a measure of departure from perfect behaviour.

Some experimental values of  $Z$  are plotted in Fig. 1C.3. At very low pressures, all the gases shown have  $Z \approx 1$  and behave nearly perfectly. At high pressures, all the gases have  $Z > 1$ , signifying that they have a larger molar volume than a perfect gas. Repulsive forces are now dominant. At intermediate pressures, most gases have  $Z < 1$ , indicating that the attractive forces are reducing the molar volume relative to that of a perfect gas.

**Figure 1C.3** The variation of the compression factor,  $Z$ , with pressure for several gases at 0 °C. A perfect gas has  $Z=1$  at all pressures. Notice that, although the curves approach 1 as  $p \rightarrow 0$ , they do so with different slopes.

**Brief illustration 1C.1** The compression factor

The molar volume of a perfect gas at 500 K and 100 bar is  $V_m^\circ = 0.416 \text{ dm}^3 \text{ mol}^{-1}$ . The molar volume of carbon dioxide under the same conditions is  $V_m = 0.366 \text{ dm}^3 \text{ mol}^{-1}$ . It follows that at 500 K

$$Z = \frac{0.366 \text{ dm}^3 \text{ mol}^{-1}}{0.416 \text{ dm}^3 \text{ mol}^{-1}} = 0.880$$

The fact that  $Z < 1$  indicates that attractive forces dominate repulsive forces under these conditions.

**Self-test 1C.1** The mean molar volume of air at 60 bar and 400 K is  $0.9474 \text{ dm}^3 \text{ mol}^{-1}$ . Are attractions or repulsions dominant?

Answer: Repulsions

**(b) Virial coefficients**

Now we relate  $Z$  to the experimental isotherms in Fig. 1C.2. At large molar volumes and high temperatures the real-gas isotherms do not differ greatly from perfect-gas isotherms. The small differences suggest that the perfect gas law  $pV_m = RT$  is in fact the first term in an expression of the form

$$pV_m = RT(1 + B'p + C'p^2 + \dots) \quad (1C.3a)$$

This expression is an example of a common procedure in physical chemistry, in which a simple law that is known to be a good first approximation (in this case  $pV_m = RT$ ) is treated as the first term in a series in powers of a variable (in this case  $p$ ). A more convenient expansion for many applications is

$$pV_m = RT \left( 1 + \frac{B}{V_m} + \frac{C}{V_m^2} + \dots \right) \quad \text{Virial equation of state} \quad (1C.3b)$$

These two expressions are two versions of the **virial equation of state**.<sup>1</sup> By comparing the expression with eqn 1C.2 we see that the term in parentheses in eqn 1C.3b is just the compression factor,  $Z$ .

The coefficients  $B, C, \dots$ , which depend on the temperature, are the second, third, ... **virial coefficients** (Table 1C.1); the first virial coefficient is 1. The third virial coefficient,  $C$ , is usually less important than the second coefficient,  $B$ , in the sense that at typical molar volumes  $C/V_m^2 \ll B/V_m$ . The values of the virial coefficients of a gas are determined from measurements of its compression factor.

<sup>1</sup> The name comes from the Latin word for force. The coefficients are sometimes denoted  $B_2, B_3, \dots$

**Table 1C.1\*** Second virial coefficients,  $B/(\text{cm}^3 \text{ mol}^{-1})$

	Temperature	
	273 K	600 K
Ar	-21.7	11.9
CO <sub>2</sub>	-149.7	-12.4
N <sub>2</sub>	-10.5	21.7
Xe	-153.7	-19.6

\* More values are given in the *Resource section*.

**Brief illustration 1C.2** The virial equation of state

To use eqn 1C.3b (up to the  $B$  term), to calculate the pressure exerted at 100 K by 0.104 mol O<sub>2</sub>(g) in a vessel of volume 0.225 dm<sup>3</sup>, we begin by calculating the molar volume:

$$V_m = \frac{V}{n_{\text{O}_2}} = \frac{0.225 \text{ dm}^3}{0.104 \text{ mol}} = 2.16 \text{ dm}^3 \text{ mol}^{-1} = 2.16 \times 10^{-3} \text{ m}^3 \text{ mol}^{-1}$$

Then, by using the value of  $B$  found in Table 1C.1 of the *Resource section*,

$$\begin{aligned} p &= \frac{RT}{V_m} \left( 1 + \frac{B}{V_m} \right) \\ &= \frac{(8.3145 \text{ J mol}^{-1} \text{ K}^{-1}) \times (100 \text{ K})}{2.16 \times 10^{-3} \text{ m}^3 \text{ mol}^{-1}} \left( 1 - \frac{1.975 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}}{2.16 \times 10^{-3} \text{ m}^3 \text{ mol}^{-1}} \right) \\ &= 3.50 \times 10^5 \text{ Pa, or } 350 \text{ kPa} \end{aligned}$$

where we have used  $1 \text{ Pa} = 1 \text{ J m}^{-3}$ . The perfect gas equation of state would give the calculated pressure as 385 kPa, or 10 per cent higher than the value calculated by using the virial equation of state. The deviation is significant because under these conditions  $B/V_m \approx 0.1$  which is not negligible relative to 1.

**Self-test 1C.2** What pressure would 4.56 g of nitrogen gas in a vessel of volume 2.25 dm<sup>3</sup> exert at 273 K if it obeyed the virial equation of state?

Answer: 104 kPa

An important point is that although the equation of state of a real gas may coincide with the perfect gas law as  $p \rightarrow 0$ , not all its properties necessarily coincide with those of a perfect gas in that limit. Consider, for example, the value of  $dZ/dp$ , the slope of the graph of compression factor against pressure. For a perfect gas  $dZ/dp = 0$  (because  $Z = 1$  at all pressures), but for a real gas from eqn 1C.3a we obtain

$$\frac{dZ}{dp} = B' + 2pC' + \dots \rightarrow B' \text{ as } p \rightarrow 0 \quad (1C.4a)$$

However,  $B'$  is not necessarily zero, so the slope of  $Z$  with respect to  $p$  does not necessarily approach 0 (the perfect gas

**Figure 1C.4** The compression factor,  $Z$ , approaches 1 at low pressures, but does so with different slopes. For a perfect gas, the slope is zero, but real gases may have either positive or negative slopes, and the slope may vary with temperature. At the Boyle temperature, the slope is zero and the gas behaves perfectly over a wider range of conditions than at other temperatures.

value), as we can see in Fig. 1C.4. Because several physical properties of gases depend on derivatives, the properties of real gases do not always coincide with the perfect gas values at low pressures. By a similar argument,

$$\frac{dZ}{d(1/V_m)} \rightarrow B \text{ as } V_m \rightarrow \infty \quad (1C.4b)$$

Because the virial coefficients depend on the temperature, there may be a temperature at which  $Z \rightarrow 1$  with zero slope at low pressure or high molar volume (as in Fig. 1C.4). At this temperature, which is called the **Boyle temperature**,  $T_B$ , the properties of the real gas do coincide with those of a perfect gas as  $p \rightarrow 0$ . According to eqn 1C.4b,  $Z$  has zero slope as  $p \rightarrow 0$  if  $B=0$ , so we can conclude that  $B=0$  at the Boyle temperature. It then follows from eqn 1C.3 that  $pV_m \approx RT_B$  over a more extended range of pressures than at other temperatures because the first term after 1 (that is,  $B/V_m$ ) in the virial equation is zero and  $C/V_m^2$  and higher terms are negligibly small. For helium  $T_B=22.64$  K; for air  $T_B=346.8$  K; more values are given in Table 1C.2.

### (c) Critical constants

The isotherm at the temperature  $T_c$  (304.19 K, or 31.04 °C for  $\text{CO}_2$ ) plays a special role in the theory of the states of matter.

**Table 1C.2\*** Critical constants of gases

	$p_c/\text{atm}$	$V_c/(\text{cm}^3 \text{ mol}^{-1})$	$T_c/\text{K}$	$Z_c$	$T_B/\text{K}$
Ar	48.0	75.3	150.7	0.292	411.5
$\text{CO}_2$	72.9	94.0	304.2	0.274	714.8
He	2.26	57.8	5.2	0.305	22.64
$\text{O}_2$	50.14	78.0	154.8	0.308	405.9

\* More values are given in the *Resource section*.

An isotherm slightly below  $T_c$  behaves as we have already described: at a certain pressure, a liquid condenses from the gas and is distinguishable from it by the presence of a visible surface. If, however, the compression takes place at  $T_c$  itself, then a surface separating two phases does not appear and the volumes at each end of the horizontal part of the isotherm have merged to a single point, the **critical point** of the gas. The temperature, pressure, and molar volume at the critical point are called the **critical temperature**,  $T_c$ , **critical pressure**,  $p_c$ , and **critical molar volume**,  $V_c$ , of the substance. Collectively,  $p_c$ ,  $V_c$ , and  $T_c$  are the **critical constants** of a substance (Table 1C.2).

At and above  $T_c$  the sample has a single phase which occupies the entire volume of the container. Such a phase is, by definition, a gas. Hence, the liquid phase of a substance does not form above the critical temperature. The single phase that fills the entire volume when  $T > T_c$  may be much denser than we normally consider typical of gases, and the name **supercritical fluid** is preferred.

#### Brief illustration 1C.3 The critical temperature

The critical temperature of oxygen signifies that it is impossible to produce liquid oxygen by compression alone if its temperature is greater than 155 K. To liquefy oxygen—to obtain a fluid phase that does not occupy the entire volume—the temperature must first be lowered to below 155 K, and then the gas compressed isothermally.

**Self-test 1C.3** Under which conditions can liquid nitrogen be formed by the application of pressure?

Answer: At  $T < 126$  K

## 1C.2 The van der Waals equation

We can draw conclusions from the virial equations of state only by inserting specific values of the coefficients. It is often useful to have a broader, if less precise, view of all gases. Therefore, we introduce the approximate equation of state suggested by J.D. van der Waals in 1873. This equation is an excellent example of an expression that can be obtained by thinking scientifically about a mathematically complicated but physically simple problem; that is, it is a good example of ‘model building’.

### (a) Formulation of the equation

The van der Waals equation is

$$p = \frac{nRT}{V-nb} - a \frac{n^2}{V^2} \quad \text{Van der Waals equation of state} \quad (1C.5a)$$

and a derivation is given in the following *Justification*. The equation is often written in terms of the molar volume  $V_m = V/n$  as

$$p = \frac{RT}{V_m - b} - \frac{a}{V_m^2} \quad (1C.5b)$$

The constants  $a$  and  $b$  are called the **van der Waals coefficients**. As can be understood from the following *Justification*,  $a$  represents the strength of attractive interactions and  $b$  that of the repulsive interactions between the molecules. They are characteristic of each gas but independent of the temperature (Table 1C.3). Although  $a$  and  $b$  are not precisely defined molecular properties, they correlate with physical properties such as critical temperature, vapour pressure, and enthalpy of vaporization that reflect the strength of intermolecular interactions. Correlations have also been sought where intermolecular forces might play a role. For example, the potency of certain general anaesthetics shows a correlation in the sense that a higher activity is observed with lower values of  $a$  (Fig. 1C.5).

Table 1C.3\* van der Waals coefficients

	$a/(\text{atm dm}^6 \text{ mol}^{-2})$	$b/(10^{-2} \text{ dm}^3 \text{ mol}^{-1})$
Ar	1.337	3.20
CO <sub>2</sub>	3.610	4.29
He	0.0341	2.38
Xe	4.137	5.16

\* More values are given in the *Resource section*.

Figure 1C.5 The correlation of the effectiveness of a gas as an anaesthetic and the van der Waals parameter  $a$ . (Based on R.J. Wulf and R.M. Featherstone, *Anesthesiology* 18, 97 (1957).) The isonarcotic pressure is the pressure required to bring about the same degree of anaesthesia.

### Justification 1C.1 The van der Waals equation of state

The repulsive interactions between molecules are taken into account by supposing that they cause the molecules to behave as small but impenetrable spheres. The non-zero volume of the molecules implies that instead of moving in a volume  $V$  they are restricted to a smaller volume  $V - nb$ , where  $nb$  is approximately the total volume taken up by the molecules themselves. This argument suggests that the perfect gas law  $p = nRT/V$  should be replaced by

$$p = \frac{nRT}{V - nb}$$

when repulsions are significant. To calculate the excluded volume we note that the closest distance of two hard-sphere molecules of radius  $r$ , and volume  $V_{\text{molecule}} = \frac{4}{3}\pi r^3$ , is  $2r$ , so the volume excluded is  $\frac{4}{3}\pi(2r)^3$  or  $8V_{\text{molecule}}$ . The volume excluded per molecule is one-half this volume, or  $4V_{\text{molecule}}$ , so  $b \approx 4V_{\text{molecule}}N_A$ .

The pressure depends on both the frequency of collisions with the walls and the force of each collision. Both the frequency of the collisions and their force are reduced by the attractive interaction, which act with a strength proportional to the molar concentration,  $n/V$ , of molecules in the sample. Therefore, because both the frequency and the force of the collisions are reduced by the attractive interactions, the pressure is reduced in proportion to the square of this concentration. If the reduction of pressure is written as  $a(n/V)^2$ , where  $a$  is a positive constant characteristic of each gas, the combined effect of the repulsive and attractive forces is the van der Waals equation of state as expressed in eqn 1C.5.

In this *Justification* we have built the van der Waals equation using vague arguments about the volumes of molecules and the effects of forces. The equation can be derived in other ways, but the present method has the advantage that it shows how to derive the form of an equation out of general ideas. The derivation also has the advantage of keeping imprecise the significance of the coefficients  $a$  and  $b$ : they are much better regarded as empirical parameters that represent attractions and repulsions, respectively, rather than as precisely defined molecular properties.

### Example 1C.1 Using the van der Waals equation to estimate a molar volume

Estimate the molar volume of CO<sub>2</sub> at 500 K and 100 atm by treating it as a van der Waals gas.

**Method** We need to find an expression for the molar volume by solving the van der Waals equation, eqn 1C.5b. To do

so, we multiply both sides of the equation by  $(V_m - b)V_m^2$ , to obtain

$$(V_m - b)V_m^2 p = RTV_m^2 - (V_m - b)a$$

Then, after division by  $p$ , collect powers of  $V_m$  to obtain

$$V_m^3 - \left(b + \frac{RT}{p}\right)V_m^2 + \left(\frac{a}{p}\right)V_m = 0$$

Although closed expressions for the roots of a cubic equation can be given, they are very complicated. Unless analytical solutions are essential, it is usually more expedient to solve such equations with commercial software; graphing calculators can also be used to help identify the acceptable root.

**Answer** According to Table 1C.3,  $a = 3.592 \text{ dm}^6 \text{ atm mol}^{-2}$  and  $b = 4.267 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$ . Under the stated conditions,  $RT/p = 0.410 \text{ dm}^3 \text{ mol}^{-1}$ . The coefficients in the equation for  $V_m$  are therefore

$$b + RT/p = 0.453 \text{ dm}^3 \text{ mol}^{-1}$$

$$a/p = 3.61 \times 10^{-2} (\text{dm}^3 \text{ mol}^{-1})^2$$

$$ab/p = 1.55 \times 10^{-3} (\text{dm}^3 \text{ mol}^{-1})^3$$

Therefore, on writing  $x = V_m / (\text{dm}^3 \text{ mol}^{-1})$ , the equation to solve is

$$x^3 - 0.453x^2 + (3.61 \times 10^{-2})x - (1.55 \times 10^{-3}) = 0$$

The acceptable root is  $x = 0.366$  (Fig. 1C.6), which implies that  $V_m = 0.366 \text{ dm}^3 \text{ mol}^{-1}$ . For a perfect gas under these conditions, the molar volume is  $0.410 \text{ dm}^3 \text{ mol}^{-1}$ .

**Figure 1C.6** The graphical solution of the cubic equation for  $V$  in Example 1C.1.

**Self-test 1C.4** Calculate the molar volume of argon at  $100^\circ \text{C}$  and  $100 \text{ atm}$  on the assumption that it is a van der Waals gas.

Answer:  $0.298 \text{ dm}^3 \text{ mol}^{-1}$

## (b) The features of the equation

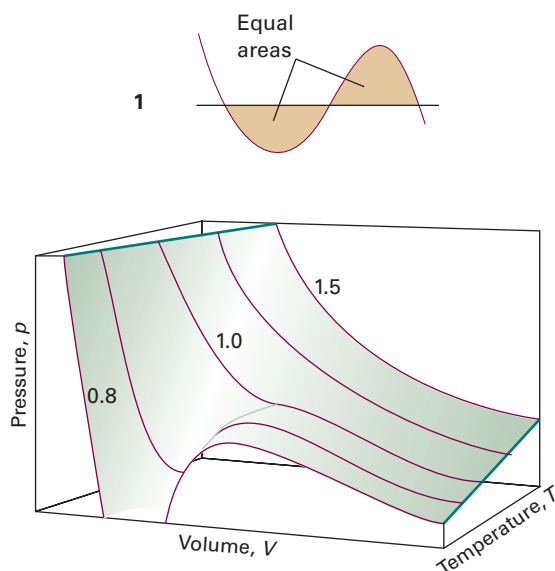

We now examine to what extent the van der Waals equation predicts the behaviour of real gases. It is too optimistic to expect a single, simple expression to be the true equation of state of all substances, and accurate work on gases must resort to the virial equation, use tabulated values of the coefficients at various temperatures, and analyse the systems numerically. The advantage of the van der Waals equation, however, is that it is analytical (that is, expressed symbolically) and allows us to draw some general conclusions about real gases. When the equation fails we must use one of the other equations of state that have been proposed (some are listed in Table 1C.4), invent a new one, or go back to the virial equation.

**Table 1C.4** Selected equations of state

	Equation	Reduced form*	Critical constants		
			$p_c$	$V_c$	$T_c$
Perfect gas	$p = \frac{nRT}{V}$				
van der Waals	$p = \frac{nRT}{V-nb} - \frac{n^2a}{V^2}$	$p_r = \frac{8T_r}{3V_r-1} - \frac{3}{V_r^2}$	$\frac{a}{27b^2}$	$3b$	$\frac{8a}{27bR}$
Berthelot	$p = \frac{nRT}{V-nb} - \frac{n^2a}{TV^2}$	$p_r = \frac{8T_r}{3V_r-1} - \frac{3}{T_r V_r^2}$	$\frac{1}{12} \left( \frac{2aR}{3b^3} \right)^{1/2}$	$3b$	$\frac{2}{3} \left( \frac{2a}{3bR} \right)^{1/2}$
Dieterici	$p = \frac{nRTe^{-aRTV/n}}{V-nb}$	$p_r = \frac{T_r e^{2(1-1/T_r V_r)}}{2V_r-1}$	$\frac{a}{4e^2 b^2}$	$2b$	$\frac{a}{4bR}$
Virial	$p = \frac{nRT}{V} \left\{ 1 + \frac{nB(T)}{V} + \frac{n^2C(T)}{V^2} + \dots \right\}$				

\* Reduced variables are defined in Section 1C.2(c). Equations of state are sometimes expressed in terms of the molar volume,  $V_m = V/n$ .

That having been said, we can begin to judge the reliability of the equation by comparing the isotherms it predicts with the experimental isotherms in Fig. 1C.2. Some calculated isotherms are shown in Fig. 1C.7 and Fig. 1C.8. Apart from the oscillations below the critical temperature, they do resemble experimental isotherms quite well. The oscillations, the **van der Waals' loops**, are unrealistic because they suggest that under some conditions an increase of pressure results in an increase of volume. Therefore they are replaced by horizontal lines drawn so the loops define equal areas above and below the lines: this procedure is called the **Maxwell construction (1)**. The van der Waals coefficients, such as those in Table 1C.3, are found by fitting the calculated curves to the experimental curves.

**Figure 1C.7** The surface of possible states allowed by the van der Waals equation. Compare this surface with that shown in Fig. 1C.8.

**Figure 1C.8** van der Waals isotherms at several values of  $T/T_c$ . Compare these curves with those in Fig. 1C.2. The van der Waals loops are normally replaced by horizontal straight lines. The critical isotherm is the isotherm for  $T/T_c = 1$ .

The principal features of the van der Waals equation can be summarized as follows.

1. Perfect gas isotherms are obtained at high temperatures and large molar volumes.

When the temperature is high,  $RT$  may be so large that the first term in eqn 1C.5b greatly exceeds the second. Furthermore, if the molar volume is large in the sense  $V_m \gg b$ , then the denominator  $V_m - b \approx V_m$ . Under these conditions, the equation reduces to  $p = RT/V_m$ , the perfect gas equation.

2. Liquids and gases coexist when the attractive and repulsive effects are in balance.

The van der Waals loops occur when both terms in eqn 1C.5b have similar magnitudes. The first term arises from the kinetic energy of the molecules and their repulsive interactions; the second represents the effect of the attractive interactions.

3. The critical constants are related to the van der Waals coefficients.

For  $T < T_c$ , the calculated isotherms oscillate, and each one passes through a minimum followed by a maximum. These extrema converge as  $T \rightarrow T_c$  and coincide at  $T = T_c$ ; at the critical point the curve has a flat inflexion (2). From the properties of curves, we know that an inflexion of this type occurs when both the first and second derivatives are zero. Hence, we can find the critical constants by calculating these derivatives and setting them equal to zero at the critical point:

$$\frac{dp}{dV_m} = -\frac{RT}{(V_m - b)^2} + \frac{2a}{V_m^3} = 0$$

$$\frac{d^2p}{dV_m^2} = \frac{2RT}{(V_m - b)^3} - \frac{6a}{V_m^4} = 0$$

The solutions of these two equations (and using eqn 1C.5b to calculate  $p_c$  from  $V_c$  and  $T_c$ ) are

$$V_c = 3b \quad p_c = \frac{a}{27b^2} \quad T_c = \frac{8a}{27Rb} \quad (1C.6)$$

These relations provide an alternative route to the determination of  $a$  and  $b$  from the values of the critical constants. They can be tested by noting that the **critical compression factor**,  $Z_c$ , is predicted to be equal to

$$Z_c = \frac{p_c V_c}{RT_c} = \frac{3}{8} \quad (1C.7)$$

for all gases that are described by the van der Waals equation near the critical point. We see from Table 1C.2 that although  $Z_c < \frac{3}{8} = 0.375$ , it is approximately constant (at 0.3) and the discrepancy is reasonably small.

#### Brief illustration 1C.4 Criteria for perfect gas behaviour

For benzene  $a = 18.57 \text{ atm dm}^6 \text{ mol}^{-2}$  ( $1.882 \text{ Pa m}^6 \text{ mol}^{-2}$ ) and  $b = 0.1193 \text{ dm}^3 \text{ mol}^{-1}$  ( $1.193 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$ ); its normal boiling point is 353 K. Treated as a perfect gas at  $T = 400 \text{ K}$  and  $p = 1.0 \text{ atm}$ , benzene vapour has a molar volume of  $V_m = RT/p = 33 \text{ dm}^3 \text{ mol}^{-1}$ , so the criterion  $V_m \gg b$  for perfect gas behaviour is satisfied. It follows that  $a/V_m^2 \approx 0.017 \text{ atm}$ , which is 1.7 per cent of 1.0 atm. Therefore, we can expect benzene vapour to deviate only slightly from perfect gas behaviour at this temperature and pressure.

**Self-test 1C.5** Can argon gas be treated as a perfect gas at 400 K and 3.0 atm?

Answer: Yes

### (c) The principle of corresponding states

An important general technique in science for comparing the properties of objects is to choose a related fundamental property of the same kind and to set up a relative scale on that basis. We have seen that the critical constants are characteristic properties of gases, so it may be that a scale can be set up by using them as yardsticks. We therefore introduce the dimensionless **reduced variables** of a gas by dividing the actual variable by the corresponding critical constant:

$$V_r = \frac{V_m}{V_c} \quad p_r = \frac{p}{p_c} \quad T_r = \frac{T}{T_c} \quad \text{Definition} \quad \text{Reduced variables} \quad (1C.8)$$

If the reduced pressure of a gas is given, we can easily calculate its actual pressure by using  $p = p_r p_c$ , and likewise for the volume and temperature. van der Waals, who first tried this procedure, hoped that gases confined to the same reduced volume,  $V_r$ , at the same reduced temperature,  $T_r$ , would exert the same reduced pressure,  $p_r$ . The hope was largely fulfilled (Fig. 1C.9). The illustration shows the dependence of the compression factor on the reduced pressure for a variety of gases at various reduced temperatures. The success of the procedure is strikingly clear: compare this graph with Fig. 1C.3, where similar data are plotted without using reduced variables. The observation that real gases at the same reduced volume and reduced temperature exert the same reduced pressure is called the **principle of corresponding states**. The principle is only an approximation. It works best for gases composed of spherical molecules; it fails, sometimes badly, when the molecules are non-spherical or polar.

**Figure 1C.9** The compression factors of four of the gases shown in Fig. 1C.3 plotted using reduced variables. The curves are labelled with the reduced temperature  $T_r = T/T_c$ . The use of reduced variables organizes the data on to single curves.

#### Brief illustration 1C.5 Corresponding states

The critical constants of argon and carbon dioxide are given in Table 1C.2. Suppose argon is at 23 atm and 200 K, its reduced pressure and temperature are then

$$p_r = \frac{23 \text{ atm}}{48.0 \text{ atm}} = 0.48 \quad T_r = \frac{200 \text{ K}}{150.7 \text{ K}} = 1.33$$

For carbon dioxide to be in a corresponding state, its pressure and temperature would need to be

$$p = 0.48 \times (72.9 \text{ atm}) = 35 \text{ atm} \quad T = 1.33 \times 304.2 \text{ K} = 405 \text{ K}$$

**Self-test 1C.6** What would be the corresponding state of ammonia?

Answer: 53 atm, 539 K

The van der Waals equation sheds some light on the principle. First, we express eqn 1C.5b in terms of the reduced variables, which gives

$$p_r p_c = \frac{RT_r T_c}{V_r V_c - b} - \frac{a}{V_r^2 V_c^2}$$

Then we express the critical constants in terms of  $a$  and  $b$  by using eqn 1C.8:

$$\frac{ap_r}{27b^2} = \frac{8aT_r/27b}{3bp_r V_r - b} - \frac{a}{9b^2 V_r^2}$$

which can be reorganized into

$$p_r = \frac{8T_r}{3V_r - 1} - \frac{3}{V_r^2} \quad (1C.9)$$

This equation has the same form as the original, but the coefficients  $a$  and  $b$ , which differ from gas to gas, have disappeared. It follows that if the isotherms are plotted in terms of the reduced variables (as we did in fact in Fig. 1C.8 without drawing attention to the fact), then the same curves are obtained whatever the gas. This is precisely the content of the principle of corresponding states, so the van der Waals equation is compatible with it.

Looking for too much significance in this apparent triumph is mistaken, because other equations of state also accommodate

the principle (like those in Table 1C.4). In fact, all we need are two parameters playing the roles of  $a$  and  $b$ , for then the equation can always be manipulated into reduced form. The observation that real gases obey the principle approximately amounts to saying that the effects of the attractive and repulsive interactions can each be approximated in terms of a single parameter. The importance of the principle is then not so much its theoretical interpretation but the way that it enables the properties of a range of gases to be coordinated on to a single diagram (for example, Fig. 1C.9 instead of Fig. 1C.3).

## Checklist of concepts

- 1. The extent of deviations from perfect behaviour is summarized by introducing the **compression factor**.
- 2. The **virial equation** is an empirical extension of the perfect gas equation that summarizes the behaviour of real gases over a range of conditions.
- 3. The isotherms of a real gas introduce the concepts of **vapour pressure** and **critical behaviour**.
- 4. A gas can be liquefied by pressure alone only if its temperature is at or below its **critical temperature**.
- 5. The **van der Waals equation** is a model equation of state for a real gas expressed in terms of two parameters, one ( $a$ ) corresponding to molecular attractions and the other ( $b$ ) to molecular repulsions.
- 6. The van der Waals equation captures the general features of the behaviour of real gases, including their critical behaviour.
- 7. The properties of real gases are coordinated by expressing their equations of state in terms of **reduced variables**.

## Checklist of equations

Property	Equation	Comment	Equation number
Compression factor	$Z = V_m/V_m^\circ$	Definition	1C.1
Virial equation of state	$pV_m = RT(1 + B/V_m + C/V_m^2 + \dots)$	$B, C$ depend on temperature	1C.3
van der Waals equation of state	$p = nRT/(V - nb) - a(n/V)^2$	$a$ parameterizes attractions, $b$ parameterizes repulsions	1C.5
Reduced variables	$X_r = X/X_c$	$X = p, V_m, \text{ or } T$	1C.8

# CHAPTER 1 The properties of gases

## TOPIC 1A The perfect gas

### Discussion questions

**1A.1** Explain how the perfect gas equation of state arises by combination of Boyle's law, Charles's law, and Avogadro's principle.

**1A.2** Explain the term 'partial pressure' and explain why Dalton's law is a limiting law.

### Exercises

**1A.1(a)** Could 131 g of xenon gas in a vessel of volume 1.0 dm<sup>3</sup> exert a pressure of 20 atm at 25 °C if it behaved as a perfect gas? If not, what pressure would it exert?

**1A.1(b)** Could 25 g of argon gas in a vessel of volume 1.5 dm<sup>3</sup> exert a pressure of 2.0 bar at 30 °C if it behaved as a perfect gas? If not, what pressure would it exert?

**1A.2(a)** A perfect gas undergoes isothermal compression, which reduces its volume by 2.20 dm<sup>3</sup>. The final pressure and volume of the gas are 5.04 bar and 4.65 dm<sup>3</sup>, respectively. Calculate the original pressure of the gas in (i) bar, (ii) atm.

**1A.2(b)** A perfect gas undergoes isothermal compression, which reduces its volume by 1.80 dm<sup>3</sup>. The final pressure and volume of the gas are 1.97 bar and 2.14 dm<sup>3</sup>, respectively. Calculate the original pressure of the gas in (i) bar, (ii) torr.

**1A.3(a)** A car tyre (i.e. an automobile tire) was inflated to a pressure of 24 lb in<sup>-2</sup> (1.00 atm = 14.7 lb in<sup>-2</sup>) on a winter's day when the temperature was -5 °C. What pressure will be found, assuming no leaks have occurred and that the volume is constant, on a subsequent summer's day when the temperature is 35 °C? What complications should be taken into account in practice?

**1A.3(b)** A sample of hydrogen gas was found to have a pressure of 125 kPa when the temperature was 23 °C. What can its pressure be expected to be when the temperature is 11 °C?

**1A.4(a)** A sample of 255 mg of neon occupies 3.00 dm<sup>3</sup> at 122 K. Use the perfect gas law to calculate the pressure of the gas.

**1A.4(b)** A homeowner uses 4.00 × 10<sup>3</sup> m<sup>3</sup> of natural gas in a year to heat a home. Assume that natural gas is all methane, CH<sub>4</sub>, and that methane is a perfect gas for the conditions of this problem, which are 1.00 atm and 20 °C. What is the mass of gas used?

**1A.5(a)** A diving bell has an air space of 3.0 m<sup>3</sup> when on the deck of a boat. What is the volume of the air space when the bell has been lowered to a depth of 50 m? Take the mean density of sea water to be 1.025 g cm<sup>-3</sup> and assume that the temperature is the same as on the surface.

**1A.5(b)** What pressure difference must be generated across the length of a 15 cm vertical drinking straw in order to drink a water-like liquid of density 1.0 g cm<sup>-3</sup>?

**1A.6(a)** A manometer consists of a U-shaped tube containing a liquid. One side is connected to the apparatus and the other is open to the atmosphere. The pressure inside the apparatus is then determined from the difference in heights of the liquid. Suppose the liquid is water, the external pressure is 770 Torr, and the open side is 10.0 cm lower than the side connected to the apparatus. What is the pressure in the apparatus? (The density of water at 25 °C is 0.997 07 g cm<sup>-3</sup>.)

**1A.6(b)** A manometer like that described in Exercise 1.6(a) contained mercury in place of water. Suppose the external pressure is 760 Torr, and the open side is 10.0 cm higher than the side connected to the apparatus. What is the pressure in the apparatus? (The density of mercury at 25 °C is 13.55 g cm<sup>-3</sup>.)

**1A.7(a)** In an attempt to determine an accurate value of the gas constant,  $R$ , a student heated a container of volume 20.000 dm<sup>3</sup> filled with 0.251 32 g of helium gas to 500 °C and measured the pressure as 206.402 cm of water in a manometer at 25 °C. Calculate the value of  $R$  from these data. (The density of water at 25 °C is 0.997 07 g cm<sup>-3</sup>; the construction of a manometer is described in Exercise 1.6(a).)

**1A.7(b)** The following data have been obtained for oxygen gas at 273.15 K. Calculate the best value of the gas constant  $R$  from them and the best value of the molar mass of O<sub>2</sub>.

$p/\text{atm}$	0.750 000	0.500 000	0.250 000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	29.9649	44.8090	89.6384

**1A.8(a)** At 500 °C and 93.2 kPa, the mass density of sulfur vapour is 3.710 kg m<sup>-3</sup>. What is the molecular formula of sulfur under these conditions?

**1A.8(b)** At 100 °C and 16.0 kPa, the mass density of phosphorus vapour is 0.6388 kg m<sup>-3</sup>. What is the molecular formula of phosphorus under these conditions?

**1A.9(a)** Calculate the mass of water vapour present in a room of volume 400 m<sup>3</sup> that contains air at 27 °C on a day when the relative humidity is 60 per cent.

**1A.9(b)** Calculate the mass of water vapour present in a room of volume 250 m<sup>3</sup> that contains air at 23 °C on a day when the relative humidity is 53 per cent.

**1A.10(a)** Given that the density of air at 0.987 bar and 27 °C is 1.146 kg m<sup>-3</sup>, calculate the mole fraction and partial pressure of nitrogen and oxygen assuming that (i) air consists only of these two gases, (ii) air also contains 1.0 mole per cent Ar.

**1A.10(b)** A gas mixture consists of 320 mg of methane, 175 mg of argon, and 225 mg of neon. The partial pressure of neon at 300 K is 8.87 kPa. Calculate (i) the volume and (ii) the total pressure of the mixture.

**1A.11(a)** The density of a gaseous compound was found to be 1.23 kg m<sup>-3</sup> at 330 K and 20 kPa. What is the molar mass of the compound?

**1A.11(b)** In an experiment to measure the molar mass of a gas, 250 cm<sup>3</sup> of the gas was confined in a glass vessel. The pressure was 152 Torr at 298 K, and after correcting for buoyancy effects, the mass of the gas was 33.5 mg. What is the molar mass of the gas?

**1A.12(a)** The densities of air at -85 °C, 0 °C, and 100 °C are 1.877 g dm<sup>-3</sup>, 1.294 g dm<sup>-3</sup>, and 0.946 g dm<sup>-3</sup>, respectively. From these data, and assuming that air obeys Charles's law, determine a value for the absolute zero of temperature in degrees Celsius.

**1A.12(b)** A certain sample of a gas has a volume of 20.00 dm<sup>3</sup> at 0 °C and 1.000 atm. A plot of the experimental data of its volume against the Celsius temperature,  $\theta$ , at constant  $p$ , gives a straight line of slope 0.0741 dm<sup>3</sup> °C<sup>-1</sup>. From these data determine the absolute zero of temperature in degrees Celsius.

**1A.13(a)** A vessel of volume 22.4 dm<sup>3</sup> contains 2.0 mol H<sub>2</sub> and 1.0 mol N<sub>2</sub> at 273.15 K. Calculate (i) the mole fractions of each component, (ii) their partial pressures, and (iii) their total pressure.

**1A.13(b)** A vessel of volume 22.4 dm<sup>3</sup> contains 1.5 mol H<sub>2</sub> and 2.5 mol N<sub>2</sub> at 273.15 K. Calculate (i) the mole fractions of each component, (ii) their partial pressures, and (iii) their total pressure.

## Problems

**1A.1** Recent communication with the inhabitants of Neptune have revealed that they have a Celsius-type temperature scale, but based on the melting point (0 °N) and boiling point (100 °N) of their most common substance, hydrogen. Further communications have revealed that the Neptunians know about perfect gas behaviour and they find that in the limit of zero pressure, the value of  $pV$  is 28 dm<sup>3</sup> atm at 0 °N and 40 dm<sup>3</sup> atm at 100 °N. What is the value of the absolute zero of temperature on their temperature scale?

**1A.2** Deduce the relation between the pressure and mass density,  $\rho$ , of a perfect gas of molar mass  $M$ . Confirm graphically, using the following data on dimethyl ether at 25 °C, that perfect behaviour is reached at low pressures and find the molar mass of the gas.

$p/\text{kPa}$	12.223	25.20	36.97	60.37	85.23	101.3
$\rho/(\text{kg m}^{-3})$	0.225	0.456	0.664	1.062	1.468	1.734

**1A.3** Charles's law is sometimes expressed in the form  $V = V_0(1 + \alpha\theta)$ , where  $\theta$  is the Celsius temperature,  $\alpha$  is a constant, and  $V_0$  is the volume of the sample at 0 °C. The following values for  $\alpha$  have been reported for nitrogen at 0 °C:

$p/\text{Torr}$	749.7	599.6	333.1	98.6
$10^3 \alpha/^\circ\text{C}^{-1}$	3.6717	3.6697	3.6665	3.6643

For these data calculate the best value for the absolute zero of temperature on the Celsius scale.

**1A.4** The molar mass of a newly synthesized fluorocarbon was measured in a gas microbalance. This device consists of a glass bulb forming one end of a beam, the whole surrounded by a closed container. The beam is pivoted, and the balance point is attained by raising the pressure of gas in the container, so increasing the buoyancy of the enclosed bulb. In one experiment, the balance point was reached when the fluorocarbon pressure was 327.10 Torr; for the same setting of the pivot, a balance was reached when CHF<sub>3</sub> ( $M = 70.014 \text{ g mol}^{-1}$ ) was introduced at 423.22 Torr. A repeat of the experiment with a different setting of the pivot required a pressure of 293.22 Torr of the fluorocarbon and 427.22 Torr of the CHF<sub>3</sub>. What is the molar mass of the fluorocarbon? Suggest a molecular formula.

**1A.5** A constant-volume perfect gas thermometer indicates a pressure of 6.69 kPa at the triple point temperature of water (273.16 K). (a) What change of pressure indicates a change of 1.00 K at this temperature? (b) What pressure indicates a temperature of 100.00 °C? (c) What change of pressure indicates a change of 1.00 K at the latter temperature?

**1A.6** A vessel of volume 22.4 dm<sup>3</sup> contains 2.0 mol H<sub>2</sub> and 1.0 mol N<sub>2</sub> at 273.15 K initially. All the H<sub>2</sub> reacted with sufficient N<sub>2</sub> to form NH<sub>3</sub>. Calculate the partial pressures and the total pressure of the final mixture.

**1A.7** Atmospheric pollution is a problem that has received much attention. Not all pollution, however, is from industrial sources. Volcanic eruptions can be a significant source of air pollution. The Kilauea volcano in Hawaii emits 200–300 t of SO<sub>2</sub> per day. If this gas is emitted at 800 °C and 1.0 atm, what volume of gas is emitted?

**1A.8** Ozone is a trace atmospheric gas which plays an important role in screening the Earth from harmful ultraviolet radiation, and the abundance of ozone is commonly reported in *Dobson units*. One Dobson unit is the thickness, in thousandths of a centimetre, of a column of gas if it were collected as a pure gas at 1.00 atm and 0 °C. What amount of O<sub>3</sub> (in moles) is found in a column of atmosphere with a cross-sectional area of 1.00 dm<sup>2</sup> if the abundance is 250 Dobson units (a typical mid-latitude value)? In the seasonal Antarctic ozone hole, the column abundance drops below 100 Dobson units; how many moles of O<sub>3</sub> are found in such a column of air above a 1.00 dm<sup>2</sup> area? Most atmospheric ozone is found between 10 and 50 km above the surface of the earth. If that ozone is spread uniformly through this portion of the atmosphere, what is the average molar concentration corresponding to (a) 250 Dobson units, (b) 100 Dobson units?

**1A.9** The barometric formula (see *Impact* 1.1) relates the pressure of a gas of molar mass  $M$  at an altitude  $h$  to its pressure  $p_0$  at sea level. Derive this relation by showing that the change in pressure  $dp$  for an infinitesimal change in altitude  $dh$  where the density is  $\rho$  is  $dp = -\rho g dh$ . Remember that  $\rho$  depends on the pressure. Evaluate (a) the pressure difference between the top and bottom of a laboratory vessel of height 15 cm, and (b) the external atmospheric pressure at a typical cruising altitude of an aircraft (11 km) when the pressure at ground level is 1.0 atm.

**1A.10** Balloons are still used to deploy sensors that monitor meteorological phenomena and the chemistry of the atmosphere. It is possible to investigate some of the technicalities of ballooning by using the perfect gas law. Suppose your balloon has a radius of 3.0 m and that it is spherical. (a) What amount of H<sub>2</sub> (in moles) is needed to inflate it to 1.0 atm in an ambient temperature of 25 °C at sea level? (b) What mass can the balloon lift at sea level, where the density of air is 1.22 kg m<sup>-3</sup>? (c) What would be the payload if He were used instead of H<sub>2</sub>?

**1A.11\*** The preceding problem is most readily solved with the use of Archimedes principle, which states that the lifting force is equal to the difference between the weight of the displaced air and the weight of the balloon. Prove Archimedes principle for the atmosphere from the barometric formula. *Hint*: Assume a simple shape for the balloon, perhaps a right circular cylinder of cross-sectional area  $A$  and height  $h$ .

**1A.12\*** Chlorofluorocarbons such as CCl<sub>3</sub>F and CCl<sub>2</sub>F<sub>2</sub> have been linked to ozone depletion in Antarctica. As of 1994, these gases were found in quantities of 261 and 509 parts per trillion (10<sup>12</sup>) by volume (World Resources Institute, *World resources* 1996–97). Compute the molar concentration of these gases under conditions typical of (a) the mid-latitude troposphere (10 °C and 1.0 atm) and (b) the Antarctic stratosphere (200 K and 0.050 atm).

**1A.13\*** The composition of the atmosphere is approximately 80 per cent nitrogen and 20 per cent oxygen by mass. At what height above the surface of the Earth would the atmosphere become 90 per cent nitrogen and 10 per cent oxygen by mass? Assume that the temperature of the atmosphere is constant at 25 °C. What is the pressure of the atmosphere at that height?

\* These problems were supplied by Charles Trapp and Carmen Giunta.

## TOPIC 1B The kinetic model

### Discussion questions

**1B.1** Specify and analyse critically the assumptions that underlie the kinetic model of gases.

**1B.2** Provide molecular interpretations for the dependencies of the mean free path on the temperature, pressure, and size of gas molecules.

### Exercises

**1B.1(a)** Determine the ratios of (i) the mean speeds, (ii) the mean translational kinetic energies of H<sub>2</sub> molecules and Hg atoms at 20 °C.

**1B.1(b)** Determine the ratios of (i) the mean speeds, (ii) the mean kinetic energies of He atoms and Hg atoms at 25 °C.

**1B.2(a)** Calculate the root mean square speeds of H<sub>2</sub> and O<sub>2</sub> molecules at 20 °C.

**1B.2(b)** Calculate the root mean square speeds of CO<sub>2</sub> molecules and He atoms at 20 °C.

**1B.3(a)** Use the Maxwell–Boltzmann distribution of speeds to estimate the fraction of N<sub>2</sub> molecules at 400 K that have speeds in the range 200 to 210 m s<sup>-1</sup>.

**1B.3(b)** Use the Maxwell–Boltzmann distribution of speeds to estimate the fraction of CO<sub>2</sub> molecules at 400 K that have speeds in the range 400 to 405 m s<sup>-1</sup>.

**1B.4(a)** Calculate the most probable speed, the mean speed, and the mean relative speed of CO<sub>2</sub> molecules in air at 20 °C.

**1B.4(b)** Calculate the most probable speed, the mean speed, and the mean relative speed of H<sub>2</sub> molecules in air at 20 °C.

**1B.5(a)** Assume that air consists of N<sub>2</sub> molecules with a collision diameter of 395 pm. Calculate (i) the mean speed of the molecules, (ii) the mean free path, (iii) the collision frequency in air at 1.0 atm and 25 °C.

**1B.5(b)** The best laboratory vacuum pump can generate a vacuum of about 1 nTorr. At 25 °C and assuming that air consists of N<sub>2</sub> molecules with a collision diameter of 395 pm, calculate (i) the mean speed of the molecules, (ii) the mean free path, (iii) the collision frequency in the gas.

**1B.6(a)** At what pressure does the mean free path of argon at 20 °C become comparable to the diameter of a 100 cm<sup>3</sup> vessel that contains it? Take  $\sigma = 0.36 \text{ nm}^2$ .

**1B.6(b)** At what pressure does the mean free path of argon at 20 °C become comparable to 10 times the diameters of the atoms themselves?

**1B.7(a)** At an altitude of 20 km the temperature is 217 K and the pressure 0.050 atm. What is the mean free path of N<sub>2</sub> molecules? ( $\sigma = 0.43 \text{ nm}^2$ ).

**1B.7(b)** At an altitude of 15 km the temperature is 217 K and the pressure 12.1 kPa. What is the mean free path of N<sub>2</sub> molecules? ( $\sigma = 0.43 \text{ nm}^2$ ).

### Problems

**1B.1** A rotating slotted-disc apparatus like that in Fig. 1B.5 consists of five coaxial 5.0 cm diameter disks separated by 1.0 cm, the slots in their rims being displaced by 2.0° between neighbours. The relative intensities,  $I$ , of the detected beam of Kr atoms for two different temperatures and at a series of rotation rates were as follows:

$\nu/\text{Hz}$	20	40	80	100	120
$I$ (40 K)	0.846	0.513	0.069	0.015	0.002
$I$ (100 K)	0.592	0.485	0.217	0.119	0.057

Find the distributions of molecular velocities,  $f(v_x)$ , at these temperatures, and check that they conform to the theoretical prediction for a one-dimensional system.

**1B.2** A Knudsen cell was used to determine the vapour pressure of germanium at 1000 °C. During an interval of 7200 s the mass loss through a hole of radius 0.50 mm amounted to 43 μg. What is the vapour pressure of germanium at 1000 °C? Assume the gas to be monatomic.

**1B.3** Start from the Maxwell–Boltzmann distribution and derive an expression for the most probable speed of a gas of molecules at a temperature  $T$ . Go on to demonstrate the validity of the equipartition conclusion that the average translational kinetic energy of molecules free to move in three dimensions is  $\frac{3}{2}kT$ .

**1B.4** Consider molecules that are confined to move in a plane (a two-dimensional gas). Calculate the distribution of speeds and determine the mean speed of the molecules at a temperature  $T$ .

**1B.5** A specially constructed velocity-selector accepts a beam of molecules from an oven at a temperature  $T$  but blocks the passage of molecules with a speed greater than the mean. What is the mean speed of the emerging beam, relative to the initial value, treated as a one-dimensional problem?

**1B.6** What, according to the Maxwell–Boltzmann distribution, is the proportion of gas molecules having (a) more than, (b) less than the root mean square speed? (c) What are the proportions having speeds greater and smaller than the mean speed?

**1B.7** Calculate the fractions of molecules in a gas that have a speed in a range  $\Delta v$  at the speed  $nv_{\text{mp}}$  relative to those in the same range at  $v_{\text{m}}$  itself? This calculation can be used to estimate the fraction of very energetic molecules (which is important for reactions). Evaluate the ratio for  $n=3$  and  $n=4$ .

**1B.8** Derive an expression for  $\langle v^n \rangle^{1/n}$  from the Maxwell–Boltzmann distribution of speeds. You will need standard integrals given in the *Resource section*.

**1B.9** Calculate the escape velocity (the minimum initial velocity that will take an object to infinity) from the surface of a planet of radius  $R$ . What is the value for (a) the Earth,  $R=6.37 \times 10^6 \text{ m}$ ,  $g=9.81 \text{ m s}^{-2}$ , (b) Mars,  $R=3.38 \times 10^6 \text{ m}$ ,  $m_{\text{Mars}}/m_{\text{Earth}}=0.108$ . At what temperatures do H<sub>2</sub>, He, and O<sub>2</sub> molecules have mean speeds equal to their escape speeds? What proportion of the molecules have enough speed to escape when the temperature is (a) 240 K, (b) 1500 K? Calculations of this kind are very important in considering the composition of planetary atmospheres.

**1B.10** The principal components of the atmosphere of the Earth are diatomic molecules, which can rotate as well as translate. Given that the translational kinetic energy density of the atmosphere is  $0.15 \text{ J cm}^{-3}$ , what is the total kinetic energy density, including rotation? The average rotational energy of a linear molecule is  $kT$ .

**1B.11** Plot different Maxwell–Boltzmann speed distributions by keeping the molar mass constant at  $100 \text{ g mol}^{-1}$  and varying the temperature of the sample between 200 K and 2000 K.

**1B.12** Evaluate numerically the fraction of molecules with speeds in the range  $100 \text{ m s}^{-1}$  to  $200 \text{ m s}^{-1}$  at 300 K and 1000 K.

## TOPIC 1C Real gases

### Discussion questions

**1C.1** Explain how the compression factor varies with pressure and temperature and describe how it reveals information about intermolecular interactions in real gases.

**1C.2** What is the significance of the critical constants?

**1C.3** Describe the formulation of the van der Waals equation and suggest a rationale for one other equation of state in Table 1C.6.

**1C.4** Explain how the van der Waals equation accounts for critical behaviour.

### Exercises

**1C.1(a)** Calculate the pressure exerted by 1.0 mol  $C_2H_6$  behaving as a van der Waals gas when it is confined under the following conditions: (i) at 273.15 K in 22.414 dm<sup>3</sup>, (ii) at 1000 K in 100 cm<sup>3</sup>. Use the data in Table 1C.3.

**1C.1(b)** Calculate the pressure exerted by 1.0 mol  $H_2S$  behaving as a van der Waals gas when it is confined under the following conditions: (i) at 273.15 K in 22.414 dm<sup>3</sup>, (ii) at 500 K in 150 cm<sup>3</sup>. Use the data in Table 1C.3.

**1C.2(a)** Express the van der Waals parameters  $a=0.751 \text{ atm dm}^6 \text{ mol}^{-2}$  and  $b=0.0226 \text{ dm}^3 \text{ mol}^{-1}$  in SI base units.

**1C.2(b)** Express the van der Waals parameters  $a=1.32 \text{ atm dm}^6 \text{ mol}^{-2}$  and  $b=0.0436 \text{ dm}^3 \text{ mol}^{-1}$  in SI base units.

**1C.3(a)** A gas at 250 K and 15 atm has a molar volume 12 per cent smaller than that calculated from the perfect gas law. Calculate (i) the compression factor under these conditions and (ii) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

**1C.3(b)** A gas at 350 K and 12 atm has a molar volume 12 per cent larger than that calculated from the perfect gas law. Calculate (i) the compression factor under these conditions and (ii) the molar volume of the gas. Which are dominating in the sample, the attractive or the repulsive forces?

**1C.4(a)** In an industrial process, nitrogen is heated to 500 K at a constant volume of 1.000 m<sup>3</sup>. The gas enters the container at 300 K and 100 atm. The mass of the gas is 92.4 kg. Use the van der Waals equation to determine the approximate pressure of the gas at its working temperature of 500 K. For nitrogen,  $a=1.352 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b=0.0387 \text{ dm}^3 \text{ mol}^{-1}$ .

**1C.4(b)** Cylinders of compressed gas are typically filled to a pressure of 200 bar. For oxygen, what would be the molar volume at this pressure and 25 °C based on (i) the perfect gas equation, (ii) the van der Waals equation? For oxygen,  $a=1.364 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b=3.19 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1}$ .

**1C.5(a)** Suppose that 10.0 mol  $C_2H_6(g)$  is confined to 4.860 dm<sup>3</sup> at 27 °C. Predict the pressure exerted by the ethane from (i) the perfect gas and (ii) the van der Waals equations of state. Calculate the compression factor based on these calculations. For ethane,  $a=5.507 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b=0.0651 \text{ dm}^3 \text{ mol}^{-1}$ .

**1C.5(b)** At 300 K and 20 atm, the compression factor of a gas is 0.86. Calculate (i) the volume occupied by 8.2 mmol of the gas under these conditions and (ii) an approximate value of the second virial coefficient  $B$  at 300 K.

**1C.6(a)** The critical constants of methane are  $p_c=45.6 \text{ atm}$ ,  $V_c=98.7 \text{ cm}^3 \text{ mol}^{-1}$ , and  $T_c=190.6 \text{ K}$ . Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

**1C.6(b)** The critical constants of ethane are  $p_c=48.20 \text{ atm}$ ,  $V_c=148 \text{ cm}^3 \text{ mol}^{-1}$ , and  $T_c=305.4 \text{ K}$ . Calculate the van der Waals parameters of the gas and estimate the radius of the molecules.

**1C.7(a)** Use the van der Waals parameters for chlorine in Table 1C.3 of the *Resource section* to calculate approximate values of (i) the Boyle temperature of chlorine and (ii) the radius of a  $Cl_2$  molecule regarded as a sphere.

**1C.7(b)** Use the van der Waals parameters for hydrogen sulfide in Table 1C.3 of the *Resource section* to calculate approximate values of (i) the Boyle temperature of the gas and (ii) the radius of a  $H_2S$  molecule regarded as a sphere.

**1C.8(a)** Suggest the pressure and temperature at which 1.0 mol of (i)  $NH_3$ , (ii) Xe, (iii) He will be in states that correspond to 1.0 mol  $H_2$  at 1.0 atm and 25 °C.

**1C.8(b)** Suggest the pressure and temperature at which 1.0 mol of (i)  $H_2S$ , (ii)  $CO_2$ , (iii) Ar will be in states that correspond to 1.0 mol  $N_2$  at 1.0 atm and 25 °C.

**1C.9(a)** A certain gas obeys the van der Waals equation with  $a=0.50 \text{ m}^6 \text{ Pa mol}^{-2}$ . Its volume is found to be  $5.00 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$  at 273 K and 3.0 MPa. From this information calculate the van der Waals constant  $b$ . What is the compression factor for this gas at the prevailing temperature and pressure?

**1C.9(b)** A certain gas obeys the van der Waals equation with  $a=0.76 \text{ m}^6 \text{ Pa mol}^{-2}$ . Its volume is found to be  $4.00 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$  at 288 K and 4.0 MPa. From this information calculate the van der Waals constant  $b$ . What is the compression factor for this gas at the prevailing temperature and pressure?

### Problems

**1C.1** Calculate the molar volume of chlorine gas at 350 K and 2.30 atm using (a) the perfect gas law and (b) the van der Waals equation. Use the answer to (a) to calculate a first approximation to the correction term for attraction and then use successive approximations to obtain a numerical answer for part (b).

**1C.2** At 273 K measurements on argon gave  $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$  and  $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$ , where  $B$  and  $C$  are the second and third virial coefficients in the expansion of  $Z$  in powers of  $1/V_m$ . Assuming that the perfect gas law holds sufficiently well for the estimation of the second and third terms of the expansion, calculate the compression factor of argon at 100 atm and 273 K. From your result, estimate the molar volume of argon under these conditions.

**1C.3** Calculate the volume occupied by 1.00 mol  $N_2$  using the van der Waals equation in the form of a virial expansion at (a) its critical temperature, (b) its Boyle temperature, and (c) its inversion temperature. Assume that the pressure

is 10 atm throughout. At what temperature is the gas most perfect? Use the following data:  $T_c=126.3 \text{ K}$ ,  $a=1.352 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b=0.0387 \text{ dm}^3 \text{ mol}^{-1}$ .

**1C.4<sup>†</sup>** The second virial coefficient of methane can be approximated by the empirical equation  $B(T) = a + be^{-c/T^2}$ , where  $a = -0.1993 \text{ bar}^{-1}$ ,  $b = 0.2002 \text{ bar}^{-1}$ , and  $c = 1131 \text{ K}^2$  with  $300 \text{ K} < T < 600 \text{ K}$ . What is the Boyle temperature of methane?

**1C.5** The mass density of water vapour at 327.6 atm and 776.4 K is 133.2 kg m<sup>-3</sup>. Given that for water  $T_c=647.4 \text{ K}$ ,  $p_c=21.3 \text{ atm}$ ,  $a=5.464 \text{ dm}^6 \text{ atm mol}^{-2}$ ,  $b=0.03049 \text{ dm}^3 \text{ mol}^{-1}$ , and  $M=18.02 \text{ g mol}^{-1}$ , calculate (a) the molar volume. Then calculate the compression factor (b) from the data, (c) from the virial expansion of the van der Waals equation.

**1C.6** The critical volume and critical pressure of a certain gas are 160 cm<sup>3</sup> mol<sup>-1</sup> and 40 atm, respectively. Estimate the critical temperature by assuming

that the gas obeys the Berthelot equation of state. Estimate the radii of the gas molecules on the assumption that they are spheres.

**1C.7** Estimate the coefficients  $a$  and  $b$  in the Dieterici equation of state from the critical constants of xenon. Calculate the pressure exerted by 1.0 mol Xe when it is confined to 1.0 dm<sup>3</sup> at 25°C.

**1C.8** Show that the van der Waals equation leads to values of  $Z < 1$  and  $Z > 1$ , and identify the conditions for which these values are obtained.

**1C.9** Express the van der Waals equation of state as a virial expansion in powers of  $1/V_m$  and obtain expressions for  $B$  and  $C$  in terms of the parameters  $a$  and  $b$ . The expansion you will need is  $(1-x)^{-1} = 1+x+x^2+\dots$ . Measurements on argon gave  $B = -21.7 \text{ cm}^3 \text{ mol}^{-1}$  and  $C = 1200 \text{ cm}^6 \text{ mol}^{-2}$  for the virial coefficients at 273 K. What are the values of  $a$  and  $b$  in the corresponding van der Waals equation of state?

**1C.10\*** Derive the relation between the critical constants and the Dieterici equation parameters. Show that  $Z_c = 2e^{-2}$  and derive the reduced form of the Dieterici equation of state. Compare the van der Waals and Dieterici predictions of the critical compression factor. Which is closer to typical experimental values?

**1C.11** A scientist proposed the following equation of state:

$$p = \frac{RT}{V_m} - \frac{B}{V_m^2} + \frac{C}{V_m^3}$$

Show that the equation leads to critical behaviour. Find the critical constants of the gas in terms of  $B$  and  $C$  and an expression for the critical compression factor.

**1C.12** Equations 1C.3a and 1C.3b are expansions in  $p$  and  $1/V_m$ , respectively. Find the relation between  $B$ ,  $C$  and  $B'$ ,  $C'$ .

**1C.13** The second virial coefficient  $B'$  can be obtained from measurements of the density  $\rho$  of a gas at a series of pressures. Show that the graph of  $p/\rho$  against  $p$  should be a straight line with slope proportional to  $B'$ . Use the data on dimethyl ether in Problem 1A.2 to find the values of  $B'$  and  $B$  at 25°C.

**1C.14** The equation of state of a certain gas is given by  $p = RT/V_m + (a+bT)/V_m^2$ , where  $a$  and  $b$  are constants. Find  $(\partial V/\partial T)_p$ .

**1C.15** The following equations of state are occasionally used for approximate calculations on gases: (gas A)  $pV_m = RT(1+b/V_m)$ , (gas B)  $p(V_m-b) = RT$ . Assuming that there were gases that actually obeyed these equations of state, would it be possible to liquefy either gas A or B? Would they have a critical temperature? Explain your answer.

**1C.16** Derive an expression for the compression factor of a gas that obeys the equation of state  $p(V-nb) = nRT$ , where  $b$  and  $R$  are constants. If the pressure

and temperature are such that  $V_m = 10b$ , what is the numerical value of the compression factor?

**1C.17\*** The discovery of the element argon by Lord Rayleigh and Sir William Ramsay had its origins in Rayleigh's measurements of the density of nitrogen with an eye toward accurate determination of its molar mass. Rayleigh prepared some samples of nitrogen by chemical reaction of nitrogen-containing compounds; under his standard conditions, a glass globe filled with this 'chemical nitrogen' had a mass of 2.2990 g. He prepared other samples by removing oxygen, carbon dioxide, and water vapor from atmospheric air; under the same conditions, this 'atmospheric nitrogen' had a mass of 2.3102 g (Lord Rayleigh, *Royal Institution Proceedings* 14, 524 (1895)). With the hindsight of knowing accurate values for the molar masses of nitrogen and argon, compute the mole fraction of argon in the latter sample on the assumption that the former was pure nitrogen and the latter a mixture of nitrogen and argon.

**1C.18\*** A substance as elementary and well known as argon still receives research attention. Stewart and Jacobsen have published a review of thermodynamic properties of argon (R.B. Stewart and R.T. Jacobsen, *J. Phys. Chem. Ref. Data* 18, 639 (1989)) which included the following 300 K isotherm.

$p/\text{MPa}$	0.4000	0.5000	0.6000	0.8000	1.000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	6.2208	4.9736	4.1423	3.1031	2.4795
$p/\text{MPa}$	1.500	2.000	2.500	3.000	4.000
$V_m/(\text{dm}^3 \text{ mol}^{-1})$	1.6483	1.2328	0.98357	0.81746	0.60998

(a) Compute the second virial coefficient,  $B$ , at this temperature. (b) Use non-linear curve-fitting software to compute the third virial coefficient,  $C$ , at this temperature.

**1C.19** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to: (a) Explore how the pressure of 1.5 mol CO<sub>2</sub>(g) varies with volume as it is compressed at (a) 273 K, (b) 373 K from 30 dm<sup>3</sup> to 15 dm<sup>3</sup>. (c) Plot the data as  $p$  against  $1/V$ .

**1C.20** Calculate the molar volume of chlorine gas on the basis of the van der Waals equation of state at 250 K and 150 kPa and calculate the percentage difference from the value predicted by the perfect gas equation.

**1C.21** Is there a set of conditions at which the compression factor of a van der Waals gas passes through a minimum? If so, how does the location and value of the minimum value of  $Z$  depend on the coefficients  $a$  and  $b$ ?

## Mathematical background 1 Differentiation and integration

Two of the most important mathematical techniques in the physical sciences are differentiation and integration. They occur throughout the subject, and it is essential to be aware of the procedures involved.

### MB1.1 Differentiation: definitions

Differentiation is concerned with the slopes of functions, such as the rate of change of a variable with time. The formal definition of the **derivative**,  $df/dx$ , of a function  $f(x)$  is

$$\frac{df}{dx} = \lim_{\delta x \rightarrow 0} \frac{f(x + \delta x) - f(x)}{\delta x} \quad \text{Definition First derivative (MB1.1)}$$

As shown in Fig. MB1.1, the derivative can be interpreted as the slope of the tangent to the graph of  $f(x)$ . A positive first derivative indicates that the function slopes upwards (as  $x$  increases), and a negative first derivative indicates the opposite. It is sometimes convenient to denote the first derivative as  $f'(x)$ . The **second derivative**,  $d^2f/dx^2$ , of a function is the derivative of the first derivative (here denoted  $f'$ ):

$$\frac{d^2f}{dx^2} = \lim_{\delta x \rightarrow 0} \frac{f'(x + \delta x) - f'(x)}{\delta x} \quad \text{Definition Second derivative (MB1.2)}$$

It is sometimes convenient to denote the second derivative  $f''$ . As shown in Fig. MB1.1, the second derivative of a function can be interpreted as an indication of the sharpness of the curvature of the function. A positive second derivative indicates that the function is  $\cup$  shaped, and a negative second derivative indicates that it is  $\cap$  shaped.

**Figure MB1.1** (a) The first derivative of a function is equal to the slope of the tangent to the graph of the function at that point. The small circle indicates the extremum (in this case, maximum) of the function, where the slope is zero. (b) The second derivative of the same function is the slope of the tangent to a graph of the first derivative of the function. It can be interpreted as an indication of the curvature of the function at that point.

The derivatives of some common functions are as follows:

$$\frac{d}{dx} x^n = nx^{n-1} \quad (\text{MB1.3a})$$

$$\frac{d}{dx} e^{ax} = ae^{ax} \quad (\text{MB1.3b})$$

$$\frac{d}{dx} \sin ax = a \cos ax \quad \frac{d}{dx} \cos ax = -a \sin ax \quad (\text{MB1.3c})$$

$$\frac{d}{dx} \ln ax = \frac{1}{x} \quad (\text{MB1.3d})$$

When a function depends on more than one variable, we need the concept of a **partial derivative**,  $\partial f/\partial x$ . Note the change from  $d$  to  $\partial$ : partial derivatives are dealt with at length in *Mathematical background 2*; all we need know at this stage is that they signify that all variables other than the stated variable are regarded as constant when evaluating the derivative.

#### Brief illustration MB1.1 Partial derivatives

Suppose we are told that  $f$  is a function of two variables, and specifically  $f = 4x^2y^3$ . Then, to evaluate the partial derivative of  $f$  with respect to  $x$ , we regard  $y$  as a constant (just like the 4), and obtain

$$\frac{\partial f}{\partial x} = \frac{\partial}{\partial x} (4x^2y^3) = 4y^3 \frac{\partial}{\partial x} x^2 = 8xy^3$$

Similarly, to evaluate the partial derivative of  $f$  with respect to  $y$ , we regard  $x$  as a constant (again, like the 4), and obtain

$$\frac{\partial f}{\partial y} = \frac{\partial}{\partial y} (4x^2y^3) = 4x^2 \frac{\partial}{\partial y} y^3 = 12x^2y^2$$

### MB1.2 Differentiation: manipulations

It follows from the definition of the derivative that a variety of combinations of functions can be differentiated by using the following rules:

$$\frac{d}{dx} (u+v) = \frac{du}{dx} + \frac{dv}{dx} \quad (\text{MB1.4a})$$

$$\frac{d}{dx} uv = u \frac{dv}{dx} + v \frac{du}{dx} \quad (\text{MB1.4b})$$

$$\frac{d}{dx} \frac{u}{v} = \frac{1}{v} \frac{du}{dx} - \frac{u}{v^2} \frac{dv}{dx} \quad (\text{MB1.4c})$$

**Brief illustration MB1.2** Derivatives

To differentiate the function  $f = \sin^2 ax/x^2$  use eqn MB1.4 to write

$$\begin{aligned} \frac{d}{dx} \frac{\sin^2 ax}{x^2} &= \frac{d}{dx} \left( \frac{\sin ax}{x} \right) \left( \frac{\sin ax}{x} \right) = 2 \left( \frac{\sin ax}{x} \right) \frac{d}{dx} \left( \frac{\sin ax}{x} \right) \\ &= 2 \left( \frac{\sin ax}{x} \right) \left\{ \frac{1}{x} \frac{d}{dx} \sin ax + \sin ax \frac{d}{dx} \frac{1}{x} \right\} \\ &= 2 \left\{ \frac{a}{x^2} \sin ax \cos ax - \frac{\sin^2 ax}{x^3} \right\} \end{aligned}$$

The function and this first derivative are plotted in Fig. MB1.2.

**Figure MB1.2** The function considered in *Brief illustration MB1.2* and its first derivative.

**MB1.3 Series expansions**

One application of differentiation is to the development of power series for functions. The **Taylor series** for a function  $f(x)$  in the vicinity of  $x=a$  is

$$\begin{aligned} f(x) &= f(a) + \left( \frac{df}{dx} \right)_a (x-a) + \frac{1}{2!} \left( \frac{d^2f}{dx^2} \right)_a (x-a)^2 + \dots \\ &= \sum_{n=0}^{\infty} \frac{1}{n!} \left( \frac{d^n f}{dx^n} \right)_a (x-a)^n \end{aligned} \quad \text{Taylor series (MB1.5)}$$

where the notation  $(\dots)_a$  means that the derivative is evaluated at  $x=a$  and  $n!$  denotes a **factorial** given by

$$n! = n(n-1)(n-2)\dots 1, \quad 0! = 1 \quad \text{Factorial (MB1.6)}$$

The **Maclaurin series** for a function is a special case of the Taylor series in which  $a=0$ .

**Brief illustration MB1.3** Series expansion

To evaluate the expansion of  $\cos x$  around  $x=0$  we note that

$$\left( \frac{d}{dx} \cos x \right)_0 = (-\sin x)_0 = 0 \quad \left( \frac{d^2}{dx^2} \cos x \right)_0 = (-\cos x)_0 = -1$$

and in general

$$\left( \frac{d^n}{dx^n} \cos x \right)_0 = \begin{cases} 0 & \text{for } n \text{ odd} \\ (-1)^{n/2} & \text{for } n \text{ even} \end{cases}$$

Therefore,

$$\cos x = \sum_{n \text{ even}} \frac{(-1)^{n/2}}{n!} x^n = 1 - \frac{1}{2} x^2 + \frac{1}{24} x^4 - \dots$$

The following Taylor series (specifically, Maclaurin series) are used at various stages in the text:

$$(1+x)^{-1} = 1 - x + x^2 - \dots = \sum_{n=0}^{\infty} (-1)^n x^n \quad \text{(MB1.7a)}$$

$$e^x = 1 + x + \frac{1}{2} x^2 + \dots = \sum_{n=0}^{\infty} \frac{x^n}{n!} \quad \text{(MB1.7b)}$$

$$\ln(1+x) = x - \frac{1}{2} x^2 + \frac{1}{3} x^3 - \dots = \sum_{n=1}^{\infty} (-1)^{n+1} \frac{x^n}{n} \quad \text{(MB1.7c)}$$

Taylor series are used to simplify calculations, for when  $x \ll 1$  it is possible, to a good approximation, to terminate the series after one or two terms. Thus, provided  $x \ll 1$  we can write

$$(1+x)^{-1} \approx 1 - x \quad \text{(MB1.8a)}$$

$$e^x \approx 1 + x \quad \text{(MB1.8b)}$$

$$\ln(1+x) \approx x \quad \text{(MB1.8c)}$$

A series is said to **converge** if the sum approaches a finite, definite value as  $n$  approaches infinity. If the sum does not approach a finite, definite value, then the series is said to **diverge**. Thus, the series in eqn MB1.7a converges for  $x < 1$  and diverges for  $x \geq 1$ . There are a variety of tests for convergence, which are explained in mathematics texts.

**MB1.4 Integration: definitions**

Integration (which formally is the inverse of differentiation) is concerned with the areas under curves. The **integral** of a

**Figure MB1.3** A definite integral is evaluated by forming the product of the value of the function at each point and the increment  $\delta x$ , with  $\delta x \rightarrow 0$ , and then summing the products  $f(x)\delta x$  for all values of  $x$  between the limits  $a$  and  $b$ . It follows that the value of the integral is the area under the curve between the two limits.

function  $f(x)$ , which is denoted  $\int f dx$  (the symbol  $\int$  is an elongated S denoting a sum), between the two values  $x=a$  and  $x=b$  is defined by imagining the  $x$  axis as divided into strips of width  $\delta x$  and evaluating the following sum:

$$\int_a^b f(x)dx = \lim_{\delta x \rightarrow 0} \sum_i f(x_i)\delta x \quad \text{Definition Integration (MB1.9)}$$

As can be appreciated from Fig. MB1.3, the integral is the area under the curve between the limits  $a$  and  $b$ . The function to be integrated is called the **integrand**. It is an astonishing mathematical fact that the integral of a function is the inverse of the differential of that function in the sense that if we differentiate  $f$  and then integrate the resulting function, then we obtain the original function  $f$  (to within a constant). The function in eqn MB1.9 with the limits specified is called a **definite integral**. If it is written without the limits specified, then we have an **indefinite integral**. If the result of carrying out an indefinite integration is  $g(x) + C$ , where  $C$  is a constant, the following notation is used to evaluate the corresponding definite integral:

$$I = \int_a^b f(x)dx = \{g(x) + C\}_a^b = \{g(b) + C\} - \{g(a) + C\} \\ = g(b) - g(a) \quad \text{Definite integral (MB1.10)}$$

Note that the constant of integration disappears. The definite and indefinite integrals encountered in this text are listed in the *Resource section*.

### MB1.5 Integration: manipulations

When an indefinite integral is not in the form of one of those listed in the *Resource section* it is sometimes possible to

transform it into one of the forms by using integration techniques such as:

**Substitution.** Introduce a variable  $u$  related to the independent variable  $x$  (for example, an algebraic relation such as  $u=x^2-1$  or a trigonometric relation such as  $u=\sin x$ ). Express the differential  $dx$  in terms of  $du$  (for these substitutions,  $du=2x dx$  and  $du=\cos x dx$ , respectively). Then transform the original integral written in terms of  $x$  into an integral in terms of  $u$  upon which, in some cases, a standard form such as one of those listed in the *Resource section* can be used.

#### Brief illustration MB1.4 Integration by substitution

To evaluate the indefinite integral  $\int \cos^2 x \sin x dx$  we make the substitution  $u = \cos x$ . It follows that  $du/dx = -\sin x$ , and therefore that  $\sin x dx = -du$ . The integral is therefore

$$\int \cos^2 x \sin x dx = -\int u^2 du = -\frac{1}{3}u^3 + C = -\frac{1}{3}\cos^3 x + C$$

To evaluate the corresponding definite integral, we have to convert the limits on  $x$  into limits on  $u$ . Thus, if the limits are  $x=0$  and  $x=\pi$ , the limits become  $u=\cos 0=1$  and  $u=\cos \pi=-1$ :

$$\int_0^\pi \cos^2 x \sin x dx = -\int_1^{-1} u^2 du = \left\{ -\frac{1}{3}u^3 + C \right\}_1^{-1} = \frac{2}{3}$$

**Integration by parts.** For two functions  $f(x)$  and  $g(x)$ :

$$\int f \frac{dg}{dx} dx = fg - \int g \frac{df}{dx} dx \quad \text{Integration by parts (MB1.11a)}$$

which may be abbreviated as:

$$\int f dg = fg - \int g df \quad \text{(MB1.11b)}$$

#### Brief illustration MB1.5 Integration by parts

Integrals over  $xe^{-ax}$  and their analogues occur commonly in the discussion of atomic structure and spectra. They may be integrated by parts, as in the following:

$$\int_0^\infty \overbrace{x}^f \overbrace{e^{-ax}}^{dg/dx} dx = \overbrace{x}^f \overbrace{\frac{e^{-ax}}{-a}}^g \Big|_0^\infty - \int_0^\infty \overbrace{\frac{e^{-ax}}{-a}}^g \overbrace{1}^{df/dx} dx \\ = -\frac{xe^{-ax}}{a} \Big|_0^\infty + \frac{1}{a} \int_0^\infty e^{-ax} dx = 0 - \frac{e^{-ax}}{a^2} \Big|_0^\infty \\ = \frac{1}{a^2}$$

## MB1.6 Multiple integrals

A function may depend on more than one variable, in which case we may need to integrate over both the variables:

$$I = \int_a^b \int_c^d f(x, y) dx dy \quad (\text{MB1.12})$$

We (but not everyone) adopt the convention that  $a$  and  $b$  are the limits of the variable  $x$  and  $c$  and  $d$  are the limits for  $y$  (as depicted by the colours in this instance). This procedure is simple if the function is a product of functions of each variable and of the form  $f(x, y) = X(x)Y(y)$ . In this case, the double integral is just a product of each integral:

$$I = \int_a^b \int_c^d X(x)Y(y) dx dy = \int_a^b X(x) dx \int_c^d Y(y) dy \quad (\text{MB1.13})$$

### Brief illustration MB1.6 A double integral

Double integrals of the form

$$I = \int_0^{L_1} \int_0^{L_2} \sin^2(\pi x/L_1) \sin^2(\pi y/L_2) dx dy$$

occur in the discussion of the translational motion of a particle in two dimensions, where  $L_1$  and  $L_2$  are the maximum extents of travel along the  $x$ - and  $y$ -axes, respectively. To evaluate  $I$  we use eqn MB1.13 and an integral listed in the *Resource section* to write

$$\begin{aligned} I &\stackrel{\text{Integral T.2}}{=} \int_0^{L_1} \sin^2(\pi x/L_1) dx \int_0^{L_2} \sin^2(\pi y/L_2) dy \\ &= \left\{ \frac{1}{2}x - \frac{\sin(2\pi x/L_1)}{4\pi/L_1} + C \right\} \Big|_0^{L_1} \left\{ \frac{1}{2}y - \frac{\sin(2\pi y/L_2)}{4\pi/L_2} + C \right\} \Big|_0^{L_2} \\ &= \frac{1}{4}L_1L_2 \end{aligned}$$

# CHAPTER 2

## The First Law

The release of energy can be used to provide heat when a fuel burns in a furnace, to produce mechanical work when a fuel burns in an engine, and to generate electrical work when a chemical reaction pumps electrons through a circuit. In chemistry, we encounter reactions that can be harnessed to provide heat and work, reactions that liberate energy that is unused but which give products we require, and reactions that constitute the processes of life. **Thermodynamics**, the study of the transformations of energy, enables us to discuss all these matters quantitatively and to make useful predictions.

### 2A Internal energy

First, we examine the ways in which a system can exchange energy with its surroundings in terms of the work it may do or have done on it or the heat that it may produce or absorb. These considerations lead to the definition of the ‘internal energy’, the total energy of a system, and the formulation of the ‘First Law’ of thermodynamics, which states that the internal energy of an isolated system is constant.

### 2B Enthalpy

The second major concept of the chapter is ‘enthalpy’, which is a very useful book-keeping property for keeping track of the heat output (or requirements) of physical processes and chemical reactions that take place at constant pressure. Experimentally, changes in internal energy or enthalpy may be measured by techniques known collectively as ‘calorimetry’.

### 2C Thermochemistry

‘Thermochemistry’ is the study of heat transactions during chemical reactions. We describe both computational and

experimental methods for the determination of enthalpy changes associated with both physical and chemical changes.

### 2D State functions and exact differentials

We also begin to unfold some of the power of thermodynamics by showing how to establish relations between different properties of a system. We see that one very useful aspect of thermodynamics is that a property can be measured indirectly by measuring others and then combining their values. The relations we derive also enable us to discuss the liquefaction of gases and to establish the relation between the heat capacities of a substance under different conditions.

### 2E Adiabatic changes

‘Adiabatic’ processes occur without transfer of energy as heat. We focus on adiabatic changes involving perfect gases because they figure prominently in our presentation of thermodynamics.

## What is the impact of this material?

Concepts of thermochemistry apply to the chemical reactions associated with the conversion of food into energy in organisms, and so form a basis for the discussion of bioenergetics. In *Impact* I2.1, we explore some of the thermochemical calculations related to the metabolism of fats, carbohydrates, and proteins.

### ► Why do you need to know this material?

The First Law of thermodynamics is the foundation of the discussion of the role of energy in chemistry. Wherever we are interested in the generation or use of energy in physical transformations or chemical reactions, lying in the background are the concepts introduced by the First Law.

### ► What is the key idea?

The total energy of an isolated system is constant.

### ► What do you need to know already?

This Topic makes use of the discussion of the properties of gases (Topic 1A), particularly the perfect gas law. It builds on the definition of work given in *Foundations B*.

For the purposes of thermodynamics, the universe is divided into two parts, the system and its surroundings. The **system** is the part of the world in which we have a special interest. It may be a reaction vessel, an engine, an electrochemical cell, a biological cell, and so on. The **surroundings** comprise the region outside the system and are where we make our measurements. The type of system depends on the characteristics of the boundary that divides it from the surroundings (Fig. 2A.1). If matter can be transferred through the boundary between the system and its surroundings the system is classified as **open**. If matter cannot pass through the boundary the system is classified as **closed**. Both open and closed systems can exchange energy with their surroundings. For example, a closed system can expand and thereby raise a weight in the surroundings; a closed system may also transfer energy to the surroundings if they are at a lower temperature. An **isolated system** is a closed system that has neither mechanical nor thermal contact with its surroundings.

**Figure 2A.1** (a) An open system can exchange matter and energy with its surroundings. (b) A closed system can exchange energy with its surroundings, but it cannot exchange matter. (c) An isolated system can exchange neither energy nor matter with its surroundings.

## 2A.1 Work, heat, and energy

Although thermodynamics deals with observations on bulk systems, it is immeasurably enriched by understanding the molecular origins of these observations. In each case we shall set out the bulk observations on which thermodynamics is based and then describe their molecular interpretations.

### (a) Operational definitions

The fundamental physical property in thermodynamics is work: **work** is done to achieve motion against an opposing force. A simple example is the process of raising a weight against the pull of gravity. A process does work if in principle it can be harnessed to raise a weight somewhere in the surroundings. An example of doing work is the expansion of a gas that pushes out a piston: the motion of the piston can in principle be used to raise a weight. A chemical reaction that drives an electric current through a resistance also does work, because the same current could be passed through a motor and used to raise a weight.

The **energy** of a system is its capacity to do work. When work is done on an otherwise isolated system (for instance, by compressing a gas or winding a spring), the capacity of the system to do work is increased; in other words, the energy of the system is increased. When the system does work (i.e. when the piston moves out or the spring unwinds), the energy of the system is reduced and it can do less work than before.

Experiments have shown that the energy of a system may be changed by means other than work itself. When the energy of a system changes as a result of a temperature difference between the system and its surroundings we say that energy has been transferred as **heat**. When a heater is immersed in a beaker of water (the system), the capacity of the system to do work increases because hot water can be used to do more work than the same amount of cold water. Not all boundaries permit the transfer of energy even though there is a temperature difference between the system and its surroundings. Boundaries that do permit the transfer of energy as heat are called **diathermic**; those that do not are called **adiabatic**.

An **exothermic process** is a process that releases energy as heat into its surroundings. All combustion reactions are exothermic. An **endothermic process** is a process in which energy is acquired from its surroundings as heat. An example of an endothermic process is the vaporization of water. To avoid a lot of awkward language, we say that in an exothermic process energy is transferred 'as heat' to the surroundings and in an endothermic process energy is transferred 'as heat' from the surroundings into the system. However, it must never be forgotten that heat is a process (the transfer of energy as a result of a temperature difference), not an entity. An endothermic process in a diathermic container results in

energy flowing into the system as heat to restore the temperature to that of the surroundings. An exothermic process in a similar diathermic container results in a release of energy as heat into the surroundings. When an endothermic process takes place in an adiabatic container, it results in a lowering of temperature of the system; an exothermic process results in a rise of temperature. These features are summarized in Fig. 2A.2.

**Figure 2A.2** (a) When an endothermic process occurs in an adiabatic system, the temperature falls; (b) if the process is exothermic, then the temperature rises. (c) When an endothermic process occurs in a diathermic container, energy enters as heat from the surroundings, and the system remains at the same temperature. (d) If the process is exothermic, then energy leaves as heat, and the process is isothermal.

#### Brief illustration 2A.1 Combustions in adiabatic and diathermic containers

Combustions are chemical reactions in which substances react with oxygen, normally with a flame. An example is the combustion of methane gas,  $\text{CH}_4(\text{g})$ :

All combustions are exothermic. Although the temperature typically rises in the course of the combustion, if we wait long enough, the system returns to the temperature of its surroundings so we can speak of a combustion 'at 25 °C', for instance. If the combustion takes place in an adiabatic container, the energy released as heat remains inside the container and results in a permanent rise in temperature.

**Self-test 2A.1** How may the isothermal expansion of a gas be achieved?

Answer: Immerse the system in a water bath

## (b) The molecular interpretation of heat and work

In molecular terms, heating is the transfer of energy that makes use of disorderly, apparently random, molecular motion in the surroundings. The disorderly motion of molecules is called **thermal motion**. The thermal motion of the molecules in the hot surroundings stimulates the molecules in the cooler system to move more vigorously and, as a result, the energy of the system is increased. When a system heats its surroundings, molecules of the system stimulate the thermal motion of the molecules in the surroundings (Fig. 2A.3).

In contrast, work is the transfer of energy that makes use of organized motion in the surroundings (Fig. 2A.4). When a weight is raised or lowered, its atoms move in an organized way (up or down). The atoms in a spring move in an orderly way

**Figure 2A.3** When energy is transferred to the surroundings as heat, the transfer stimulates random motion of the atoms in the surroundings. Transfer of energy from the surroundings to the system makes use of random motion (thermal motion) in the surroundings.

**Figure 2A.4** When a system does work, it stimulates orderly motion in the surroundings. For instance, the atoms shown here may be part of a weight that is being raised. The ordered motion of the atoms in a falling weight does work on the system.

when it is wound; the electrons in an electric current move in the same direction. When a system does work it causes atoms or electrons in its surroundings to move in an organized way. Likewise, when work is done on a system, molecules in the surroundings are used to transfer energy to it in an organized way, as the atoms in a weight are lowered or a current of electrons is passed.

The distinction between work and heat is made in the surroundings. The fact that a falling weight may stimulate thermal motion in the system is irrelevant to the distinction between heat and work: work is identified as energy transfer making use of the organized motion of atoms in the surroundings, and heat is identified as energy transfer making use of thermal motion in the surroundings. In the adiabatic compression of a gas, for instance, work is done on the system as the atoms of the compressing weight descend in an orderly way, but the effect of the incoming piston is to accelerate the gas molecules to higher average speeds. Because collisions between molecules quickly randomize their directions, the orderly motion of the atoms of the weight is in effect stimulating thermal motion in the gas. We observe the falling weight, the orderly descent of its atoms, and report that work is being done even though it is stimulating thermal motion.

## 2A.2 The definition of internal energy

In thermodynamics, the total energy of a system is called its **internal energy**,  $U$ . The internal energy is the total kinetic and potential energy of the constituents (the atoms, ions, or molecules) of the system. It does not include the kinetic energy arising from the motion of the system as a whole, such as its kinetic energy as it accompanies the Earth on its orbit round the Sun. That is, the internal energy is the energy ‘internal’ to the system. We denote by  $\Delta U$  the change in internal energy when a system changes from an initial state  $i$  with internal energy  $U_i$  to a final state  $f$  of internal energy  $U_f$ :

$$\Delta U = U_f - U_i \quad (2A.1)$$

Throughout thermodynamics, we use the convention that  $\Delta X = X_f - X_i$ , where  $X$  is a property (a ‘state function’) of the system.

The internal energy is a **state function** in the sense that its value depends only on the current state of the system and is independent of how that state has been prepared. In other words, internal energy is a function of the properties that determine the current state of the system. Changing any one of the state variables, such as the pressure, results in a change in internal energy. That the internal energy is a state function has consequences of the greatest importance, as we shall start to unfold in Topic 2D.

The internal energy is an extensive property of a system (a property that depends on the amount of substance present, *Foundations A*) and is measured in joules ( $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ ). The molar internal energy,  $U_{\text{m}}$ , is the internal energy divided by the amount of substance in a system,  $U_{\text{m}} = U/n$ ; it is an intensive property (a property independent of the amount of substance) and commonly reported in kilojoules per mole ( $\text{kJ mol}^{-1}$ ).

### (a) Molecular interpretation of internal energy

A molecule has a certain number of motional degrees of freedom, such as the ability to translate (the motion of its centre of mass through space), rotate around its centre of mass, or vibrate (as its bond lengths and angles change, leaving its centre of mass unmoved). Many physical and chemical properties depend on the energy associated with each of these modes of motion. For example, a chemical bond might break if a lot of energy becomes concentrated in it, for instance as vigorous vibration.

The ‘equipartition theorem’ of classical mechanics introduced in *Foundations B* can be used to predict the contributions of each mode of motion of a molecule to the total energy of a collection of non-interacting molecules (that is, of a perfect gas, and providing quantum effects can be ignored). For translation and rotational modes the contribution of a mode is proportional to the temperature, so the internal energy of a sample increases as the temperature is raised.

#### Brief illustration 2A.2 The internal energy of a perfect gas

In *Foundations B* it is shown that the mean energy of a molecule due to its translational motion is  $\frac{3}{2}kT$  and therefore to the molar energy of a collection the contribution is  $\frac{3}{2}RT$ . Therefore, considering only the translational contribution to internal energy,

$$U_{\text{m}}(T) = U_{\text{m}}(0) + \frac{3}{2}N_{\text{A}}kT = U_{\text{m}}(0) + \frac{3}{2}RT$$

where  $U_{\text{m}}(0)$ , the internal energy at  $T=0$ , can be greater than zero (see, for example, Chapter 8). At  $25^\circ\text{C}$ ,  $RT = 2.48 \text{ kJ mol}^{-1}$ , so the translational motion contributes  $3.72 \text{ kJ mol}^{-1}$  to the molar internal energy of gases.

**Self-test 2A.2** Calculate the molar internal energy of carbon dioxide at  $25^\circ\text{C}$ , taking into account its translational and rotational degrees of freedom.

Answer:  $U_{\text{m}}(T) = U_{\text{m}}(0) + \frac{5}{2}RT$

The contribution to the internal energy of a collection of perfect gas molecules is independent of the volume occupied by the molecules: there are no intermolecular interactions in a

perfect gas, so the distance between the molecules has no effect on the energy. That is, *the internal energy of a perfect gas is independent of the volume it occupies.*

The internal energy of interacting molecules in condensed phases also has a contribution from the potential energy of their interaction, but no simple expressions can be written down in general. Nevertheless, it remains true that as the temperature of a system is raised, the internal energy increases as the various modes of motion become more highly excited.

### (b) The formulation of the First Law

It has been found experimentally that the internal energy of a system may be changed either by doing work on the system or by heating it. Whereas we may know how the energy transfer has occurred (because we can see if a weight has been raised or lowered in the surroundings, indicating transfer of energy by doing work, or if ice has melted in the surroundings, indicating transfer of energy as heat), the system is blind to the mode employed. *Heat and work are equivalent ways of changing a system's internal energy.* A system is like a bank: it accepts deposits in either currency, but stores its reserves as internal energy. It is also found experimentally that if a system is isolated from its surroundings, then no change in internal energy takes place. This summary of observations is now known as the **First Law of thermodynamics** and is expressed as follows:

The internal energy of an isolated system is constant.

First Law of thermodynamics

We cannot use a system to do work, leave it isolated, and then come back expecting to find it restored to its original state with the same capacity for doing work. The experimental evidence for this observation is that no ‘perpetual motion machine’, a machine that does work without consuming fuel or using some other source of energy, has ever been built.

These remarks may be summarized as follows. If we write  $w$  for the work done on a system,  $q$  for the energy transferred as heat to a system, and  $\Delta U$  for the resulting change in internal energy, then it follows that

$$\Delta U = q + w \quad \text{Mathematical statement of the First Law} \quad (2A.2)$$

Equation 2A.2 summarizes the equivalence of heat and work and the fact that the internal energy is constant in an isolated system (for which  $q=0$  and  $w=0$ ). The equation states that the change in internal energy of a closed system is equal to the energy that passes through its boundary as heat or work. It employs the ‘acquisitive convention’, in which  $w$  and  $q$  are positive if energy is transferred to the system as work or heat and are negative if energy is lost from the system. In other words, we view the flow of energy as work or heat from the system's perspective.

**Brief illustration 2A.3** Changes in internal energy

If an electric motor produced 15 kJ of energy each second as mechanical work and lost 2 kJ as heat to the surroundings, then the change in the internal energy of the motor each second is  $\Delta U = -2 \text{ kJ} - 15 \text{ kJ} = -17 \text{ kJ}$ . Suppose that, when a spring was wound, 100 J of work was done on it but 15 J escaped to the surroundings as heat. The change in internal energy of the spring is  $\Delta U = 100 \text{ J} - 15 \text{ J} = +85 \text{ J}$ .

*A note on good practice* Always include the sign of  $\Delta U$  (and of  $\Delta X$  in general), even if it is positive.

**Self-test 2A.3** A generator does work on an electric heater by forcing an electric current through it. Suppose 1 kJ of work is done on the heater and it heats its surroundings by 1 kJ. What is the change in internal energy of the heater?

Answer: 0

## 2A.3 Expansion work

The way is opened to powerful methods of calculation by switching attention to infinitesimal changes of state (such as infinitesimal change in temperature) and infinitesimal changes in the internal energy  $dU$ . Then, if the work done on a system is  $dw$  and the energy supplied to it as heat is  $dq$ , in place of eqn 2A.2 we have

$$dU = dq + dw \quad (2A.3)$$

To use this expression we must be able to relate  $dq$  and  $dw$  to events taking place in the surroundings.

We begin by discussing **expansion work**, the work arising from a change in volume. This type of work includes the work done by a gas as it expands and drives back the atmosphere. Many chemical reactions result in the generation of gases (for instance, the thermal decomposition of calcium carbonate or the combustion of octane), and the thermodynamic characteristics of the reaction depend on the work that must be done to make room for the gas it has produced. The term 'expansion work' also includes work associated with negative changes of volume, that is, compression.

### (a) The general expression for work

The calculation of expansion work starts from the definition used in physics, which states that the work required to move an object a distance  $dz$  against an opposing force of magnitude  $|F|$  is

$$dw = -|F|dz \quad \text{Definition Work done} \quad (2A.4)$$

The negative sign tells us that, when the system moves an object against an opposing force of magnitude  $|F|$ , and there are no

other changes, then the internal energy of the system doing the work will decrease. That is, if  $dz$  is positive (motion to positive  $z$ ),  $dw$  is negative, and the internal energy decreases ( $dU$  in eqn 2A.3 is negative provided that  $dq=0$ ).

Now consider the arrangement shown in Fig. 2A.5, in which one wall of a system is a massless, frictionless, rigid, perfectly fitting piston of area  $A$ . If the external pressure is  $p_{\text{ex}}$ , the magnitude of the force acting on the outer face of the piston is  $|F| = p_{\text{ex}}A$ . When the system expands through a distance  $dz$  against an external pressure  $p_{\text{ex}}$ , it follows that the work done is  $dw = -p_{\text{ex}}Adz$ . The quantity  $Adz$  is the change in volume,  $dV$ , in the course of the expansion. Therefore, the work done when the system expands by  $dV$  against a pressure  $p_{\text{ex}}$  is

$$dw = -p_{\text{ex}}dV \quad \text{Expansion work} \quad (2A.5a)$$

To obtain the total work done when the volume changes from an initial value  $V_i$  to a final value  $V_f$  we integrate this expression between the initial and final volumes:

$$w = -\int_{V_i}^{V_f} p_{\text{ex}}dV \quad (2A.5b)$$

The force acting on the piston,  $p_{\text{ex}}A$ , is equivalent to the force arising from a weight that is raised as the system expands. If the system is compressed instead, then the same weight is lowered in the surroundings and eqn 2A.5b can still be used, but now  $V_f < V_i$ . It is important to note that it is still the external pressure that determines the magnitude of the work. This somewhat perplexing conclusion seems to be inconsistent with the fact that the gas *inside* the container is opposing the compression. However, when a gas is compressed, the ability of the *surroundings* to do work is diminished by an amount determined by the weight that is lowered, and it is this energy that is transferred into the system.

Other types of work (for example, electrical work), which we shall call either **non-expansion work** or **additional work**, have

**Figure 2A.5** When a piston of area  $A$  moves out through a distance  $dz$ , it sweeps out a volume  $dV = Adz$ . The external pressure  $p_{\text{ex}}$  is equivalent to a weight pressing on the piston, and the magnitude of the force opposing expansion is  $|F| = p_{\text{ex}}A$ .

Table 2A.1 Varieties of work\*

Type of work	$dw$	Comments	Units <sup>†</sup>
Expansion	$-p_{\text{ex}}dV$	$p_{\text{ex}}$ is the external pressure $dV$ is the change in volume	$\text{Pa m}^3$
Surface expansion	$\gamma d\sigma$	$\gamma$ is the surface tension $d\sigma$ is the change in area	$\text{N m}^{-1} \text{m}^2$
Extension	$f dl$	$f$ is the tension $dl$ is the change in length	$\text{N m}$
Electrical	$\phi dQ$	$\phi$ is the electric potential $dQ$ is the change in charge	$\text{V C}$
	$Q d\phi$	$d\phi$ is the potential difference $Q$ is the charge transferred	$\text{V C}$

\* In general, the work done on a system can be expressed in the form  $dw = -|F|dz$ , where  $|F|$  is the magnitude of a 'generalized force' and  $dz$  is a 'generalized displacement'.

<sup>†</sup> For work in joules (J). Note that  $1 \text{ N m} = 1 \text{ J}$  and  $1 \text{ V C} = 1 \text{ J}$ .

analogous expressions, with each one the product of an intensive factor (the pressure, for instance) and an extensive factor (the change in volume). Some are collected in Table 2A.1. For the present we continue with the work associated with changing the volume, the expansion work, and see what we can extract from eqn 2A.5b.

#### Brief illustration 2A.4 The work of extension

To establish an expression for the work of stretching an elastomer, a polymer that can stretch and contract, to an extension  $l$  given that the force opposing extension is proportional to the displacement from the resting state of the elastomer we write  $|F| = k_f x$ , where  $k_f$  is a constant and  $x$  is the displacement. It then follows from eqn 2A.4 that for an infinitesimal displacement from  $x$  to  $x + dx$ ,  $dw = -k_f x dx$ . For the overall work of displacement from  $x = 0$  to the final extension  $l$ ,

$$w = -\int_0^l k_f x dx = -\frac{1}{2} k_f l^2$$

**Self-test 2A.4** Suppose the restoring force weakens as the elastomer is stretched, and  $k_f(x) = a - bx^{1/2}$ . Evaluate the work of extension to  $l$ .

$$\text{Answer: } w = -\frac{1}{2} al^2 + \frac{2}{5} bl^{5/2}$$

### (b) Expansion against constant pressure

Suppose that the external pressure is constant throughout the expansion. For example, the piston may be pressed on by the atmosphere, which exerts the same pressure throughout the expansion. A chemical example of this condition is the expansion of a gas formed in a chemical reaction in a container that can expand. We can evaluate eqn 2A.5b by taking the constant  $p_{\text{ex}}$  outside the integral:

Figure 2A.6 The work done by a gas when it expands against a constant external pressure,  $p_{\text{ex}}$ , is equal to the shaded area in this example of an indicator diagram.

$$w = -p_{\text{ex}} \int_{V_i}^{V_f} dV = -p_{\text{ex}} (V_f - V_i)$$

Therefore, if we write the change in volume as  $\Delta V = V_f - V_i$ ,

$$w = -p_{\text{ex}} \Delta V \quad \text{Constant external pressure} \quad \text{Expansion work} \quad (2A.6)$$

This result is illustrated graphically in Fig. 2A.6, which makes use of the fact that an integral can be interpreted as an area. The magnitude of  $w$ , denoted  $|w|$ , is equal to the area beneath the horizontal line at  $p = p_{\text{ex}}$  lying between the initial and final volumes. A  $pV$ -graph used to illustrate expansion work is called an **indicator diagram**; James Watt first used one to indicate aspects of the operation of his steam engine.

**Free expansion** is expansion against zero opposing force. It occurs when  $p_{\text{ex}} = 0$ . According to eqn 2A.6,

$$w = 0 \quad \text{Work of free expansion} \quad (2A.7)$$

That is, no work is done when a system expands freely. Expansion of this kind occurs when a gas expands into a vacuum.

#### Example 2A.1 Calculating the work of gas production

Calculate the work done when 50 g of iron reacts with hydrochloric acid to produce  $\text{FeCl}_2(\text{aq})$  and hydrogen in (a) a closed vessel of fixed volume, (b) an open beaker at  $25^\circ\text{C}$ .

**Method** We need to judge the magnitude of the volume change and then to decide how the process occurs. If there is no change in volume, there is no expansion work however the process takes place. If the system expands against a constant external pressure, the work can be calculated from eqn 2A.6. A general feature of processes in which a condensed phase changes into a gas is that the volume of the former may usually be neglected relative to that of the gas it forms.

**Answer** In (a) the volume cannot change, so no expansion work is done and  $w = 0$ . In (b) the gas drives back the atmosphere and therefore  $w = -p_{\text{ex}} \Delta V$ . We can neglect the initial

volume because the final volume (after the production of gas) is so much larger and  $\Delta V = V_f - V_i \approx V_f = nRT/p_{\text{ex}}$ , where  $n$  is the amount of  $\text{H}_2$  produced. Therefore,

$$w = -p_{\text{ex}}\Delta V \approx -p_{\text{ex}} \times \frac{nRT}{p_{\text{ex}}} = -nRT$$

Because the reaction is  $\text{Fe(s)} + 2 \text{HCl(aq)} \rightarrow \text{FeCl}_2\text{(aq)} + \text{H}_2\text{(g)}$ , we know that 1 mol  $\text{H}_2$  is generated when 1 mol Fe is consumed, and  $n$  can be taken as the amount of Fe atoms that react. Because the molar mass of Fe is  $55.85 \text{ g mol}^{-1}$ , it follows that

$$w = -\frac{50 \text{ g}}{55.85 \text{ g mol}^{-1}} \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \\ \approx -2.2 \text{ kJ}$$

The system (the reaction mixture) does 2.2 kJ of work driving back the atmosphere. Note that (for this perfect gas system) the magnitude of the external pressure does not affect the final result: the lower the pressure, the larger the volume occupied by the gas, so the effects cancel.

**Self-test 2A.5** Calculate the expansion work done when 50 g of water is electrolysed under constant pressure at  $25^\circ\text{C}$ .

Answer:  $-10 \text{ kJ}$

### (c) Reversible expansion

A **reversible change** in thermodynamics is a change that can be reversed by an infinitesimal modification of a variable. The key word ‘infinitesimal’ sharpens the everyday meaning of the word ‘reversible’ as something that can change direction. One example of reversibility that we have encountered already is the thermal equilibrium of two systems with the same temperature. The transfer of energy as heat between the two is reversible because, if the temperature of either system is lowered infinitesimally, then energy flows into the system with the lower temperature. If the temperature of either system at thermal equilibrium is raised infinitesimally, then energy flows out of the hotter system. There is obviously a very close relationship between reversibility and equilibrium: systems at equilibrium are poised to undergo reversible change.

Suppose a gas is confined by a piston and that the external pressure,  $p_{\text{ex}}$ , is set equal to the pressure,  $p$ , of the confined gas. Such a system is in mechanical equilibrium with its surroundings because an infinitesimal change in the external pressure in either direction causes changes in volume in opposite directions. If the external pressure is reduced infinitesimally, the gas expands slightly. If the external pressure is increased infinitesimally, the gas contracts slightly. In either case the change is reversible in the thermodynamic sense. If, on the other hand, the external pressure differs measurably from the internal pressure, then changing  $p_{\text{ex}}$  infinitesimally will not decrease it below the pressure of the gas, so will not change the direction of the process. Such a system is not in mechanical equilibrium

with its surroundings and the expansion is thermodynamically irreversible.

To achieve reversible expansion we set  $p_{\text{ex}}$  equal to  $p$  at each stage of the expansion. In practice, this equalization could be achieved by gradually removing weights from the piston so that the downward force due to the weights always matches the changing upward force due to the pressure of the gas. When we set  $p_{\text{ex}} = p$ , eqn 2A.5a becomes

$$dw = -p_{\text{ex}} dV = -pdV \quad \text{Reversible expansion work} \quad (2A.8a)$$

Although the pressure inside the system appears in this expression for the work, it does so only because  $p_{\text{ex}}$  has been set equal to  $p$  to ensure reversibility. The total work of reversible expansion from an initial volume  $V_i$  to a final volume  $V_f$  is therefore

$$w = -\int_{V_i}^{V_f} p dV \quad (2A.8b)$$

The integral can be evaluated once we know how the pressure of the confined gas depends on its volume. Equation 2A.8b is the link with the material covered in the Topics of Chapter 1 for, if we know the equation of state of the gas, then we can express  $p$  in terms of  $V$  and evaluate the integral.

### (d) Isothermal reversible expansion

Consider the isothermal, reversible expansion of a perfect gas. The expansion is made isothermal by keeping the system in thermal contact with its surroundings (which may be a constant-temperature bath). Because the equation of state is  $pV = nRT$ , we know that at each stage  $p = nRT/V$ , with  $V$  the volume at that stage of the expansion. The temperature  $T$  is constant in an isothermal expansion, so (together with  $n$  and  $R$ ) it may be taken outside the integral. It follows that the work of reversible isothermal expansion of a perfect gas from  $V_i$  to  $V_f$  at a temperature  $T$  is

$$w = -nRT \int_{V_i}^{V_f} \frac{dV}{V} \stackrel{\text{Integral A.2}}{=} -nRT \ln \frac{V_f}{V_i} \\ \text{Perfect gas, reversible, isothermal} \quad \text{Work of expansion} \quad (2A.9)$$

#### Brief illustration 2A.5 The work of isothermal reversible expansion

When a sample of 1.00 mol Ar, regarded here as a perfect gas, undergoes an isothermal reversible expansion at  $20.0^\circ\text{C}$  from  $10.0 \text{ dm}^3$  to  $30.0 \text{ dm}^3$  the work done is

$$w = -(1.00 \text{ mol}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (293.2 \text{ K}) \ln \frac{30.0 \text{ dm}^3}{10.0 \text{ dm}^3} \\ = -2.68 \text{ kJ}$$

**Self-test 2A.6** Suppose that attractions are important between gas molecules, and the equation of state is  $p = nRT/V - n^2a/V^2$ . Derive an expression for the reversible, isothermal expansion of this gas. Is more or less work done *on the surroundings* when it expands (compared with a perfect gas)?

Answer:  $w = -nRT \ln(V_f/V_i) - n^2a(1/V_f - 1/V_i)$ ; less

When the final volume is greater than the initial volume, as in an expansion, the logarithm in eqn 2A.9 is positive and hence  $w < 0$ . In this case, the system has done work on the surroundings and there is a corresponding negative contribution to its internal energy. (Note the cautious language: we shall see later that there is a compensating influx of energy as heat, so overall the internal energy is constant for the isothermal expansion of a perfect gas.) The equations also show that more work is done for a given change of volume when the temperature is increased: at a higher temperature the greater pressure of the confined gas needs a higher opposing pressure to ensure reversibility and the work done is correspondingly greater.

We can express the result of the calculation as an indicator diagram, for the magnitude of the work done is equal to the area under the isotherm  $p = nRT/V$  (Fig. 2A.7). Superimposed on the diagram is the rectangular area obtained for irreversible expansion against constant external pressure fixed at the same final value as that reached in the reversible expansion. More work is obtained when the expansion is reversible (the area is greater) because matching the external pressure to the internal pressure at each stage of the process ensures that none of the system's pushing power is wasted. We cannot obtain more work than for the reversible process because increasing the external pressure even infinitesimally at any stage results in compression. We may infer from this discussion that, because some pushing power is wasted when  $p > p_{\text{ex}}$ , the maximum work

**Figure 2A.7** The work done by a perfect gas when it expands reversibly and isothermally is equal to the area under the isotherm  $p = nRT/V$ . The work done during the irreversible expansion against the same final pressure is equal to the rectangular area shown slightly darker. Note that the reversible work is greater than the irreversible work.

available from a system operating between specified initial and final states and passing along a specified path is obtained when the change takes place reversibly.

We have introduced the connection between reversibility and maximum work for the special case of a perfect gas undergoing expansion. In Topic 3A we see that it applies to all substances and to all kinds of work.

## 2A.4 Heat transactions

In general, the change in internal energy of a system is

$$dU = dq + dw_{\text{exp}} + dw_e \quad (2A.10)$$

where  $dw_e$  is work in addition (e for 'extra') to the expansion work,  $dw_{\text{exp}}$ . For instance,  $dw_e$  might be the electrical work of driving a current through a circuit. A system kept at constant volume can do no expansion work, so  $dw_{\text{exp}} = 0$ . If the system is also incapable of doing any other kind of work (if it is not, for instance, an electrochemical cell connected to an electric motor), then  $dw_e = 0$  too. Under these circumstances:

$$dU = dq \quad \text{Heat transferred at constant volume} \quad (2A.11a)$$

We express this relation by writing  $dU = dq_V$ , where the subscript implies a change at constant volume. For a measurable change between states i and f along a path at constant volume,

$$\int_i^f dU = \int_i^f dq$$

which we summarize as

$$\Delta U = q_V \quad (2A.11b)$$

Note that we do not write the integral over  $dq$  as  $\Delta q$  because  $q$ , unlike  $U$ , is not a state function. It follows that, by measuring the energy supplied to a constant-volume system as heat ( $q_V > 0$ ) or released from it as heat ( $q_V < 0$ ) when it undergoes a change of state, we are in fact measuring the change in its internal energy.

### (a) Calorimetry

**Calorimetry** is the study of the transfer of energy as heat during physical and chemical processes. A **calorimeter** is a device for measuring energy transferred as heat. The most common device for measuring  $q_V$  (and therefore  $\Delta U$ ) is an **adiabatic bomb calorimeter** (Fig. 2A.8). The process we wish to study—which may be a chemical reaction—is initiated inside a constant-volume container, the 'bomb'. The bomb is immersed in

**Figure 2A.8** A constant-volume bomb calorimeter. The ‘bomb’ is the central vessel, which is strong enough to withstand high pressures. The calorimeter (for which the heat capacity must be known) is the entire assembly shown here. To ensure adiabaticity, the calorimeter is immersed in a water bath with a temperature continuously readjusted to that of the calorimeter at each stage of the combustion.

a stirred water bath, and the whole device is the calorimeter. The calorimeter is also immersed in an outer water bath. The water in the calorimeter and of the outer bath are both monitored and adjusted to the same temperature. This arrangement ensures that there is no net loss of heat from the calorimeter to the surroundings (the bath) and hence that the calorimeter is adiabatic.

The change in temperature,  $\Delta T$ , of the calorimeter is proportional to the energy that the reaction releases or absorbs as heat. Therefore, by measuring  $\Delta T$  we can determine  $q_V$  and hence find  $\Delta U$ . The conversion of  $\Delta T$  to  $q_V$  is best achieved by calibrating the calorimeter using a process of known energy output and determining the **calorimeter constant**, the constant  $C$  in the relation

$$q = C\Delta T \quad (2A.12)$$

The calorimeter constant may be measured electrically by passing a constant current,  $I$ , from a source of known potential difference,  $\Delta\phi$ , through a heater for a known period of time,  $t$ , for then

$$q = It\Delta\phi \quad (2A.13)$$

Electrical charge is measured in *coulombs*,  $C$ . The motion of charge gives rise to an electric current,  $I$ , measured in coulombs per second, or *amperes*,  $A$ , where  $1 A = 1 C s^{-1}$ . If a constant current  $I$  flows through a potential difference  $\Delta\phi$  (measured in volts,  $V$ ), the total energy supplied in an interval  $t$  is  $It\Delta\phi$ . Because  $1 A V s = 1 (C s^{-1}) V s = 1 C V = 1 J$ , the energy is obtained in joules with the current in amperes, the potential difference in volts, and the time in seconds.

### Brief illustration 2A.6 Electrical heating

If a current of  $10.0 A$  from a  $12 V$  supply is passed for  $300 s$ , then from eqn 2A.13 the energy supplied as heat is

$$q = (10.0 A) \times (12 V) \times (300 s) = 3.6 \times 10^4 A V s = 36 kJ$$

because  $1 A V s = 1 J$ . If the observed rise in temperature is  $5.5 K$ , then the calorimeter constant is  $C = (36 kJ)/(5.5 K) = 6.5 kJ K^{-1}$ .

**Self-test 2A.7** What is the value of the calorimeter constant if the temperature rises by  $4.8^\circ C$  when a current of  $8.6 A$  from an  $11 V$  supply is passed for  $280 s$ ?

Answer:  $5.5 kJ K^{-1}$

Alternatively,  $C$  may be determined by burning a known mass of substance (benzoic acid is often used) that has a known heat output. With  $C$  known, it is simple to interpret an observed temperature rise as a release of heat.

### (b) Heat capacity

The internal energy of a system increases when its temperature is raised. The increase depends on the conditions under which the heating takes place and for the present we suppose that the system has a constant volume. For example, it may be a gas in a container of fixed volume. If the internal energy is plotted against temperature, then a curve like that in Fig. 2A.9 may be obtained. The slope of the tangent to the curve at any temperature is called the **heat capacity** of the system at that temperature. The **heat capacity at constant volume** is denoted  $C_V$  and is defined formally as

**Figure 2A.9** The internal energy of a system increases as the temperature is raised; this graph shows its variation as the system is heated at constant volume. The slope of the tangent to the curve at any temperature is the heat capacity at constant volume at that temperature. Note that, for the system illustrated, the heat capacity is greater at B than at A.

**Figure 2A.10** The internal energy of a system varies with volume and temperature, perhaps as shown here by the surface. The variation of the internal energy with temperature at one particular constant volume is illustrated by the curve drawn parallel to  $T$ . The slope of this curve at any point is the partial derivative  $(\partial U/\partial T)_V$ .

$$C_V = \left( \frac{\partial U}{\partial T} \right)_V \quad \text{Definition} \quad \text{Heat capacity at constant volume} \quad (2A.14)$$

Partial derivatives are reviewed in *Mathematical background 2* following this chapter. The internal energy varies with the temperature and the volume of the sample, but here we are interested only in its variation with the temperature, the volume being held constant (Fig. 2A.10).

#### Brief illustration 2A.7 Heat capacity

The heat capacity of a monatomic perfect gas can be calculated by inserting the expression for the internal energy derived in *Brief illustration 2A.2* where we saw that  $U_m(T) = U_m(0) + \frac{3}{2}RT$ , so from eqn 2A.14

$$C_{V,m} = \frac{\partial}{\partial T} \left\{ U_m(0) + \frac{3}{2}RT \right\} = \frac{3}{2}R$$

The numerical value is  $12.47 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Self-test 2A.8** Estimate the molar constant-volume heat capacity of carbon dioxide.

Answer:  $\frac{5}{2}R = 21 \text{ J K}^{-1} \text{ mol}^{-1}$

Heat capacities are extensive properties: 100 g of water, for instance, has 100 times the heat capacity of 1 g of water (and therefore requires 100 times the energy as heat to bring about the same rise in temperature). The **molar heat capacity at constant volume**,  $C_{V,m} = C_V/n$ , is the heat capacity per mole of substance, and is an intensive property (all molar quantities are intensive). Typical values of  $C_{V,m}$  for polyatomic gases are close to  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ . For certain applications it is useful to know the **specific heat capacity** (more informally, the ‘specific heat’) of a

substance, which is the heat capacity of the sample divided by the mass, usually in grams:  $C_{V,s} = C_V/m$ . The specific heat capacity of water at room temperature is close to  $4.2 \text{ J K}^{-1} \text{ g}^{-1}$ . In general, heat capacities depend on the temperature and decrease at low temperatures. However, over small ranges of temperature at and above room temperature, the variation is quite small and for approximate calculations heat capacities can be treated as almost independent of temperature.

The heat capacity is used to relate a change in internal energy to a change in temperature of a constant-volume system. It follows from eqn 2A.14 that

$$dU = C_V dT \quad \text{Constant volume} \quad (2A.15a)$$

That is, at constant volume, an infinitesimal change in temperature brings about an infinitesimal change in internal energy, and the constant of proportionality is  $C_V$ . If the heat capacity is independent of temperature over the range of temperatures of interest, then

$$\Delta U = \int_{T_1}^{T_2} C_V dT = C_V \int_{T_1}^{T_2} dT = C_V \overbrace{(T_2 - T_1)}^{\Delta T}$$

and a measurable change of temperature,  $\Delta T$ , brings about a measurable change in internal energy,  $\Delta U$ , where

$$\Delta U = C_V \Delta T \quad \text{Constant volume} \quad (2A.15b)$$

Because a change in internal energy can be identified with the heat supplied at constant volume (eqn 2A.11b), the last equation can also be written

$$q_V = C_V \Delta T \quad (2A.16)$$

This relation provides a simple way of measuring the heat capacity of a sample: a measured quantity of energy is transferred as heat to the sample (electrically, for example), and the resulting increase in temperature is monitored. The ratio of the energy transferred as heat to the temperature rise it causes ( $q_V/\Delta T$ ) is the constant-volume heat capacity of the sample.

#### Brief illustration 2A.8 The determination of a heat capacity

Suppose a 55 W electric heater immersed in a gas in a constant-volume adiabatic container was on for 120 s and it was found that the temperature of the gas rose by  $5.0^\circ\text{C}$  (an increase equivalent to 5.0 K). The heat supplied is  $(55 \text{ W}) \times (120 \text{ s}) = 6.6 \text{ kJ}$  (we have used 1 J = 1 W s), so the heat capacity of the sample is

$$C_V = \frac{6.6 \text{ kJ}}{5.0 \text{ K}} = 1.3 \text{ kJ K}^{-1}$$

**Self-test 2A.9** When 229 J of energy is supplied as heat to 3.0 mol of a gas at constant volume, the temperature of the gas increases by 2.55 °C. Calculate  $C_V$  and the molar heat capacity at constant volume.

Answer: 89.8 J K<sup>-1</sup>, 29.9 J K<sup>-1</sup> mol<sup>-1</sup>

A large heat capacity implies that, for a given quantity of energy transferred as heat, there will be only a small increase in temperature (the sample has a large capacity for heat). An

infinite heat capacity implies that there will be no increase in temperature however much energy is supplied as heat. At a phase transition, such as at the boiling point of water, the temperature of a substance does not rise as energy is supplied as heat: the energy is used to drive the endothermic transition, in this case to vaporize the water, rather than to increase its temperature. Therefore, at the temperature of a phase transition, the heat capacity of a sample is infinite. The properties of heat capacities close to phase transitions are treated more fully in Topic 4B.

## Checklist of concepts

- 1. **Work** is done to achieve motion against an opposing force
- 2. **Energy** is the capacity to do work.
- 3. **Heating** is the transfer of energy that makes use of disorderly molecular motion.
- 4. Work is the transfer of energy that makes use of organized motion.
- 5. **Internal energy**, the total energy of a system, is a state function.
- 6. The **equipartition theorem** can be used to estimate the contribution to the internal energy of classical modes of motion.
- 7. The **First Law** states that the internal energy of an isolated system is constant.
- 8. Free expansion (expansion against zero pressure) does no work.
- 9. To achieve **reversible expansion**, the external pressure is matched at every stage to the pressure of the system.
- 10. The energy transferred as heat at constant volume is equal to the change in internal energy of the system.
- 11. **Calorimetry** is the measurement of heat transactions.

## Checklist of equations

Property	Equation	Comment	Equation number
First Law of thermodynamics	$\Delta U = q + w$	Acquisitive convention	2A.2
Work of expansion	$dw = -p_{\text{ex}} dV$		2A.5a
Work of expansion against a constant external pressure	$w = -p_{\text{ex}} \Delta V$	$p_{\text{ex}} = 0$ corresponds to free expansion	2A.6
Reversible work of expansion of a gas	$w = -nRT \ln(V_f/V_i)$	Isothermal, perfect gas	2A.9
Internal energy change	$\Delta U = q_V$	Constant volume, no other forms of work	2A.11b
Electrical heating	$q = It\Delta\phi$		2A.13
Heat capacity at constant volume	$C_V = (\partial U / \partial T)_V$	Definition	2A.14

### ► Why do you need to know this material?

The concept of enthalpy is central to many thermodynamic discussions about processes taking place under conditions of constant pressure, such as the discussion of the heat requirements or output of physical transformations and chemical reactions.

### ► What is the key idea?

A change in enthalpy is equal to the energy transferred as heat at constant pressure.

### ► What do you need to know already?

This Topic makes use of the discussion of internal energy (Topic 2A) and draws on some aspects of perfect gases (Topic 1A).

The change in internal energy is not equal to the energy transferred as heat when the system is free to change its volume, such as when it is able to expand or contract under conditions of constant pressure. Under these circumstances some of the energy supplied as heat to the system is returned to the surroundings as expansion work (Fig. 2B.1), so  $dU$  is less than  $dq$ . In this case the energy supplied as heat at constant pressure is equal to the change in another thermodynamic property of the system, the enthalpy.

**Figure 2B.1** When a system is subjected to constant pressure and is free to change its volume, some of the energy supplied as heat may escape back into the surroundings as work. In such a case, the change in internal energy is smaller than the energy supplied as heat.

## 2B.1 The definition of enthalpy

The enthalpy,  $H$ , is defined as

$$H = U + pV \quad \text{Definition Enthalpy (2B.1)}$$

where  $p$  is the pressure of the system and  $V$  is its volume. Because  $U$ ,  $p$ , and  $V$  are all state functions, the enthalpy is a state function too. As is true of any state function, the change in enthalpy,  $\Delta H$ , between any pair of initial and final states is independent of the path between them.

### (a) Enthalpy change and heat transfer

Although the definition of enthalpy may appear arbitrary, it has important implications for thermochemistry. For instance, we show in the following *Justification* that eqn 2B.1 implies that *the change in enthalpy is equal to the energy supplied as heat at constant pressure* (provided the system does no additional work):

$$dH = dq_p \quad \text{Heat transferred at constant pressure (2B.2a)}$$

For a measurable change between states  $i$  and  $f$  along a path at constant pressure, we write

$$\int_i^f dH = \int_i^f dq_p$$

and summarize the result as

$$\Delta H = q_p \quad (2B.2b)$$

Note that we do not write the integral over  $dq$  as  $\Delta q$  because  $q$ , unlike  $H$ , is not a state function.

### Brief illustration 2B.1 A change in enthalpy

Water is heated to boiling under a pressure of 1.0 atm. When an electric current of 0.50 A from a 12 V supply is passed for 300 s through a resistance in thermal contact with it, it is found that 0.798 g of water is vaporized. The enthalpy change is

$$\Delta H = q_p = It\Delta\phi = (0.50 \text{ A}) \times (12 \text{ V}) \times (300 \text{ s}) = (0.50 \times 12 \times 300) \text{ J}$$

Here we have used  $1 \text{ A V s} = 1 \text{ J}$ . Because 0.798 g of water is  $(0.798 \text{ g}) / (18.02 \text{ g mol}^{-1}) = (0.798 / 18.02) \text{ mol H}_2\text{O}$ , the enthalpy of vaporization per mole of  $\text{H}_2\text{O}$  is

$$\Delta H_m = \frac{(0.50 \times 12 \times 300) \text{ J}}{(0.798 / 18.02) \text{ mol}} = +41 \text{ kJ mol}^{-1}$$

**Self-test 2B.1** The molar enthalpy of vaporization of benzene at its boiling point (353.25 K) is  $30.8 \text{ kJ mol}^{-1}$ . For how long would the same 12 V source need to supply a 0.50 A current in order to vaporize a 10 g sample?

Answer:  $6.6 \times 10^2 \text{ s}$

### Justification 2B.1 The relation $\Delta H = q_p$

For a general infinitesimal change in the state of the system,  $U$  changes to  $U + dU$ ,  $p$  changes to  $p + dp$ , and  $V$  changes to  $V + dV$ , so from the definition in eqn 2B.1,  $H$  changes from  $U + pV$  to

$$\begin{aligned} H + dH &= (U + dU) + (p + dp)(V + dV) \\ &= U + dU + pV + pdV + Vdp + dpdV \end{aligned}$$

The last term is the product of two infinitesimally small quantities and can therefore be neglected. As a result, after recognizing  $U + pV = H$  on the right (in blue), we find that  $H$  changes to

$$H + dH = H + dU + pdV + Vdp$$

and hence that

$$dH = dU + pdV + Vdp$$

If we now substitute  $dU = dq + dw$  into this expression, we get

$$dH = dq + dw + pdV + Vdp$$

If the system is in mechanical equilibrium with its surroundings at a pressure  $p$  and does only expansion work, we can write  $dw = -pdV$  and obtain

$$dH = dq + Vdp$$

Now we impose the condition that the heating occurs at constant pressure by writing  $dp = 0$ . Then

$$dH = dq \quad (\text{at constant pressure, no additional work})$$

as in eqn 2B.2a. Equation 2B.2b then follows, as explained in the text.

## (b) Calorimetry

The process of measuring heat transactions between a system and its surroundings is called **calorimetry**. An enthalpy change can be measured calorimetrically by monitoring the temperature change that accompanies a physical or chemical change occurring at constant pressure. A calorimeter for studying processes at constant pressure is called an **isobaric calorimeter**. A simple example is a thermally insulated vessel open to the atmosphere: the heat released in the reaction is monitored by measuring the change in temperature of the contents. For a combustion reaction an **adiabatic flame calorimeter** may be used to measure  $\Delta T$  when a given amount of substance burns in a supply of oxygen (Fig. 2B.2).

Another route to  $\Delta H$  is to measure the internal energy change by using a bomb calorimeter, and then to convert  $\Delta U$  to  $\Delta H$ . Because solids and liquids have small molar volumes, for them  $pV_m$  is so small that the molar enthalpy and molar internal energy are almost identical ( $H_m = U_m + pV_m \approx U_m$ ). Consequently, if a process involves only solids or liquids, the values of  $\Delta H$  and  $\Delta U$  are almost identical. Physically, such processes are accompanied by a very small change in volume; the system does negligible work on the surroundings when the process occurs, so the energy supplied as heat stays entirely

**Figure 2B.2** A constant-pressure flame calorimeter consists of this component immersed in a stirred water bath. Combustion occurs as a known amount of reactant is passed through to fuel the flame, and the rise of temperature is monitored.

within the system. The most sophisticated way to measure enthalpy changes, however, is to use a *differential scanning calorimeter* (DSC), as explained in Topic 2C. Changes in enthalpy and internal energy may also be measured by non-calorimetric methods (see Topic 6C).

### Example 2B.1 Relating $\Delta H$ and $\Delta U$

The change in molar internal energy when  $\text{CaCO}_3(\text{s})$  as calcite converts to another form, aragonite, is  $+0.21 \text{ kJ mol}^{-1}$ . Calculate the difference between the molar enthalpy and internal energy changes when the pressure is 1.0 bar given that the densities of the polymorphs are  $2.71 \text{ g cm}^{-3}$  (calcite) and  $2.93 \text{ g cm}^{-3}$  (aragonite).

**Method** The starting point for the calculation is the relation between the enthalpy of a substance and its internal energy (eqn 2B.1). The difference between the two quantities can be expressed in terms of the pressure and the difference of their molar volumes, and the latter can be calculated from their molar masses,  $M$ , and their mass densities,  $\rho$ , by using  $\rho = M/V_m$ .

**Answer** The change in enthalpy when the transition occurs is

$$\begin{aligned}\Delta H_m &= H_m(\text{aragonite}) - H_m(\text{calcite}) \\ &= \{U_m(\text{a}) + pV_m(\text{a})\} - \{U_m(\text{c}) + pV_m(\text{c})\} \\ &= \Delta U_m + p\{V_m(\text{a}) - V_m(\text{c})\}\end{aligned}$$

where a denotes aragonite and c calcite. It follows by substituting  $V_m = M/\rho$  that

$$\Delta H_m - \Delta U_m = pM \left( \frac{1}{\rho(\text{a})} - \frac{1}{\rho(\text{c})} \right)$$

Substitution of the data, using  $M = 100.09 \text{ g mol}^{-1}$ , gives

$$\begin{aligned}\Delta H_m - \Delta U_m &= (1.0 \times 10^5 \text{ Pa}) \times (100.09 \text{ g mol}^{-1}) \\ &\quad \times \left( \frac{1}{2.93 \text{ g cm}^{-3}} - \frac{1}{2.71 \text{ g cm}^{-3}} \right) \\ &= -2.8 \times 10^5 \text{ Pa cm}^3 \text{ mol}^{-1} = -0.28 \text{ Pa m}^3 \text{ mol}^{-1}\end{aligned}$$

Hence (because  $1 \text{ Pa m}^3 = 1 \text{ J}$ ),  $\Delta H_m - \Delta U_m = -0.28 \text{ J mol}^{-1}$ , which is only 0.1 per cent of the value of  $\Delta U_m$ . We see that it is usually justifiable to ignore the difference between the molar enthalpy and internal energy of condensed phases, except at very high pressures, when  $p\Delta V_m$  is no longer negligible.

**Self-test 2B.2** Calculate the difference between  $\Delta H$  and  $\Delta U$  when 1.0 mol Sn(s, grey) of density  $5.75 \text{ g cm}^{-3}$  changes to Sn(s, white) of density  $7.31 \text{ g cm}^{-3}$  at 10.0 bar. At 298 K,  $\Delta H = +2.1 \text{ kJ}$ .

Answer:  $\Delta H - \Delta U = -4.4 \text{ J}$

In contrast to processes involving condensed phases, the values of the changes in internal energy and enthalpy may differ significantly for processes involving gases. Thus, the enthalpy of a perfect gas is related to its internal energy by using  $pV = nRT$  in the definition of  $H$ :

$$H = U + pV = U + nRT \quad (2B.3)$$

This relation implies that the change of enthalpy in a reaction that produces or consumes gas under isothermal conditions is

$$\Delta H = \Delta U + \Delta n_g RT \quad (2B.4)$$

Perfect gas,  
isothermal

Relation  
between  $\Delta H$   
and  $\Delta U$

where  $\Delta n_g$  is the change in the amount of gas molecules in the reaction.

### Brief illustration 2B.2 Processes involving gases

In the reaction  $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O}(\text{l})$ , 3 mol of gas-phase molecules are replaced by 2 mol of liquid-phase molecules, so  $\Delta n_g = -3 \text{ mol}$ . Therefore, at 298 K, when  $RT = 2.5 \text{ kJ mol}^{-1}$ , the enthalpy and internal energy changes taking place in the system are related by

$$\Delta H_m - \Delta U_m = (-3 \text{ mol}) \times RT \approx -7.4 \text{ kJ mol}^{-1}$$

Note that the difference is expressed in kilojoules, not joules as in *Example 2B.2*. The enthalpy change is smaller (in this case, less negative) than the change in internal energy because, although heat escapes from the system when the reaction occurs, the system contracts when the liquid is formed, so energy is restored to it from the surroundings.

**Self-test 2B.3** Calculate the value of  $\Delta H_m - \Delta U_m$  for the reaction  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightarrow 2 \text{NH}_3(\text{g})$ .

Answer:  $-5.0 \text{ kJ mol}^{-1}$

## 2B.2 The variation of enthalpy with temperature

The enthalpy of a substance increases as its temperature is raised. The relation between the increase in enthalpy and the increase in temperature depends on the conditions (for example, constant pressure or constant volume).

### (a) Heat capacity at constant pressure

The most important condition is constant pressure, and the slope of the tangent to a plot of enthalpy against temperature at constant pressure is called the **heat capacity at constant**

**Figure 2B.3** The constant-pressure heat capacity at a particular temperature is the slope of the tangent to a curve of the enthalpy of a system plotted against temperature (at constant pressure). For gases, at a given temperature the slope of enthalpy versus temperature is steeper than that of internal energy versus temperature, and  $C_{p,m}$  is larger than  $C_{v,m}$ .

**pressure** (or *isobaric heat capacity*),  $C_p$ , at a given temperature (Fig. 2B.3). More formally:

$$C_p = \left( \frac{\partial H}{\partial T} \right)_p \quad \text{Definition} \quad \text{Heat capacity at constant pressure} \quad (2B.5)$$

The heat capacity at constant pressure is the analogue of the heat capacity at constant volume (Topic 1A) and is an extensive property. The **molar heat capacity at constant pressure**,  $C_{p,m}$ , is the heat capacity per mole of substance; it is an intensive property.

The heat capacity at constant pressure is used to relate the change in enthalpy to a change in temperature. For infinitesimal changes of temperature,

$$dH = C_p dT \quad (\text{at constant pressure}) \quad (2B.6a)$$

If the heat capacity is constant over the range of temperatures of interest, then for a measurable increase in temperature

$$\Delta H = \int_{T_1}^{T_2} C_p dT = C_p \int_{T_1}^{T_2} dT = C_p \overbrace{(T_2 - T_1)}^{\Delta T}$$

which we can summarize as

$$\Delta H = C_p \Delta T \quad (\text{at constant pressure}) \quad (2B.6b)$$

Because a change in enthalpy can be equated with the energy supplied as heat at constant pressure, the practical form of the latter equation is

$$q_p = C_p \Delta T \quad (2B.7)$$

**Table 2B.1\*** Temperature variation of molar heat capacities,  $C_{p,m}/(\text{J K}^{-1} \text{mol}^{-1}) = a + bT + c/T^2$

	$a$	$b/(\text{10}^{-3} \text{K}^{-1})$	$c/(\text{10}^5 \text{K}^2)$
C(s, graphite)	16.86	4.77	-8.54
CO <sub>2</sub> (g)	44.22	8.79	-8.62
H <sub>2</sub> O(l)	75.29	0	0
N <sub>2</sub> (g)	28.58	3.77	-0.50

\* More values are given in the *Resource section*.

This expression shows us how to measure the heat capacity of a sample: a measured quantity of energy is supplied as heat under conditions of constant pressure (as in a sample exposed to the atmosphere and free to expand), and the temperature rise is monitored.

The variation of heat capacity with temperature can sometimes be ignored if the temperature range is small; this approximation is highly accurate for a monatomic perfect gas (for instance, one of the noble gases at low pressure). However, when it is necessary to take the variation into account, a convenient approximate empirical expression is

$$C_{p,m} = a + bT + \frac{c}{T^2} \quad (2B.8)$$

The empirical parameters  $a$ ,  $b$ , and  $c$  are independent of temperature (Table 2B.1) and are found by fitting this expression to experimental data.

### Example 2B.2 Evaluating an increase in enthalpy with temperature

What is the change in molar enthalpy of N<sub>2</sub> when it is heated from 25 °C to 100 °C? Use the heat capacity information in Table 2B.1.

**Method** The heat capacity of N<sub>2</sub> changes with temperature, so we cannot use eqn 2B.6b (which assumes that the heat capacity of the substance is constant). Therefore, we must use eqn 2B.6a, substitute eqn 2B.8 for the temperature dependence of the heat capacity, and integrate the resulting expression from 25 °C (298 K) to 100 °C (373 K).

**Answer** For convenience, we denote the two temperatures  $T_1$  (298 K) and  $T_2$  (373 K). The relation we require is

$$\int_{H_m(T_1)}^{H_m(T_2)} dH_m = \int_{T_1}^{T_2} \left( a + bT + \frac{c}{T^2} \right) dT$$

After using Integral A.1 in the *Resource section*, it follows that

$$H_m(T_2) - H_m(T_1) = a(T_2 - T_1) + \frac{1}{2}b(T_2^2 - T_1^2) - c \left( \frac{1}{T_2} - \frac{1}{T_1} \right)$$

Substitution of the numerical data results in

$$H_{\text{m}}(373\text{ K}) = H_{\text{m}}(298\text{ K}) + 2.20\text{ kJ mol}^{-1}$$

If we had assumed a constant heat capacity of  $29.14\text{ J K}^{-1}\text{ mol}^{-1}$  (the value given by eqn 2B.8 for  $T = 298\text{ K}$ ), we would have found that the two enthalpies differed by  $2.19\text{ kJ mol}^{-1}$ .

**Self-test 2B.4** At very low temperatures the heat capacity of a solid is proportional to  $T^3$ , and we can write  $C_{p,m} = aT^3$ . What is the change in enthalpy of such a substance when it is heated from 0 to a temperature  $T$  (with  $T$  close to 0)?

$$\text{Answer: } \Delta H_{\text{m}} = \frac{1}{4}aT^4$$

## (b) The relation between heat capacities

Most systems expand when heated at constant pressure. Such systems do work on the surroundings and therefore some of the

energy supplied to them as heat escapes back to the surroundings. As a result, the temperature of the system rises less than when the heating occurs at constant volume. A smaller increase in temperature implies a larger heat capacity, so we conclude that in most cases the heat capacity at constant pressure of a system is larger than its heat capacity at constant volume. We show in Topic 2D that there is a simple relation between the two heat capacities of a perfect gas:

$$C_p - C_v = nR \quad \text{Perfect gas} \quad \text{Relation between heat capacities} \quad (2B.9)$$

It follows that the molar heat capacity of a perfect gas is about  $8\text{ J K}^{-1}\text{ mol}^{-1}$  larger at constant pressure than at constant volume. Because the molar constant-volume heat capacity of a monatomic gas is about  $\frac{3}{2}R = 12\text{ J K}^{-1}\text{ mol}^{-1}$ , the difference is highly significant and must be taken into account.

## Checklist of concepts

- 1. Energy transferred as heat at constant pressure is equal to the change in **enthalpy** of a system.
- 2. Enthalpy changes are measured in a constant-pressure calorimeter.
- 3. The **heat capacity at constant pressure** is equal to the slope of enthalpy with temperature.

## Checklist of equations

Property	Equation	Comment	Equation number
Enthalpy	$H = U + pV$	Definition	2B.1
Heat transfer at constant pressure	$dH = dq_p$ $\Delta H = q_p$	No additional work	2B.2
Relation between $\Delta H$ and $\Delta U$	$\Delta H = \Delta U + \Delta n_g RT$	Molar volumes of the participating condensed phases are negligible; isothermal process	2B.4
Heat capacity at constant pressure	$C_p = (\partial H / \partial T)_p$	Definition	2B.5
Relation between heat capacities	$C_p - C_v = nR$	Perfect gas	2B.9

### ► What do you need to know already?

You need to be aware of the definition of enthalpy and its status as a state function (Topic 2B). The material on temperature dependence of reaction enthalpies makes use of information on heat capacity (Topic 2B).

The study of the energy transferred as heat during the course of chemical reactions is called **thermochemistry**. Thermochemistry is a branch of thermodynamics because a reaction vessel and its contents form a system, and chemical reactions result in the exchange of energy between the system and the surroundings. Thus we can use calorimetry to measure the energy supplied or discarded as heat by a reaction, and can identify  $q$  with a change in internal energy if the reaction occurs at constant volume or with a change in enthalpy if the reaction occurs at constant pressure. Conversely, if we know  $\Delta U$  or  $\Delta H$  for a reaction, we can predict the heat the reaction can produce.

As pointed out in Topic 2A, a process that releases energy as heat into the surroundings is classified as exothermic and one that absorbs energy as heat from the surroundings is classified as endothermic. Because the release of heat at constant pressure signifies a decrease in the enthalpy of a system, it follows that an exothermic process is one for which  $\Delta H < 0$ . Conversely, because the absorption of heat results in an increase in enthalpy, an endothermic process has  $\Delta H > 0$ :

$$\text{exothermic process: } \Delta H < 0 \quad \text{endothermic process: } \Delta H > 0$$

### ► Why do you need to know this material?

Thermochemistry is one of the principal applications of thermodynamics in chemistry, for thermochemical data provide a way of assessing the heat output of chemical reactions, including those involved in the consumption of fuels and foods. The data are also used widely in other chemical applications of thermodynamics.

### ► What is the key idea?

Reaction enthalpies can be combined to provide data on other reactions of interest.

## 2C.1 Standard enthalpy changes

Changes in enthalpy are normally reported for processes taking place under a set of standard conditions. In most of our discussions we shall consider the **standard enthalpy change**,  $\Delta H^\ominus$ , the change in enthalpy for a process in which the initial and final substances are in their standard states:

The **standard state** of a substance at a specified temperature is its pure form at 1 bar.

Specification  
of standard  
state

For example, the standard state of liquid ethanol at 298 K is pure liquid ethanol at 298 K and 1 bar; the standard state of solid iron at 500 K is pure iron at 500 K and 1 bar. The definition of standard state is more sophisticated for solutions (Topic 5E). The standard enthalpy change for a reaction or a physical process is the difference between the products in their standard states and the reactants in their standard states, all at the same specified temperature.

As an example of a standard enthalpy change, the *standard enthalpy of vaporization*,  $\Delta_{\text{vap}}H^\ominus$ , is the enthalpy change per mole of molecules when a pure liquid at 1 bar vaporizes to a gas at 1 bar, as in

As implied by the examples, standard enthalpies may be reported for any temperature. However, the conventional temperature for reporting thermodynamic data is 298.15 K. Unless otherwise mentioned or indicated by attaching the temperature to  $\Delta H^\ominus$ , all thermodynamic data in this text are for this conventional temperature.

*A note on good practice* The attachment of the name of the transition to the symbol  $\Delta$ , as in  $\Delta_{\text{vap}}H$ , is the current convention. However, the older convention,  $\Delta H_{\text{vap}}$ , is still widely used. The current convention is more logical because the subscript identifies the type of change, not the physical observable related to the change.

### (a) Enthalpies of physical change

The standard enthalpy change that accompanies a change of physical state is called the **standard enthalpy of transition** and is denoted  $\Delta_{\text{trs}}H^\ominus$  (Table 2C.1). The **standard enthalpy of vaporization**,  $\Delta_{\text{vap}}H^\ominus$ , is one example. Another is the **standard enthalpy of fusion**,  $\Delta_{\text{fus}}H^\ominus$ , the standard enthalpy change accompanying the conversion of a solid to a liquid, as in

**Table 2C.1\*** Standard enthalpies of fusion and vaporization at the transition temperature,  $\Delta_{\text{trs}}H^\ominus/(\text{kJ mol}^{-1})$

	$T_f/\text{K}$	Fusion	$T_b/\text{K}$	Vaporization
Ar	83.81	1.188	87.29	6.506
C <sub>6</sub> H <sub>6</sub>	278.61	10.59	353.2	30.8
H <sub>2</sub> O	273.15	6.008	373.15	40.656 (44.016 at 298 K)
He	3.5	0.021	4.22	0.084

\* More values are given in the *Resource section*.

**Table 2C.2** Enthalpies of transition

Transition	Process	Symbol*
Transition	Phase $\alpha \rightarrow$ phase $\beta$	$\Delta_{\text{trs}}H$
Fusion	$s \rightarrow l$	$\Delta_{\text{fus}}H$
Vaporization	$l \rightarrow g$	$\Delta_{\text{vap}}H$
Sublimation	$s \rightarrow g$	$\Delta_{\text{sub}}H$
Mixing	Pure $\rightarrow$ mixture	$\Delta_{\text{mix}}H$
Solution	Solute $\rightarrow$ solution	$\Delta_{\text{sol}}H$
Hydration	$X^\pm(\text{g}) \rightarrow X^\pm(\text{aq})$	$\Delta_{\text{hyd}}H$
Atomization	Species(s, l, g) $\rightarrow$ atoms(g)	$\Delta_{\text{at}}H$
Ionization	$X(\text{g}) \rightarrow X^+(\text{g}) + e^-(\text{g})$	$\Delta_{\text{ion}}H$
Electron gain	$X(\text{g}) + e^-(\text{g}) \rightarrow X^-(\text{g})$	$\Delta_{\text{eg}}H$
Reaction	Reactants $\rightarrow$ products	$\Delta_rH$
Combustion	Compound(s, l, g) + O <sub>2</sub> (g) $\rightarrow$ CO <sub>2</sub> (g), H <sub>2</sub> O(l, g)	$\Delta_cH$
Formation	Elements $\rightarrow$ compound	$\Delta_fH$
Activation	Reactants $\rightarrow$ activated complex	$\Delta^\ddagger H$

\* IUPAC recommendations. In common usage, the transition subscript is often attached to  $\Delta H$ , as in  $\Delta H_{\text{trs}}$ .

As in this case, it is sometimes convenient to know the standard enthalpy change at the transition temperature as well as at the conventional temperature of 298 K. The different types of enthalpies encountered in thermochemistry are summarized in Table 2C.2. We meet them again in various locations throughout the text.

Because enthalpy is a state function, a change in enthalpy is independent of the path between the two states. This feature is of great importance in thermochemistry, for it implies that the same value of  $\Delta H^\ominus$  will be obtained however the change is brought about between the same initial and final states. For example, we can picture the conversion of a solid to a vapour either as occurring by sublimation (the direct conversion from solid to vapour),

or as occurring in two steps, first fusion (melting) and then vaporization of the resulting liquid:

Because the overall result of the indirect path is the same as that of the direct path, the overall enthalpy change is the same in each case (1), and we can conclude that (for processes occurring at the same temperature)

$$\Delta_{\text{sub}}H^\ominus = \Delta_{\text{fus}}H^\ominus + \Delta_{\text{vap}}H^\ominus \quad (2C.1)$$

An immediate conclusion is that, because all enthalpies of fusion are positive, the enthalpy of sublimation of a substance is greater than its enthalpy of vaporization (at a given temperature).

Another consequence of  $H$  being a state function is that the standard enthalpy changes of a forward process and its reverse differ in sign (2):

$$\Delta H^\ominus(A \rightarrow B) = -\Delta H^\ominus(B \rightarrow A) \quad (2C.2)$$

For instance, because the enthalpy of vaporization of water is  $+44 \text{ kJ mol}^{-1}$  at 298 K, its enthalpy of condensation at that temperature is  $-44 \text{ kJ mol}^{-1}$ .

The vaporization of a solid often involves a large increase in energy, especially when the solid is ionic and the strong Coulombic interaction of the ions must be overcome in a process such as

The **lattice enthalpy**,  $\Delta H_L$ , is the change in standard molar enthalpy for this process. The lattice enthalpy is equal to the lattice internal energy at  $T=0$ ; at normal temperatures they differ by only a few kilojoules per mole, and the difference is normally neglected.

Experimental values of the lattice enthalpy are obtained by using a **Born–Haber cycle**, a closed path of transformations starting and ending at the same point, one step of which is the formation of the solid compound from a gas of widely separated ions.

### Brief illustration 2C.1 A Born–Haber cycle

A typical Born–Haber cycle, for potassium chloride, is shown in Fig. 2C.1.

**Figure 2C.1** The Born–Haber cycle for KCl at 298 K. Enthalpy changes are in kilojoules per mole.

It consists of the following steps (for convenience, starting at the elements):

	$\Delta H^\ominus / (\text{kJ mol}^{-1})$	
1. Sublimation of K(s)	+89	[dissociation enthalpy of K(s)]
2. Dissociation of $\frac{1}{2} \text{Cl}_2(\text{g})$	+122	$[\frac{1}{2} \times \text{dissociation enthalpy of } \text{Cl}_2(\text{g})]$
3. Ionization of K(g)	+418	[ionization enthalpy of K(g)]
4. Electron attachment to Cl(g)	-349	[electron gain enthalpy of Cl(g)]
5. Formation of solid from gas	$-\Delta H_L / (\text{kJ mol}^{-1})$	
6. Decomposition of compound	+437	[negative of enthalpy of formation of KCl(s)]

Because the sum of these enthalpy changes is equal to zero, we can infer from

$$89 + 122 + 418 - 349 - \Delta H_L / (\text{kJ mol}^{-1}) + 437 = 0$$

that  $\Delta H_L = +717 \text{ kJ mol}^{-1}$ .

**Self-test 2C.1** Assemble a similar cycle for the lattice enthalpy of magnesium chloride.

Answer:  $2523 \text{ kJ mol}^{-1}$

Lattice enthalpies obtained in the same way as in *Brief illustration 2C.1* are listed in Table 2C.3. They are large when the ions are highly charged and small, for then they are close together and attract each other strongly. We examine the quantitative relation between lattice enthalpy and structure in Topic 18B.

### (b) Enthalpies of chemical change

Now we consider enthalpy changes that accompany chemical reactions. There are two ways of reporting the change in enthalpy that accompanies a chemical reaction. One is to write

**Table 2C.3\*** Lattice enthalpies at 298 K,  $\Delta H_L$ /(kJ mol<sup>-1</sup>)

NaF	787
NaBr	751
MgO	3850
MgS	3406

\* More values are given in the *Resource section*.

the **thermochemical equation**, a combination of a chemical equation and the corresponding change in standard enthalpy:

$\Delta H^\ominus$  is the change in enthalpy when reactants in their standard states change to products in their standard states:

Pure, separate reactants in their standard states  
 → pure, separate products in their standard states

Except in the case of ionic reactions in solution, the enthalpy changes accompanying mixing and separation are insignificant in comparison with the contribution from the reaction itself. For the combustion of methane, the standard value refers to the reaction in which 1 mol CH<sub>4</sub> in the form of pure methane gas at 1 bar reacts completely with 2 mol O<sub>2</sub> in the form of pure oxygen gas to produce 1 mol CO<sub>2</sub> as pure carbon dioxide at 1 bar and 2 mol H<sub>2</sub>O as pure liquid water at 1 bar; the numerical value is for the reaction at 298.15 K.

Alternatively, we write the chemical equation and then report the **standard reaction enthalpy**,  $\Delta_r H^\ominus$  (or 'standard enthalpy of reaction'). Thus, for the combustion of methane, we write

For a reaction of the form  $2 \text{A} + \text{B} \rightarrow 3 \text{C} + \text{D}$  the standard reaction enthalpy would be

$$\Delta_r H^\ominus = \{3H_m^\ominus(\text{C}) + H_m^\ominus(\text{D})\} - \{2H_m^\ominus(\text{A}) + H_m^\ominus(\text{B})\}$$

where  $H_m^\ominus(\text{J})$  is the standard molar enthalpy of species J at the temperature of interest. Note how the 'per mole' of  $\Delta_r H^\ominus$  comes directly from the fact that molar enthalpies appear in this expression. We interpret the 'per mole' by noting the stoichiometric coefficients in the chemical equation. In this case, 'per mole' in  $\Delta_r H^\ominus$  means 'per 2 mol A', 'per mole B', 'per 3 mol C', or 'per mol D'. In general,

$$\Delta_r H^\ominus = \sum_{\text{Products}} \nu H_m^\ominus - \sum_{\text{Reactants}} \nu H_m^\ominus \quad \text{Definition} \quad \text{Standard reaction enthalpy} \quad (2\text{C.3})$$

where in each case the molar enthalpies of the species are multiplied by their (dimensionless and positive) stoichiometric coefficients,  $\nu$ . This formal definition is of little practical value

because the absolute values of the standard molar enthalpies are unknown: we see in Section 2C.2a how that problem is overcome.

Some standard reaction enthalpies have special names and a particular significance. For instance, the **standard enthalpy of combustion**,  $\Delta_c H^\ominus$ , is the standard reaction enthalpy for the complete oxidation of an organic compound to CO<sub>2</sub> gas and liquid H<sub>2</sub>O if the compound contains C, H, and O, and to N<sub>2</sub> gas if N is also present.

### Brief illustration 2C.2 Enthalpy of combustion

The combustion of glucose is

The value quoted shows that 2808 kJ of heat is released when 1 mol C<sub>6</sub>H<sub>12</sub>O<sub>6</sub> burns under standard conditions (at 298 K). More values are given in Table 2C.4.

**Self-test 2C.2** Predict the heat output of the combustion of 1.0 dm<sup>3</sup> of octane at 298 K. Its mass density is 0.703 g cm<sup>-3</sup>.

Answer: 34 MJ

**Table 2C.4\*** Standard enthalpies of formation ( $\Delta_f H^\ominus$ ) and combustion ( $\Delta_c H^\ominus$ ) of organic compounds at 298 K

	$\Delta_f H^\ominus$ /(kJ mol <sup>-1</sup> )	$\Delta_c H^\ominus$ /(kJ mol <sup>-1</sup> )
Benzene, C <sub>6</sub> H <sub>6</sub> (l)	+49.0	-3268
Ethane, C <sub>2</sub> H <sub>6</sub> (g)	-84.7	-1560
Glucose, C <sub>6</sub> H <sub>12</sub> O <sub>6</sub> (s)	-1274	-2808
Methane, CH <sub>4</sub> (g)	-74.8	-890
Methanol, CH <sub>3</sub> OH(l)	-238.7	-721

\* More values are given in the *Resource section*.

## (c) Hess's law

Standard enthalpies of individual reactions can be combined to obtain the enthalpy of another reaction. This application of the First Law is called **Hess's law**:

The standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.

Hess's law

The individual steps need not be realizable in practice: they may be hypothetical reactions, the only requirement being that their chemical equations should balance. The thermodynamic basis of the law is the path-independence of the value of  $\Delta_r H^\ominus$  and the implication that we may take the specified reactants, pass through any (possibly hypothetical) set of reactions to the specified products, and overall obtain the same change of enthalpy. The importance of Hess's law is that

information about a reaction of interest, which may be difficult to determine directly, can be assembled from information on other reactions.

### Example 2C.1 Using Hess's law

The standard reaction enthalpy for the hydrogenation of propene,

is  $-124\text{ kJ mol}^{-1}$ . The standard reaction enthalpy for the combustion of propane,

is  $-2220\text{ kJ mol}^{-1}$ . The standard reaction enthalpy for the formation of water,

is  $-286\text{ kJ mol}^{-1}$ . Calculate the standard enthalpy of combustion of propene.

**Method** The skill to develop is the ability to assemble a given thermochemical equation from others. Add or subtract the reactions given, together with any others needed, so as to reproduce the reaction required. Then add or subtract the reaction enthalpies in the same way.

**Answer** The combustion reaction we require is

This reaction can be recreated from the following sum:

	$\Delta_r H^\ominus / (\text{kJ mol}^{-1})$
$\text{C}_3\text{H}_6(\text{g})+\text{H}_2(\text{g})\rightarrow\text{C}_3\text{H}_8(\text{g})$	-124
$\text{C}_3\text{H}_8(\text{g})+5\text{ O}_2(\text{g})\rightarrow 3\text{ CO}_2(\text{g})+4\text{ H}_2\text{O}(\text{l})$	-2220
$\text{H}_2\text{O}(\text{l})\rightarrow\text{H}_2(\text{g})+\frac{1}{2}\text{ O}_2(\text{g})$	+286
$\text{C}_3\text{H}_6(\text{g})+\frac{9}{2}\text{ O}_2(\text{g})\rightarrow 3\text{ CO}_2(\text{g})+3\text{ H}_2\text{O}(\text{l})$	-2058

**Self-test 2C.3** Calculate the enthalpy of hydrogenation of benzene from its enthalpy of combustion and the enthalpy of combustion of cyclohexane.

Answer:  $-206\text{ kJ mol}^{-1}$

## 2C.2 Standard enthalpies of formation

The **standard enthalpy of formation**,  $\Delta_f H^\ominus$ , of a substance is the standard reaction enthalpy for the formation of the compound from its elements in their reference states:

The **reference state** of an element is its most stable state at the specified temperature and 1 bar.

Specification of reference state

For example, at 298 K the reference state of nitrogen is a gas of  $\text{N}_2$  molecules, that of mercury is liquid mercury, that of carbon is graphite, and that of tin is the white (metallic) form. There is one exception to this general prescription of reference states: the reference state of phosphorus is taken to be white phosphorus despite this allotrope not being the most stable form but simply the more reproducible form of the element. Standard enthalpies of formation are expressed as enthalpies per mole of molecules or (for ionic substances) formula units of the compound. The standard enthalpy of formation of liquid benzene at 298 K, for example, refers to the reaction

and is  $+49.0\text{ kJ mol}^{-1}$ . The standard enthalpies of formation of elements in their reference states are zero at all temperatures because they are the enthalpies of such 'null' reactions as  $\text{N}_2(\text{g})\rightarrow\text{N}_2(\text{g})$ . Some enthalpies of formation are listed in Tables 2C.5 and 2C.6.

The standard enthalpy of formation of ions in solution poses a special problem because it is impossible to prepare a solution of cations alone or of anions alone. This problem is solved by

**Table 2C.5\*** Standard enthalpies of formation of inorganic compounds at 298 K,  $\Delta_f H^\ominus / (\text{kJ mol}^{-1})$

	$\Delta_f H^\ominus / (\text{kJ mol}^{-1})$
$\text{H}_2\text{O}(\text{l})$	-285.83
$\text{H}_2\text{O}(\text{g})$	-241.82
$\text{NH}_3(\text{g})$	-46.11
$\text{N}_2\text{H}_4(\text{l})$	+50.63
$\text{NO}_2(\text{g})$	+33.18
$\text{N}_2\text{O}_4(\text{g})$	+9.16
$\text{NaCl}(\text{s})$	-411.15
$\text{KCl}(\text{s})$	-436.75

\* More values are given in the Resource section.

**Table 2C.6\*** Standard enthalpies of formation of organic compounds at 298 K,  $\Delta_f H^\ominus / (\text{kJ mol}^{-1})$

	$\Delta_f H^\ominus / (\text{kJ mol}^{-1})$
$\text{CH}_4(\text{g})$	-74.81
$\text{C}_6\text{H}_6(\text{l})$	+49.0
$\text{C}_6\text{H}_{12}(\text{l})$	-156
$\text{CH}_3\text{OH}(\text{l})$	-238.66
$\text{CH}_3\text{CH}_2\text{OH}(\text{l})$	-277.69

\* More values are given in the Resource section.

defining one ion, conventionally the hydrogen ion, to have zero standard enthalpy of formation at all temperatures:

$$\Delta_f H^\ominus(\text{H}^+, \text{aq}) = 0 \quad \text{Convention} \quad \text{Ions in solution} \quad (2\text{C.4})$$

### Brief illustration 2C.3 Enthalpies of formation of ions in solution

If the enthalpy of formation of  $\text{HBr}(\text{aq})$  is found to be  $-122 \text{ kJ mol}^{-1}$ , then the whole of that value is ascribed to the formation of  $\text{Br}^-(\text{aq})$ , and we write  $\Delta_f H^\ominus(\text{Br}^-, \text{aq}) = -122 \text{ kJ mol}^{-1}$ . That value may then be combined with, for instance, the enthalpy of formation of  $\text{AgBr}(\text{aq})$  to determine the value of  $\Delta_f H^\ominus(\text{Ag}^+, \text{aq})$ , and so on. In essence, this definition adjusts the actual values of the enthalpies of formation of ions by a fixed amount, which is chosen so that the standard value for one of them,  $\text{H}^+(\text{aq})$ , has the value zero.

**Self-test 2C.4** Determine the value of  $\Delta_f H^\ominus(\text{Ag}^+, \text{aq})$ ; the standard enthalpy of formation of  $\text{AgBr}(\text{aq})$  is  $-17 \text{ kJ mol}^{-1}$ .

Answer:  $+105 \text{ kJ mol}^{-1}$

## (a) The reaction enthalpy in terms of enthalpies of formation

Conceptually, we can regard a reaction as proceeding by decomposing the reactants into their elements and then forming those elements into the products. The value of  $\Delta_r H^\ominus$  for the overall reaction is the sum of these ‘unforming’ and forming enthalpies. Because ‘unforming’ is the reverse of forming, the enthalpy of an unforming step is the negative of the enthalpy of formation (3).

Hence, in the enthalpies of formation of substances, we have enough information to calculate the enthalpy of any reaction by using

$$\Delta_r H^\ominus = \sum_{\text{Products}} \nu \Delta_f H^\ominus - \sum_{\text{Reactants}} \nu \Delta_f H^\ominus \quad \text{Practical implementation} \quad \text{Standard reaction enthalpy} \quad (2\text{C.5a})$$

where in each case the enthalpies of formation of the species that occur are multiplied by their stoichiometric coefficients. This procedure is the practical implementation of the formal definition in eqn 2C.3. A more sophisticated way of expressing

the same result is to introduce the **stoichiometric numbers**  $\nu_j$  (as distinct from the stoichiometric coefficients), which are positive for products and negative for reactants. Then we can write

$$\Delta_r H^\ominus = \sum_j \nu_j \Delta_f H^\ominus(j) \quad (2\text{C.5b})$$

Stoichiometric *numbers*, which have a sign, are denoted  $\nu_j$  or  $\nu(j)$ . Stoichiometric *coefficients*, which are all positive, are denoted simply  $\nu$  (with no subscript).

### Brief illustration 2C.4 Enthalpies of formation

According to eqn 2C.5a, the standard enthalpy of the reaction  $2 \text{HN}_3(\text{l}) + 2 \text{NO}(\text{g}) \rightarrow \text{H}_2\text{O}_2(\text{l}) + 4 \text{N}_2(\text{g})$  is calculated as follows:

$$\begin{aligned} \Delta_r H^\ominus &= \{\Delta_f H^\ominus(\text{H}_2\text{O}_2, \text{l}) + 4\Delta_f H^\ominus(\text{N}_2, \text{g})\} \\ &\quad - \{2\Delta_f H^\ominus(\text{HN}_3, \text{l}) + 2\Delta_f H^\ominus(\text{NO}, \text{g})\} \\ &= \{-187.78 + 4(0)\} \text{ kJ mol}^{-1} - \{2(264.0) \\ &\quad + 2(90.25)\} \text{ kJ mol}^{-1} \\ &= -896.3 \text{ kJ mol}^{-1} \end{aligned}$$

To use eqn 2C.5b, we identify  $\nu(\text{HN}_3) = -2$ ,  $\nu(\text{NO}) = -2$ ,  $\nu(\text{H}_2\text{O}_2) = +1$ , and  $\nu(\text{N}_2) = +4$ , and then write

$$\Delta_r H^\ominus = \Delta_f H^\ominus(\text{H}_2\text{O}_2, \text{l}) + 4\Delta_f H^\ominus(\text{N}_2, \text{g}) - 2\Delta_f H^\ominus(\text{HN}_3, \text{l}) - 2\Delta_f H^\ominus(\text{NO}, \text{g})$$

which gives the same result.

**Self-test 2C.5** Evaluate the standard enthalpy of the reaction  $\text{C}(\text{graphite}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{CO}(\text{g}) + \text{H}_2(\text{g})$ .

Answer:  $+131.29 \text{ kJ mol}^{-1}$

## (b) Enthalpies of formation and molecular modelling

We have seen how to construct standard reaction enthalpies by combining standard enthalpies of formation. The question that now arises is whether we can construct standard enthalpies of formation from a knowledge of the chemical constitution of the species. The short answer is that there is no thermodynamically exact way of expressing enthalpies of formation in terms of contributions from individual atoms and bonds. In the past, approximate procedures based on **mean bond enthalpies**,  $\Delta H(\text{A-B})$ , the average enthalpy change associated with the breaking of a specific A-B bond,

have been used. However, this procedure is notoriously unreliable, in part because the  $\Delta H(\text{A-B})$  are average values for a

series of related compounds. Nor does the approach distinguish between geometrical isomers, where the same atoms and bonds may be present but experimentally the enthalpies of formation might be significantly different.

Computer-aided molecular modelling has largely displaced this more primitive approach. Commercial software packages use the principles developed in Topic 10E to calculate the standard enthalpy of formation of a molecule drawn on the computer screen. These techniques can be applied to different conformations of the same molecule. In the case of methylcyclohexane, for instance, the calculated conformational energy difference ranges from 5.9 to 7.9 kJ mol<sup>-1</sup>, with the equatorial conformer having the lower standard enthalpy of formation. These estimates compare favourably with the experimental value of 7.5 kJ mol<sup>-1</sup>. However, good agreement between calculated and experimental values is relatively rare. Computational methods almost always predict correctly which conformer is more stable but do not always predict the correct magnitude of the conformational energy difference. The most reliable technique for the determination of enthalpies of formation remains calorimetry, typically by using enthalpies of combustion.

#### Brief illustration 2C.5 Molecular modelling

Each software package has its own procedures; the general approach, though, is the same in most cases: the structure of the molecule is specified and the nature of the calculation selected. When the procedure is applied to the axial and equatorial isomers of methylcyclohexane, a typical value for the standard enthalpy of formation of equatorial isomer in the gas phase is -183 kJ mol<sup>-1</sup> (using the AM1 semi-empirical procedure) whereas that for the axial isomer is -177 kJ mol<sup>-1</sup>, a difference of 6 kJ mol<sup>-1</sup>. The experimental difference is 7.5 kJ mol<sup>-1</sup>.

**Self-test 2C.6** If you have access to modelling software, repeat this calculation for the two isomers of cyclohexanol.

Answer: Using AM1: eq: -345 kJ mol<sup>-1</sup>; ax: -349 kJ mol<sup>-1</sup>

## 2C.3 The temperature dependence of reaction enthalpies

The standard enthalpies of many important reactions have been measured at different temperatures. However, in the absence of this information, standard reaction enthalpies at different temperatures may be calculated from heat capacities and the reaction enthalpy at some other temperature (Fig. 2C.2). In many cases heat capacity data are more accurate than reaction enthalpies. Therefore, providing the information is available, the procedure we are about to describe is more accurate than the direct measurement of a reaction enthalpy at an elevated temperature.

**Figure 2C.2** When the temperature is increased, the enthalpy of the products and the reactants both increase, but may do so to different extents. In each case, the change in enthalpy depends on the heat capacities of the substances. The change in reaction enthalpy reflects the difference in the changes of the enthalpies.

It follows from eqn 2B.6a ( $dH = C_p dT$ ) that, when a substance is heated from  $T_1$  to  $T_2$ , its enthalpy changes from  $H(T_1)$  to

$$H(T_2) = H(T_1) + \int_{T_1}^{T_2} C_p dT \quad (2C.6)$$

(We have assumed that no phase transition takes place in the temperature range of interest.) Because this equation applies to each substance in the reaction, the standard reaction enthalpy changes from  $\Delta_r H^\ominus(T_1)$  to

$$\Delta_r H^\ominus(T_2) = \Delta_r H^\ominus(T_1) + \int_{T_1}^{T_2} \Delta_r C_p^\ominus dT \quad \text{Kirchhoff's law} \quad (2C.7a)$$

where  $\Delta_r C_p^\ominus$  is the difference of the molar heat capacities of products and reactants under standard conditions weighted by the stoichiometric coefficients that appear in the chemical equation:

$$\Delta_r C_{p,m}^\ominus = \sum_{\text{Products}} \nu C_{p,m}^\ominus - \sum_{\text{Reactants}} \nu C_{p,m}^\ominus \quad (2C.7b)$$

or, in the notation of eqn 2C.5b,

$$\Delta_r C_{p,m}^\ominus = \sum_j \nu_j C_{p,m}^\ominus(j) \quad (2C.7c)$$

Equation 2C.7a is known as **Kirchhoff's law**. It is normally a good approximation to assume that  $\Delta_r C_p^\ominus$  is independent of the temperature, at least over reasonably limited ranges. Although the individual heat capacities may vary, their difference varies less significantly. In some cases the temperature dependence of heat capacities is taken into account by using eqn 2B.8.

**Example 2C.2** Using Kirchoff's law

The standard enthalpy of formation of  $\text{H}_2\text{O}(\text{g})$  at 298 K is  $-241.82 \text{ kJ mol}^{-1}$ . Estimate its value at  $100^\circ\text{C}$  given the following values of the molar heat capacities at constant pressure:  $\text{H}_2\text{O}(\text{g})$ :  $33.58 \text{ J K}^{-1} \text{ mol}^{-1}$ ;  $\text{H}_2(\text{g})$ :  $28.84 \text{ J K}^{-1} \text{ mol}^{-1}$ ;  $\text{O}_2(\text{g})$ :  $29.37 \text{ J}^{-1} \text{ mol}^{-1}$ . Assume that the heat capacities are independent of temperature.

**Method** When  $\Delta_r C_p^\ominus$  is independent of temperature in the range  $T_1$  to  $T_2$ , the integral in eqn 2C.7a evaluates to  $(T_2 - T_1)\Delta_r C_p^\ominus$ . Therefore,

$$\Delta_r H^\ominus(T_2) = \Delta_r H^\ominus(T_1) + (T_2 - T_1)\Delta_r C_p^\ominus$$

To proceed, write the chemical equation, identify the stoichiometric coefficients, and calculate  $\Delta_r C_p^\ominus$  from the data.

**Answer** The reaction is  $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$ , so

$$\begin{aligned} \Delta_r C_p^\ominus &= C_{p,m}^\ominus(\text{H}_2\text{O}, \text{g}) - \left\{ C_{p,m}^\ominus(\text{H}_2, \text{g}) + \frac{1}{2} C_{p,m}^\ominus(\text{O}_2, \text{g}) \right\} \\ &= -9.94 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

It then follows that

$$\begin{aligned} \Delta_r H^\ominus(373 \text{ K}) &= -241.82 \text{ kJ mol}^{-1} + (75 \text{ K}) \\ &\quad \times (-9.94 \text{ J K}^{-1} \text{ mol}^{-1}) = -242.6 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test 2C.7** Estimate the standard enthalpy of formation of cyclohexane,  $\text{C}_6\text{H}_{12}(\text{l})$ , at 400 K from the data in Table 2C.6.

Answer:  $-163 \text{ kJ mol}^{-1}$

## 2C.4 Experimental techniques

The classic tool of thermochemistry is the calorimeter, as summarized in Topic 2B. However, technological advances have been made that allow measurements to be made on samples with mass as little as a few milligrams. We describe two of them here.

### (a) Differential scanning calorimetry

A **differential scanning calorimeter** (DSC) measures the energy transferred as heat to or from a sample at constant pressure during a physical or chemical change. The term 'differential' refers to the fact that the behaviour of the sample is compared to that of a reference material that does not undergo a physical or chemical change during the analysis. The term 'scanning' refers to the fact that the temperatures of the sample and reference material are increased, or scanned, during the analysis.

A DSC consists of two small compartments that are heated electrically at a constant rate. The temperature,  $T$ , at time  $t$  during a linear scan is  $T = T_0 + \alpha t$ , where  $T_0$  is the initial temperature

**Figure 2C.3** A differential scanning calorimeter. The sample and a reference material are heated in separate but identical metal heat sinks. The output is the difference in power needed to maintain the heat sinks at equal temperatures as the temperature rises.

and  $\alpha$  is the scan rate. A computer controls the electrical power supply that maintains the same temperature in the sample and reference compartments throughout the analysis (Fig. 2C.3).

If no physical or chemical change occurs in the sample at temperature  $T$ , we write the heat transferred to the sample as  $q_p = C_p \Delta T$ , where  $\Delta T = T - T_0$  and we have assumed that  $C_p$  is independent of temperature. Because  $T = T_0 + \alpha t$ ,  $\Delta T = \alpha t$ . The chemical or physical process requires the transfer of  $q_p + q_{p,\text{ex}}$  where  $q_{p,\text{ex}}$  is the excess energy transferred as heat needed to attain the same change in temperature of the sample as the control. The quantity  $q_{p,\text{ex}}$  is interpreted in terms of an apparent change in the heat capacity at constant pressure of the sample,  $C_{p,\text{ex}}$ , during the temperature scan:

$$C_{p,\text{ex}} = \frac{q_{p,\text{ex}}}{\Delta T} = \frac{q_{p,\text{ex}}}{\alpha t} = \frac{P_{\text{ex}}}{\alpha} \quad (2C.8)$$

where  $P_{\text{ex}} = q_{p,\text{ex}}/t$  is the excess electrical power necessary to equalize the temperature of the sample and reference compartments. A DSC trace, also called a **thermogram**, consists of a plot of  $C_{p,\text{ex}}$  against  $T$  (Fig. 2C.4). The enthalpy change associated with the process is

$$\Delta H = \int_{T_1}^{T_2} C_{p,\text{ex}} dT \quad (2C.9)$$

where  $T_1$  and  $T_2$  are, respectively, the temperatures at which the process begins and ends. This relation shows that the enthalpy change is equal to the area under the plot of  $C_{p,\text{ex}}$  against  $T$ .

The technique is used, for instance, to assess the stability of proteins, nucleic acids, and membranes. The thermogram shown in Fig. 2C.4 indicates that the protein ubiquitin undergoes an endothermic conformational change in which a large number of non-covalent interactions (such as hydrogen bonds) are broken simultaneously and result in denaturation, the loss of the protein's three-dimensional structure. The area under the curve represents the heat absorbed in this process and

**Figure 2C.4** A thermogram for the protein ubiquitin at  $\text{pH} = 2.45$ . The protein retains its native structure up to about  $45^{\circ}\text{C}$  and then undergoes an endothermic conformational change. (Adapted from B. Chowdhry and S. LeHarne, *J. Chem. Educ.* **74**, 236 (1997).)

can be identified with the enthalpy change. The thermogram also reveals the formation of new intermolecular interactions in the denatured form. The increase in heat capacity accompanying the native  $\rightarrow$  denatured transition reflects the change from a more compact native conformation to one in which the more exposed amino acid side chains in the denatured form have more extensive interactions with the surrounding water molecules.

### (b) Isothermal titration calorimetry

**Isothermal titration calorimetry (ITC)** is also a ‘differential’ technique in which the thermal behaviour of a sample is compared with that of a reference. The apparatus is shown in Fig. 2C.5. One of the thermally conducting vessels, which have a volume of a few millilitres ( $10^{-6}\text{m}^3$ ), contains the reference (water for instance) and a heater rated at a few milliwatts. The second vessel contains one of the reagents, such as a solution of a macromolecule with binding sites; it also contains a heater. At the start of the experiment, both heaters are activated, and then precisely determined amounts (of volume of about a microlitre,  $10^{-9}\text{m}^3$ ) of the second reagent are added to the reaction cell. The power required to maintain the same temperature differential with the reference cell is monitored. If the reaction is exothermic, less power is needed; if it is endothermic, then more power must be supplied.

**Figure 2C.5** A schematic diagram of the apparatus used for isothermal titration calorimetry.

**Figure 2C.6** (a) The record of the power applied as each injection is made, and (b) the sum of successive enthalpy changes in the course of the titration.

A typical result is shown in Fig. 2C.6, which shows the power needed to maintain the temperature differential: from the power and the length of time,  $\delta t$ , for which it is supplied, the heat supplied,  $\delta q_i$ , for the injection  $i$  can be calculated from  $\delta q_i = P_i \delta t$ . If the volume of solution is  $V$  and the molar concentration of unreacted reagent A is  $c_i$  at the time of the  $i$ th injection, then the change in its concentration at that injection is  $\delta c_i$  and the heat generated (or absorbed) by the reaction is  $V\Delta_r H \delta c_i = \delta q_i$ . The sum of all such quantities, given that the sum of  $\delta c_i$  is the known initial concentration of the reactant, can then be interpreted as the value of  $\Delta_r H$  for the reaction.

## Checklist of concepts

- 1. The **standard enthalpy of transition** is equal to the energy transferred as heat at constant pressure in the transition.
- 2. A **thermochemical equation** is a chemical equation and its associated change in enthalpy.
- 3. **Hess’s law** states that the standard enthalpy of an overall reaction is the sum of the standard enthalpies of the individual reactions into which a reaction may be divided.

- 4. **Standard enthalpies of formation** are defined in terms of the reference states of elements.
- 5. The **standard reaction enthalpy** is expressed as the difference of the standard enthalpies of formation of products and reactants.
- 6. Computer modelling is used to estimate standard enthalpies of formation.
- 7. The temperature dependence of a reaction enthalpy is expressed by **Kirchhoff's law**.

## Checklist of equations

Property	Equation	Comment	Equation number
The standard reaction enthalpy	$\Delta_r H^\ominus = \sum_{\text{Products}} \nu \Delta_f H^\ominus - \sum_{\text{Reactants}} \nu \Delta_f H^\ominus$ $\Delta_r H^\ominus = \sum_j \nu_j \Delta_f H^\ominus(j)$	$\nu$ : stoichiometric coefficients; $\nu_j$ : (signed) stoichiometric numbers	2C.5
Kirchhoff's law	$\Delta_r H^\ominus(T_2) = \Delta_r H^\ominus(T_1) + \int_{T_1}^{T_2} \Delta_r C_p^\ominus dT$		2C.7a
	$\Delta_r C_{p,m}^\ominus = \sum_j \nu_j C_{p,m}^\ominus(j)$		2C.7c
	$\Delta_r H^\ominus(T_2) = \Delta_r H^\ominus(T_1) + (T_2 - T_1) \Delta_r C_p^\ominus$	If $\Delta_r C_p^\ominus$ independent of temperature

### ► Why do you need to know this material?

Thermodynamics gives us the power to derive relations between a variety of properties: this Topic is a first introduction to the manipulation of equations involving state functions. In the process, we obtain such important relations as that between heat capacities. An important technological consequence is the Joule–Thomson effect for cooling gases, which is derived here.

### ► What is the key idea?

The fact that internal energy and enthalpy are state functions leads to relations between thermodynamic properties.

### ► What do you need to know already?

You need to be aware that internal energy and enthalpy are state functions (Topics 2B and 2C) and be familiar with heat capacity. You need to be able to make use of several simple relations involving partial derivatives (*Mathematical background 2*).

A **state function** is a property that depends only on the current state of a system and is independent of its history. The internal energy and enthalpy are two examples of state functions. Physical quantities that do depend on the path between two states are called **path functions**. Examples of path functions are the work and the heating that are done when preparing a state. We do not speak of a system in a particular state as possessing work or heat. In each case, the energy transferred as work or heat relates to the path being taken between states, not the current state itself.

A part of the richness of thermodynamics is that it uses the mathematical properties of state functions to draw far-reaching conclusions about the relations between physical properties and thereby establish connections that may be completely unexpected. The practical importance of this ability is that we can combine measurements of different properties to obtain the value of a property we require.

## 2D.1 Exact and inexact differentials

Consider a system undergoing the changes depicted in Fig. 2D.1. The initial state of the system is  $i$  and in this state the internal energy is  $U_i$ . Work is done by the system as it expands adiabatically to a state  $f$ . In this state the system has an internal energy  $U_f$  and the work done on the system as it changes along Path 1 from  $i$  to  $f$  is  $w$ . Notice our use of language:  $U$  is a property of the state;  $w$  is a property of the path. Now consider another process, Path 2, in which the initial and final states are the same as those in Path 1 but in which the expansion is not adiabatic. The internal energy of both the initial and the final states are the same as before (because  $U$  is a state function). However, in the second path an energy  $q'$  enters the system as heat and the work  $w'$  is not the same as  $w$ . The work and the heat are path functions.

If a system is taken along a path (for example, by heating it),  $U$  changes from  $U_i$  to  $U_f$  and the overall change is the sum (integral) of all the infinitesimal changes along the path:

$$\Delta U = \int_i^f dU \quad (2D.1)$$

The value of  $\Delta U$  depends on the initial and final states of the system but is independent of the path between them. This path-independence of the integral is expressed by saying that  $dU$

**Figure 2D.1** As the volume and temperature of a system are changed, the internal energy changes. An adiabatic and a non-adiabatic path are shown as Path 1 and Path 2, respectively: they correspond to different values of  $q$  and  $w$  but to the same value of  $\Delta U$ .

is an ‘exact differential’. In general, an **exact differential** is an infinitesimal quantity that, when integrated, gives a result that is independent of the path between the initial and final states.

When a system is heated, the total energy transferred as heat is the sum of all individual contributions at each point of the path:

$$q = \int_{i, \text{path}}^f dq \quad (2D.2)$$

Notice the differences between this equation and eqn 2D.1. First, we do not write  $\Delta q$ , because  $q$  is not a state function and the energy supplied as heat cannot be expressed as  $q_f - q_i$ . Secondly, we must specify the path of integration because  $q$  depends on the path selected (for example, an adiabatic path has  $q=0$ , whereas a non-adiabatic path between the same two states would have  $q \neq 0$ ). This path-dependence is expressed by saying that  $dq$  is an ‘inexact differential’. In general, an **inexact differential** is an infinitesimal quantity that, when integrated, gives a result that depends on the path between the initial and final states. Often  $dq$  is written  $\delta q$  to emphasize that it is inexact and requires the specification of a path.

The work done on a system to change it from one state to another depends on the path taken between the two specified states; for example, in general the work is different if the change takes place adiabatically and non-adiabatically. It follows that  $\delta w$  is an inexact differential. It is often written  $\delta w$ .

### Example 2D.1 Calculating work, heat, and change in internal energy

Consider a perfect gas inside a cylinder fitted with a piston. Let the initial state be  $T, V_i$  and the final state be  $T, V_f$ . The change of state can be brought about in many ways, of which the two

simplest are the following: Path 1, in which there is free expansion against zero external pressure; Path 2, in which there is reversible, isothermal expansion. Calculate  $w$ ,  $q$ , and  $\Delta U$  for each process.

**Method** To find a starting point for a calculation in thermodynamics, it is often a good idea to go back to first principles and to look for a way of expressing the quantity we are asked to calculate in terms of other quantities that are easier to calculate. It is argued in Topic 2B that the internal energy of a perfect gas depends only on the temperature and is independent of the volume those molecules occupy, so for any isothermal change,  $\Delta U=0$ . We also know that in general  $\Delta U=q+w$ . The question depends on being able to combine the two expressions. Topic 2A presents a number of expressions for the work done in a variety of processes, and here we need to select the appropriate ones.

**Answer** Because  $\Delta U=0$  for both paths and  $\Delta U=q+w$ , in each case  $q=-w$ . The work of free expansion is zero (eqn 2A.7 of Topic 2A,  $w=0$ ); so in Path 1,  $w=0$  and therefore  $q=0$  too. For Path 2, the work is given by eqn 2A.9 of Topic 2A ( $w=-nRT \ln(V_f/V_i)$ ) and consequently  $q=nRT \ln(V_f/V_i)$ .

**Self-test 2D.1** Calculate the values of  $q$ ,  $w$ , and  $\Delta U$  for an irreversible isothermal expansion of a perfect gas against a constant nonzero external pressure.

Answer:  $q=p_{\text{ex}}\Delta V$ ,  $w=-p_{\text{ex}}\Delta V$ ,  $\Delta U=0$

## 2D.2 Changes in internal energy

We begin to unfold the consequences of  $dU$  being an exact differential by exploring a closed system of constant composition (the only type of system considered in the rest of this Topic). The internal energy  $U$  can be regarded as a function of  $V$ ,  $T$ , and  $p$ , but, because there is an equation of state (Topic 1A), stating the values of two of the variables fixes the value of the third. Therefore, it is possible to write  $U$  in terms of just two independent variables:  $V$  and  $T$ ,  $p$  and  $T$ , or  $p$  and  $V$ . Expressing  $U$  as a function of volume and temperature fits the purpose of our discussion.

### (a) General considerations

Because the internal energy is a function of the volume and the temperature, when these two quantities change, the internal energy changes by

$$dU = \left( \frac{\partial U}{\partial V} \right)_T dV + \left( \frac{\partial U}{\partial T} \right)_V dT \quad (2D.3)$$

General expression for a change in  $U$  with  $T$  and  $V$

The interpretation of this equation is that, in a closed system of constant composition, any infinitesimal change in the internal

**Figure 2D.2** An overall change in  $U$ , which is denoted  $dU$ , arises when both  $V$  and  $T$  are allowed to change. If second-order infinitesimals are ignored, the overall change is the sum of changes for each variable separately.

energy is proportional to the infinitesimal changes of volume and temperature, the coefficients of proportionality being the two partial derivatives (Fig. 2D.2).

In many cases partial derivatives have a straightforward physical interpretation, and thermodynamics gets shapeless and difficult only when that interpretation is not kept in sight. In the present case, we have already met  $(\partial U/\partial T)_V$  in Topic 2A, where we saw that it is the constant-volume heat capacity,  $C_V$ . The other coefficient,  $(\partial U/\partial V)_T$ , plays a major role in thermodynamics because it is a measure of the variation of the internal energy of a substance as its volume is changed at constant temperature (Fig. 2D.3). We shall denote it  $\pi_T$  and, because it has the same dimensions as pressure but arises from the interactions between the molecules within the sample, call it the **internal pressure**:

$$\pi_T = \left( \frac{\partial U}{\partial V} \right)_T \quad \text{Definition} \quad \text{Internal pressure} \quad (2D.4)$$

**Figure 2D.3** The internal pressure,  $\pi_T$ , is the slope of  $U$  with respect to  $V$  with the temperature  $T$  held constant.

**Figure 2D.4** For a perfect gas, the internal energy is independent of the volume (at constant temperature). If attractions are dominant in a real gas, the internal energy increases with volume because the molecules become farther apart on average. If repulsions are dominant, the internal energy decreases as the gas expands.

In terms of the notation  $C_V$  and  $\pi_T$ , eqn 2D.3 can now be written

$$dU = \pi_T dV + C_V dT \quad (2D.5)$$

When there are no interactions between the molecules, the internal energy is independent of their separation and hence independent of the volume of the sample. Therefore, for a perfect gas we can write  $\pi_T = 0$ . If the gas is described by the van der Waals equation with  $a$ , the parameter corresponding to attractive interactions, dominant, then an increase in volume increases the average separation of the molecules and therefore raises the internal energy. In this case, we expect  $\pi_T > 0$  (Fig. 2D.4).

The statement  $\pi_T = 0$  (that is, the internal energy is independent of the volume occupied by the sample) can be taken to be the definition of a perfect gas, for in Topic 3D we see that it implies the equation of state  $pV \propto T$ .

James Joule thought that he could measure  $\pi_T$  by observing the change in temperature of a gas when it is allowed to expand into a vacuum. He used two metal vessels immersed in a water bath (Fig. 2D.5). One was filled with air at about 22 atm and the other was evacuated. He then tried to measure the change

**Figure 2D.5** A schematic diagram of the apparatus used by Joule in an attempt to measure the change in internal energy when a gas expands isothermally. The heat absorbed by the gas is proportional to the change in temperature of the bath.

in temperature of the water of the bath when a stopcock was opened and the air expanded into a vacuum. He observed no change in temperature.

The thermodynamic implications of the experiment are as follows. No work was done in the expansion into a vacuum, so  $w=0$ . No energy entered or left the system (the gas) as heat because the temperature of the bath did not change, so  $q=0$ . Consequently, within the accuracy of the experiment,  $\Delta U=0$ . Joule concluded that  $U$  does not change when a gas expands isothermally and therefore that  $\pi_T=0$ . His experiment, however, was crude. In particular, the heat capacity of the apparatus was so large that the temperature change that gases do in fact cause was too small to measure. Nevertheless, from his experiment Joule had extracted an essential limiting property of a gas, a property of a perfect gas, without detecting the small deviations characteristic of real gases.

## (b) Changes in internal energy at constant pressure

Partial derivatives have many useful properties and some that we shall draw on frequently are reviewed in *Mathematical background 2*. Skilful use of them can often turn some unfamiliar quantity into a quantity that can be recognized, interpreted, or measured.

As an example, suppose we want to find out how the internal energy varies with temperature when the pressure rather than the volume of the system is kept constant. If we divide both sides of eqn 2D.5 by  $dT$  and impose the condition of constant pressure on the resulting differentials, so that  $dU/dT$  on the left becomes  $(\partial U/\partial T)_p$ , we obtain

$$\left(\frac{\partial U}{\partial T}\right)_p = \pi_T \left(\frac{\partial V}{\partial T}\right)_p + C_V$$

It is usually sensible in thermodynamics to inspect the output of a manipulation like this to see if it contains any recognizable physical quantity. The partial derivative on the right in this expression is the slope of the plot of volume against temperature (at constant pressure). This property is normally tabulated as the **expansion coefficient**,  $\alpha$ , of a substance, which is defined as

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T}\right)_p \quad \text{Definition} \quad \text{Expansion coefficient} \quad (2D.6)$$

and physically is the fractional change in volume that accompanies a rise in temperature. A large value of  $\alpha$  means that the volume of the sample responds strongly to changes in temperature. Table 2D.1 lists some experimental values of  $\alpha$ . For future reference, it also lists the **isothermal compressibility**,  $\kappa_T$  (kappa), which is defined as

**Table 2D.1\*** Expansion coefficients ( $\alpha$ ) and isothermal compressibilities ( $\kappa_T$ ) at 298 K

	$\alpha/(10^{-4} \text{ K}^{-1})$	$\kappa_T/(10^{-6} \text{ bar}^{-1})$
Benzene	12.4	90.9
Diamond	0.030	0.185
Lead	0.861	2.18
Water	2.1	49.0

\* More values are given in the *Resource section*.

$$\kappa_T = -\frac{1}{V} \left(\frac{\partial V}{\partial p}\right)_T \quad \text{Definition} \quad \text{Isothermal compressibility} \quad (2D.7)$$

The isothermal compressibility is a measure of the fractional change in volume when the pressure is increased by a small amount; the negative sign in the definition ensures that the compressibility is a positive quantity, because an increase of pressure, implying a positive  $dp$ , brings about a reduction of volume, a negative  $dV$ .

### Example 2D.2 Calculating the expansion coefficient of a gas

Derive an expression for the expansion coefficient of a perfect gas.

**Method** The expansion coefficient is defined in eqn 2D.6. To use this expression, substitute the expression for  $V$  in terms of  $T$  obtained from the equation of state for the gas. As implied by the subscript in eqn 2D.6, the pressure,  $p$ , is treated as a constant.

**Answer** Because  $pV=nRT$ , we can write

$$\alpha = \frac{1}{V} \left(\frac{\partial(nRT/p)}{\partial T}\right)_p = \frac{1}{V} \times \frac{nR}{p} \frac{dT}{dT} = \frac{nR}{pV} = \frac{1}{T}$$

The higher the temperature, the less responsive is the volume of a perfect gas to a change in temperature.

**Self-test 2D.2** Derive an expression for the isothermal compressibility of a perfect gas.

Answer:  $\kappa_T=1/p$

When we introduce the definition of  $\alpha$  into the equation for  $(\partial U/\partial T)_p$ , we obtain

$$\left(\frac{\partial U}{\partial T}\right)_p = \alpha \pi_T V + C_V \quad (2D.8)$$

This equation is entirely general (provided the system is closed and its composition is constant). It expresses the dependence of the internal energy on the temperature at constant pressure

in terms of  $C_V$ , which can be measured in one experiment, in terms of  $\alpha$ , which can be measured in another, and in terms of the quantity  $\pi_T$ . For a perfect gas,  $\pi_T=0$ , so then

$$\left(\frac{\partial U}{\partial T}\right)_p = C_V \quad (2D.9)$$

That is, although the constant-volume heat capacity of a perfect gas is defined as the slope of a plot of internal energy against temperature at constant volume, for a perfect gas  $C_V$  is also the slope at constant pressure.

Equation 2D.9 provides an easy way to derive the relation between  $C_p$  and  $C_V$  for a perfect gas. Thus, we can use it to express both heat capacities in terms of derivatives at constant pressure:

$$C_p - C_V = \overbrace{\left(\frac{\partial H}{\partial T}\right)_p}^{\text{Definition of } C_p} - \overbrace{\left(\frac{\partial U}{\partial T}\right)_p}^{\text{eqn 2D.9}}$$

Then we introduce  $H = U + pV = U + nRT$  into the first term, which results in

$$C_p - C_V = \left(\frac{\partial(U + nRT)}{\partial T}\right)_p - \left(\frac{\partial U}{\partial T}\right)_p = nR \quad (2D.10)$$

We show in the following *Justification* that in general

$$C_p - C_V = \frac{\alpha^2 TV}{\kappa_T} \quad (2D.11)$$

Equation 2D.11 applies to any substance (that is, it is ‘universally true’). It reduces to eqn 2D.10 for a perfect gas when we set  $\alpha = 1/T$  and  $\kappa_T = 1/p$ . Because expansion coefficients  $\alpha$  of liquids and solids are small, it is tempting to deduce from eqn 2D.11 that for them  $C_p \approx C_V$ . But this is not always so, because the compressibility  $\kappa_T$  might also be small, so  $\alpha^2/\kappa_T$  might be large. That is, although only a little work need be done to push back the atmosphere, a great deal of work may have to be done to pull atoms apart from one another as the solid expands.

#### Brief illustration 2D.1 The relation between heat capacities

The expansion coefficient and isothermal compressibility of water at 25 °C are given in Table 2D.1 as  $2.1 \times 10^{-4} \text{ K}^{-1}$  and  $4.96 \times 10^{-5} \text{ atm}^{-1}$  ( $4.90 \times 10^{-10} \text{ Pa}^{-1}$ ), respectively. The molar volume of water at that temperature,  $V_m = M/\rho$  (where  $\rho$  is the mass density) is  $18.1 \text{ cm}^3 \text{ mol}^{-1}$  ( $1.81 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}$ ). Therefore, from eqn 2D.11, the difference in molar heat capacities (which is given by  $V_m$  in place of  $V$ ) is

$$\begin{aligned} C_{p,m} - C_{V,m} &= \frac{(2.1 \times 10^{-4} \text{ K}^{-1})^2 \times (298 \text{ K}) \times (1.81 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1})}{4.90 \times 10^{-10} \text{ Pa}^{-1}} \\ &= 0.485 \text{ Pa m}^3 \text{ mol}^{-1} = 0.485 \text{ J mol}^{-1} \end{aligned}$$

For water,  $C_{p,m} = 75.3 \text{ J K}^{-1} \text{ mol}^{-1}$ , so  $C_{V,m} = 74.8 \text{ J K}^{-1} \text{ mol}^{-1}$ . In some cases, the two heat capacities differ by as much as 30 per cent.

**Self-test 2D.3** Evaluate the difference in molar heat capacities for benzene; use data from the *Resource section*.

Answer:  $45 \text{ J K}^{-1} \text{ mol}^{-1}$

#### Justification 2D.1 The relation between heat capacities

A useful rule when doing a problem in thermodynamics is to go back to first principles. In the present problem we do this twice, first by expressing  $C_p$  and  $C_V$  in terms of their definitions and then by inserting the definition  $H = U + pV$ :

$$\begin{aligned} C_p - C_V &= \left(\frac{\partial H}{\partial T}\right)_p - C_V \\ &= \left(\frac{\partial U}{\partial T}\right)_p + \left(\frac{\partial(pV)}{\partial T}\right)_p - C_V \end{aligned}$$

Equation 2D.8,  $(\partial U/\partial T)_p = \alpha\pi_T V + C_V$ , lets us write the difference of the first and third terms as  $\alpha\pi_T V$ . We can simplify the remaining term by noting that, because  $p$  is constant,

$$\left(\frac{\partial(pV)}{\partial T}\right)_p = p \left(\frac{\partial V}{\partial T}\right)_p = \alpha p V$$

Collecting the two contributions gives

$$C_p - C_V = \alpha(p + \pi_T)V$$

The first term on the right,  $\alpha p V$ , is a measure of the work needed to push back the atmosphere; the second term on the right,  $\alpha\pi_T V$ , is the work required to separate the molecules composing the system.

At this point we can go further by using the (Second Law) result proved in Topic 3D that

$$\pi_T = T \left(\frac{\partial p}{\partial T}\right)_V - p$$

When this expression is inserted in the last equation we obtain

$$C_p - C_V = \alpha TV \left(\frac{\partial p}{\partial T}\right)_V$$

We now transform the remaining partial derivative. With  $V$  regarded as a function of  $p$  and  $T$ , when these two quantities change the resulting change in  $V$  is

$$dV = \left(\frac{\partial V}{\partial T}\right)_p dT + \left(\frac{\partial V}{\partial p}\right)_T dp$$

For the volume to be constant,  $dV=0$  implies that

$$\left(\frac{\partial V}{\partial T}\right)_p dT = -\left(\frac{\partial V}{\partial p}\right)_T dp \text{ at constant volume}$$

On division by  $dT$ , this relation becomes

$$\left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial V}{\partial p}\right)_T \left(\frac{\partial p}{\partial T}\right)_V$$

and therefore

$$\left(\frac{\partial p}{\partial T}\right)_V = -\frac{(\partial V/\partial T)_p}{(\partial V/\partial p)_T} = \frac{\alpha}{\kappa_T}$$

Insertion of this relation into the expression above for  $C_p - C_V$  produces eqn 2D.11.

### 2D.3 The Joule–Thomson effect

We can carry out a similar set of operations on the enthalpy,  $H=U+pV$ . The quantities  $U$ ,  $p$ , and  $V$  are all state functions; therefore  $H$  is also a state function and  $dH$  is an exact differential. It turns out that  $H$  is a useful thermodynamic function when the pressure is under our control: we saw a sign of that in the relation  $\Delta H=q_p$  (this is eqn 2B.2b of Topic 2B). We shall therefore regard  $H$  as a function of  $p$  and  $T$ , and adapt the argument in Section 2D.2 for the variation of  $U$  to find an expression for the variation of  $H$  with temperature at constant volume. As explained in the following *Justification*, we find that for a closed system of constant composition,

$$dH = -\mu C_p dp + C_p dT \quad (2D.12)$$

where the **Joule–Thomson coefficient**,  $\mu$  (mu), is defined as

$$\mu = \left(\frac{\partial T}{\partial p}\right)_H \quad \text{Definition } \text{Joule–Thomson coefficient} \quad (2D.13)$$

This relation will prove useful for relating the heat capacities at constant pressure and volume and for a discussion of the liquefaction of gases.

#### Justification 2D.2 The variation of enthalpy with pressure and temperature

Because  $H$  is a function of  $p$  and  $T$  we can write, when these two quantities change by an infinitesimal amount, the enthalpy changes by

$$dH = \left(\frac{\partial H}{\partial p}\right)_T dp + \left(\frac{\partial H}{\partial T}\right)_p dT$$

The second partial derivative is  $C_p$ ; our task here is to express  $(\partial H/\partial p)_T$  in terms of recognizable quantities. If the enthalpy is constant,  $dH=0$  and this expression then requires that

$$\left(\frac{\partial H}{\partial p}\right)_T dp = -C_p dT \text{ at constant } H$$

Division of both sides by  $dp$  then gives

$$\left(\frac{\partial H}{\partial p}\right)_T = -C_p \left(\frac{\partial T}{\partial p}\right)_H = -C_p \mu$$

Equation 2D.13 now follows directly.

#### (a) Observation of the Joule–Thomson effect

The analysis of the Joule–Thomson coefficient is central to the technological problems associated with the liquefaction of gases. We need to be able to interpret it physically and to measure it. As shown in the following *Justification*, the cunning required to impose the constraint of constant enthalpy, so that the process is **isenthalpic**, was supplied by Joule and William Thomson (later Lord Kelvin). They let a gas expand through a porous barrier from one constant pressure to another and monitored the difference of temperature that arose from the expansion (Fig. 2D.6). The whole apparatus was insulated so that the process was adiabatic. They observed a lower temperature on the low pressure side, the difference in temperature being proportional to the pressure difference they maintained.

**Figure 2D.6** The apparatus used for measuring the Joule–Thomson effect. The gas expands through the porous barrier, which acts as a throttle, and the whole apparatus is thermally insulated. As explained in the text, this arrangement corresponds to an isenthalpic expansion (expansion at constant enthalpy). Whether the expansion results in a heating or a cooling of the gas depends on the conditions.

This cooling by isenthalpic expansion is now called the **Joule–Thomson effect**.

### Justification 2D.3 The Joule–Thomson effect

Here we show that the experimental arrangement results in expansion at constant enthalpy. Because all changes to the gas occur adiabatically,  $q=0$  implies that  $\Delta U=w$ . Next, consider the work done as the gas passes through the barrier. We focus on the passage of a fixed amount of gas from the high pressure side, where the pressure is  $p_i$ , the temperature  $T_i$ , and the gas occupies a volume  $V_i$  (Fig. 2D.7).

**Figure 2D.7** The thermodynamic basis of Joule–Thomson expansion. The pistons represent the upstream and downstream gases, which maintain constant pressures either side of the throttle. The transition from the top diagram to the bottom diagram, which represents the passage of a given amount of gas through the throttle, occurs without change of enthalpy.

The gas emerges on the low pressure side, where the same amount of gas has a pressure  $p_f$ , a temperature  $T_f$ , and occupies a volume  $V_f$ . The gas on the left is compressed isothermally by the upstream gas acting as a piston. The relevant pressure is  $p_i$  and the volume changes from  $V_i$  to 0; therefore, the work done on the gas is

$$w_1 = -p_i(0 - V_i) = p_i V_i$$

The gas expands isothermally on the right of the barrier (but possibly at a different constant temperature) against the pressure  $p_f$  provided by the downstream gas acting as a piston to be driven out. The volume changes from 0 to  $V_f$ , so the work done on the gas in this stage is

$$w_2 = -p_f(V_f - 0) = -p_f V_f$$

The total work done on the gas is the sum of these two quantities, or

$$w_1 + w_2 = p_i V_i - p_f V_f$$

It follows that the change of internal energy of the gas as it moves adiabatically from one side of the barrier to the other is

$$U_f - U_i = w = p_i V_i - p_f V_f$$

Reorganization of this expression gives

$$U_f + p_f V_f = U_i + p_i V_i \quad \text{or} \quad H_f = H_i$$

Therefore, the expansion occurs without change of enthalpy.

The property measured in the experiment is the ratio of the temperature change to the change of pressure,  $\Delta T/\Delta p$ . Adding the constraint of constant enthalpy and taking the limit of small  $\Delta p$  implies that the thermodynamic quantity measured is  $(\partial T/\partial p)_H$ , which is the Joule–Thomson coefficient,  $\mu$ . In other words, the physical interpretation of  $\mu$  is that it is the ratio of the change in temperature to the change in pressure when a gas expands under conditions that ensure there is no change in enthalpy.

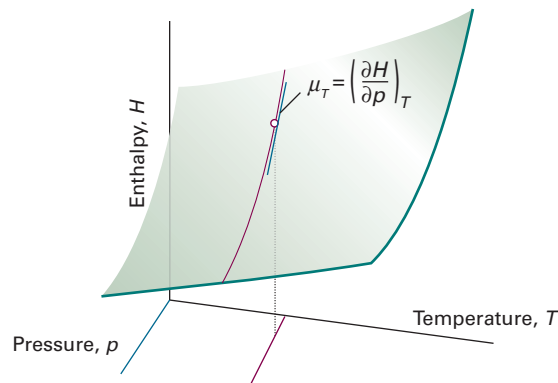

The modern method of measuring  $\mu$  is indirect, and involves measuring the **isothermal Joule–Thomson coefficient**, the quantity

$$\mu_T = \left( \frac{\partial H}{\partial p} \right)_T \quad \text{Definition} \quad \text{Isothermal Joule–Thomson coefficient} \quad (2D.14)$$

which is the slope of a plot of enthalpy against pressure at constant temperature (Fig. 2D.8). Comparing eqns 2D.13 and 2D.14, we see (from the last line of *Justification 2D.2*) that the two coefficients are related by:

$$\mu_T = -C_p \mu \quad (2D.15)$$

To measure  $\mu_T$ , the gas is pumped continuously at a steady pressure through a heat exchanger, which brings it to the required temperature, and then through a porous plug inside a thermally insulated container. The steep pressure drop is measured and the cooling effect is exactly offset by an electric heater placed immediately after the plug (Fig. 2D.9). The energy provided

**Figure 2D.8** The isothermal Joule–Thomson coefficient is the slope of the enthalpy with respect to changing pressure, the temperature being held constant.

**Figure 2D.9** A schematic diagram of the apparatus used for measuring the isothermal Joule–Thomson coefficient. The electrical heating required to offset the cooling arising from expansion is interpreted as  $\Delta H$  and used to calculate  $(\partial H/\partial p)_T$ , which is then converted to  $\mu$  as explained in the text.

**Table 2D.2\*** Inversion temperatures ( $T_i$ ), normal freezing ( $T_f$ ) and boiling ( $T_b$ ) points, and Joule–Thomson coefficients ( $\mu$ ) at 1 atm and 298 K

	$T_i$ /K	$T_f$ /K	$T_b$ /K	$\mu$ /(K bar <sup>-1</sup> )
Ar	723	83.8	87.3	
CO <sub>2</sub>	1500	194.7	+1.10	
He	40	4.2	-0.060	
N <sub>2</sub>	621	63.3	77.4	+0.25

\* More values are given in the *Resource section*.

by the heater is monitored. Because  $\Delta H = q_p$ , the energy transferred as heat can be identified with the value of  $\Delta H$ . The pressure change  $\Delta p$  is known, so we can find  $\mu_T$  from the limiting value of  $\Delta H/\Delta p$  as  $\Delta p \rightarrow 0$  and then convert it to  $\mu$ . Table 2D.2 lists some values obtained in this way.

Real gases have nonzero Joule–Thomson coefficients. Depending on the identity of the gas, the pressure, the relative magnitudes of the attractive and repulsive intermolecular forces, and the temperature, the sign of the coefficient may be either positive or negative (Fig. 2D.10). A positive sign implies that  $dT$  is negative when  $dp$  is negative, in which case the gas cools on expansion. Gases that show a heating effect ( $\mu < 0$ ) at one temperature show a cooling effect ( $\mu > 0$ ) when the temperature is below their upper **inversion temperature**,  $T_1$  (Table 2D.2, Fig. 2D.11). As indicated in Fig. 2D.11, a gas typically has two inversion temperatures.

#### Brief illustration 2D.2 The Joule–Thomson effect

The Joule–Thomson coefficient for nitrogen at 298 K and 1 atm (Table 2D.2) is  $+0.25 \text{ K bar}^{-1}$ . It follows that the change in temperature the gas undergoes when its pressure changes by  $-10$  bar under isenthalpic conditions is

$$\Delta T \approx \mu \Delta p = +(0.25 \text{ K bar}^{-1}) \times (-10 \text{ bar}) = -2.5 \text{ K}$$

At the same initial temperature and pressure, the molar isothermal Joule coefficient is

$$\begin{aligned} \mu_{T,m} &= -C_{p,m} \mu = -(29.1 \text{ J K}^{-1} \text{ mol}^{-1}) \times (+0.25 \text{ K bar}^{-1}) \\ &= -7.3 \text{ J bar}^{-1} \text{ mol}^{-1} \end{aligned}$$

Note that  $\mu$  is an intensive property but  $\mu_T$  is extensive (but  $\mu_{T,m}$ , like all molar quantities, is intensive).

**Self-test 2D.4** Evaluate the change in temperature when the pressure of carbon dioxide changes isenthalpically by  $-10$  bar at 300 K and evaluate its molar isothermal Joule coefficient.

Answer:  $-11 \text{ K}$ ,  $41.2 \text{ J bar}^{-1} \text{ mol}^{-1}$

**Figure 2D.10** The sign of the Joule–Thomson coefficient,  $\mu$ , depends on the conditions. Inside the boundary, the blue area, it is positive and outside it is negative. The temperature corresponding to the boundary at a given pressure is the ‘inversion temperature’ of the gas at that pressure. For a given pressure, the temperature must be below a certain value if cooling is required but, if it becomes too low, the boundary is crossed again and heating occurs. Reduction of pressure under adiabatic conditions moves the system along one of the isenthalps, or curves of constant enthalpy. The inversion temperature curve runs through the points of the isenthalps where their slope changes from negative to positive.

The ‘Linde refrigerator’ makes use of Joule–Thomson expansion to liquefy gases (Fig. 2D.12). The gas at high pressure is allowed to expand through a throttle; it cools and is circulated past the incoming gas. That gas is cooled, and its subsequent expansion cools it still further. There comes a stage when the circulating gas becomes so cold that it condenses to a liquid.

For a perfect gas,  $\mu = 0$ ; hence, the temperature of a perfect gas is unchanged by Joule–Thomson expansion. (Simple adiabatic expansion does cool a perfect gas, because the gas does work, Topic 2E.) This characteristic points clearly to the involvement of intermolecular forces in determining the size of the effect. However, the Joule–Thomson coefficient of a real gas

Figure 2D.11 The inversion temperatures for three real gases, nitrogen, hydrogen, and helium.

Figure 2D.12 The principle of the Linde refrigerator is shown in this diagram. The gas is recirculated, and so long as it is beneath its inversion temperature it cools on expansion through the throttle. The cooled gas cools the high-pressure gas, which cools still further as it expands. Eventually liquefied gas drips from the throttle.

does not necessarily approach zero as the pressure is reduced even though the equation of state of the gas approaches that of a perfect gas. The coefficient behaves like the properties discussed in Topic 1C in the sense that it depends on derivatives and not on  $p$ ,  $V$ , and  $T$  themselves.

## (b) The molecular interpretation of the Joule–Thomson effect

The kinetic model of gases (Topic 1B) and the equipartition theorem (*Foundations B*) jointly imply that the mean kinetic energy of molecules in a gas is proportional to the temperature. It follows that reducing the average speed of the molecules is equivalent to cooling the gas. If the speed of the molecules can be reduced to the point that neighbours can capture each other by their intermolecular attractions, then the cooled gas will condense to a liquid.

To slow the gas molecules, we make use of an effect similar to that seen when a ball is thrown into the air: as it rises it slows in response to the gravitational attraction of the Earth and its kinetic energy is converted into potential energy. We saw in Topic 1C that molecules in a real gas attract each other (the attraction is not gravitational, but the effect is the same). It follows that, if we can cause the molecules to move apart from each other, like a ball rising from a planet, then they should slow. It is very easy to move molecules apart from each other: we simply allow the gas to expand, which increases the average separation of the molecules. To cool a gas, therefore, we allow it to expand without allowing any energy to enter from outside as heat. As the gas expands, the molecules move apart to fill the available volume, struggling as they do so against the attraction of their neighbours. Because some kinetic energy must be converted into potential energy to reach greater separations, the molecules travel more slowly as their separation increases. This sequence of molecular events explains the Joule–Thomson effect: the cooling of a real gas by adiabatic expansion. The cooling effect, which corresponds to  $\mu > 0$ , is observed under conditions when attractive interactions are dominant ( $Z < 1$ , where  $Z$  is the compression factor defined in eqn 1C.1,  $Z = V_m/V_m^\circ$ ), because the molecules have to climb apart against the attractive force in order for them to travel more slowly. For molecules under conditions when repulsions are dominant ( $Z > 1$ ), the Joule–Thomson effect results in the gas becoming warmer, or  $\mu < 0$ .

## Checklist of concepts

1. The quantity  $dU$  is an exact differential;  $dw$  and  $dq$  are not.
2. The change in internal energy may be expressed in terms of changes in temperature and pressure.
3. The **internal pressure** is the variation of internal energy with volume at constant temperature.
4. **Joule's experiment** showed that the internal pressure of a perfect gas is zero.
5. The change in internal energy with pressure and temperature is expressed in terms of the internal pressure and the heat capacity and leads to a general expression for the relation between heat capacities.
6. The **Joule–Thomson effect** is the change in temperature of a gas when it undergoes isenthalpic expansion.

#### ► Why do you need to know this material?

Adiabatic processes complement isothermal processes, and are used in the discussion of the Second Law of thermodynamics.

#### ► What is the key idea?

The temperature of a perfect gas falls when it does work in an adiabatic expansion.

#### ► What do you need to know already?

This Topic makes use of the discussion of the properties of gases (Topic 1A), particularly the perfect gas law. It also uses the definitions of heat capacity at constant volume (Topic 1B) and constant pressure (Topic 2B), and the relation between them (Topic 2D).

The temperature falls when a gas expands adiabatically (in a thermally insulated container). Work is done, but as no heat enters the system, the internal energy falls, and therefore the temperature of the working gas also falls. In molecular terms, the kinetic energy of the molecules falls as work is done, so their average speed decreases, and hence the temperature falls too.

### 2E.1 The change in temperature

To calculate the change in temperature that results from a process we focus first on the change in internal energy. The change in internal energy of a perfect gas when the temperature is changed from  $T_i$  to  $T_f$  and the volume is changed from  $V_i$  to  $V_f$  can be expressed as the sum of two steps (Fig. 2E.1). In the first step, only the volume changes and the temperature is held constant at its initial value. However, because the internal

**Figure 2E.1** To achieve a change of state from one temperature and volume to another temperature and volume, we may consider the overall change as composed of two steps. In the first step, the system expands at constant temperature; there is no change in internal energy if the system consists of a perfect gas. In the second step, the temperature of the system is reduced at constant volume. The overall change in internal energy is the sum of the changes for the two steps.

energy of a perfect gas is independent of the volume the molecules occupy (Topic 2A), the overall change in internal energy arises solely from the second step, the change in temperature at constant volume. Provided the heat capacity is independent of temperature, this change is

$$\Delta U = (T_f - T_i)C_V = C_V \Delta T$$

Because the expansion is adiabatic, we know that  $q=0$ ; then because  $\Delta U = q + w$ , it follows that  $\Delta U = w_{\text{ad}}$ . The subscript 'ad' denotes an adiabatic process. Therefore, by equating the two expressions for  $\Delta U$ , we obtain

$$w_{\text{ad}} = C_V \Delta T \quad \text{Perfect gas} \quad \text{Work of adiabatic change} \quad (2E.1)$$

That is, the work done during an adiabatic expansion of a perfect gas is proportional to the temperature difference between the initial and final states. That is exactly what we expect on molecular grounds, because the mean kinetic energy is proportional to  $T$ , so a change in internal energy arising from temperature alone is also expected to be proportional to  $\Delta T$ .

In the following *Justification* we show that, based on this result, the initial and final temperatures of a perfect gas that undergoes reversible adiabatic expansion (reversible expansion in a thermally insulated container) can be calculated from

$$T_f = T_i \left( \frac{V_i}{V_f} \right)^{1/c} \quad c = C_{V,m}/R \quad \text{Adiabatic, reversible, perfect gas} \quad \text{Final temperature} \quad (2E.2a)$$

By raising each side of this expression to the power  $c$ , an equivalent expression is

$$V_i T_i^c = V_f T_f^c \quad c = C_{V,m}/R \quad \begin{array}{l} \text{Adiabatic,} \\ \text{reversible,} \\ \text{perfect} \\ \text{gas} \end{array} \quad \begin{array}{l} \text{Final} \\ \text{tempera-} \\ \text{ture} \end{array} \quad (2E.2b)$$

This result is often summarized in the form  $VT^c = \text{constant}$ .

### Brief illustration 2E.1 The change in temperature

Consider the adiabatic, reversible expansion of 0.020 mol Ar, initially at 25 °C, from 0.50 dm<sup>3</sup> to 1.00 dm<sup>3</sup>. The molar heat capacity of argon at constant volume is 12.47 J K<sup>-1</sup> mol<sup>-1</sup>, so  $c = 1.501$ . Therefore, from eqn 2B.2a,

$$T_f = (298 \text{ K}) \left( \frac{0.50 \text{ dm}^3}{1.00 \text{ dm}^3} \right)^{1/1.501} = 188 \text{ K}$$

It follows that  $\Delta T = -110 \text{ K}$ , and therefore, from eqn 2E.1, that

$$w = \{(0.020 \text{ mol}) \times (12.47 \text{ J K}^{-1} \text{ mol}^{-1})\} \times (-110 \text{ K}) = -27 \text{ J}$$

Note that temperature change is independent of the amount of gas but the work is not.

**Self-test 2E.1** Calculate the final temperature, the work done, and the change of internal energy when ammonia is used in a reversible adiabatic expansion from 0.50 dm<sup>3</sup> to 2.00 dm<sup>3</sup>, the other initial conditions being the same.

Answer: 194 K, -56 J, -56 J

### Justification 2E.1 Changes in temperature

Consider a stage in a reversible adiabatic expansion when the pressure inside and out is  $p$ . The work done when the gas expands by  $dV$  is  $dw = -pdV$ ; however, for a perfect gas,  $dU = C_V dT$ . Therefore, because for an adiabatic change ( $dq = 0$ )  $dU = dw + dq = dw$ , we can equate these two expressions for  $dU$  and write

$$C_V dT = -pdV$$

We are dealing with a perfect gas, so we can replace  $p$  by  $nRT/V$  and obtain

$$\frac{C_V dT}{T} = -\frac{nR dV}{V}$$

To integrate this expression we note that  $T$  is equal to  $T_i$  when  $V$  is equal to  $V_i$ , and is equal to  $T_f$  when  $V$  is equal to  $V_f$  at the end of the expansion. Therefore,

$$C_V \int_{T_i}^{T_f} \frac{dT}{T} = -nR \int_{V_i}^{V_f} \frac{dV}{V}$$

(We are taking  $C_V$  to be independent of temperature.) Then, because  $\int dx/x = \ln x + \text{constant}$ , we obtain

$$C_V \ln \frac{T_f}{T_i} = -nR \ln \frac{V_f}{V_i}$$

Because  $\ln(x/y) = -\ln(y/x)$ , this expression rearranges to

$$\frac{C_V}{nR} \ln \frac{T_f}{T_i} = \ln \frac{V_i}{V_f}$$

With  $c = C_V/nR$  we obtain (because  $\ln x^a = a \ln x$ )

$$\ln \left( \frac{T_f}{T_i} \right)^c = \ln \frac{V_i}{V_f}$$

which implies that  $(T_f/T_i)^c = (V_i/V_f)$  and, upon rearrangement, eqn 2E.2.

## 2E.2 The change in pressure

We show in the following *Justification* that the pressure of a perfect gas that undergoes reversible adiabatic expansion from a volume  $V_i$  to a volume  $V_f$  is related to its initial pressure by

$$p_f V_f^\gamma = p_i V_i^\gamma \quad \begin{array}{l} \text{Perfect gas} \\ \text{Reversible adiabatic} \\ \text{expansion} \end{array} \quad (2E.3)$$

where  $\gamma = C_{p,m}/C_{V,m}$ . This result is commonly summarized in the form  $pV^\gamma = \text{constant}$ .

### Justification 2E.2 The relation between pressure and volume

The initial and final states of a perfect gas satisfy the perfect gas law regardless of how the change of state takes place, so we can use  $pV = nRT$  to write

$$\frac{p_i V_i}{p_f V_f} = \frac{T_i}{T_f}$$

However, from eqn 2E.2 we know that  $T_i/T_f = (V_f/V_i)^{1/c}$ . Therefore,

$$\frac{p_i V_i}{p_f V_f} = \left( \frac{V_f}{V_i} \right)^{1/c}, \text{ so } \frac{p_i}{p_f} \left( \frac{V_i}{V_f} \right)^{1/c+1} = 1$$

We now use the result from Topic 2B that  $C_{p,m} - C_{V,m} = R$  to note that

$$\frac{1}{c} + 1 = \frac{1+c}{c} = \frac{R+C_{V,m}}{C_{V,m}} = \frac{C_{p,m}}{C_{V,m}} = \gamma$$

It follows that

$$\frac{p_i}{p_f} \left( \frac{V_i}{V_f} \right)^\gamma = 1$$

which rearranges to eqn 2E.3.

For a monatomic perfect gas,  $C_{V,m} = \frac{3}{2}R$  (Topic 2A) and  $C_{p,m} = \frac{5}{2}R$  (from  $C_{p,m} - C_{V,m} = R$ ), so  $\gamma = \frac{5}{3}$ . For a gas of nonlinear polyatomic molecules (which can rotate as well as translate; vibrations make little contribution at normal temperatures),  $C_{V,m} = 3R$  and  $C_{p,m} = 4R$ , so  $\gamma = \frac{4}{3}$ . The curves of pressure versus volume for adiabatic change are known as **adiabats**, and one for a reversible path is illustrated in Fig. 2E.2. Because  $\gamma > 1$ ,

**Figure 2E.2** An adiabat depicts the variation of pressure with volume when a gas expands adiabatically. Note that the pressure declines more steeply for an adiabat than it does for an isotherm because the temperature decreases in the former.

an adiabat falls more steeply ( $p \propto 1/V^\gamma$ ) than the corresponding isotherm ( $p \propto 1/V$ ). The physical reason for the difference is that, in an isothermal expansion, energy flows into the system as heat and maintains the temperature; as a result, the pressure does not fall as much as in an adiabatic expansion.

### Brief illustration 2E.2 Adiabatic expansion

When a sample of argon (for which  $\gamma = \frac{5}{3}$ ) at 100 kPa expands reversibly and adiabatically to twice its initial volume the final pressure will be

$$p_f = \left( \frac{V_i}{V_f} \right)^\gamma p_i = \left( \frac{1}{2} \right)^{5/3} \times (100 \text{ kPa}) = 32 \text{ kPa}$$

For an isothermal doubling of volume, the final pressure would be 50 kPa.

**Self-test 2E.2** What is the final pressure when a sample of carbon dioxide at 100 kPa expands reversibly and adiabatically to five times its initial volume?

Answer: 13 kPa

## Checklist of concepts

- 1. The temperature of a gas falls when it undergoes adiabatic expansion (and does work).
- 2. An **adiabat** is a curve showing how pressure varies with volume in an adiabatic process.

## Checklist of equations

Property	Equation	Comment	Equation number
Work of adiabatic expansion	$w_{\text{ad}} = C_V \Delta T$	Perfect gas	2E.1
Final temperature	$T_f = T_i (V_i/V_f)^{1/c}$ $c = C_{V,m}/R$	Perfect gas, reversible expansion	2E.2a
	$V_i T_i^c = V_f T_f^c$		2E.2b
Adiabats	$p_f V_f^\gamma = p_i V_i^\gamma$ , $\gamma = C_{p,m}/C_{V,m}$		2E.3

# CHAPTER 2 The First Law

Assume all gases are perfect unless stated otherwise. Unless otherwise stated, thermochemical data are for 298.15 K.

## TOPIC 2A Internal energy

### Discussion questions

**2A.1** Describe and distinguish the various uses of the words 'system' and 'state' in physical chemistry.

**2A.2** Describe the distinction between heat and work in thermodynamic and molecular terms, the latter in terms of populations and energy levels.

**2A.3** Identify varieties of additional work.

### Exercises

**2A.1(a)** Use the equipartition theorem to estimate the molar internal energy relative to  $U(0)$  of (i)  $I_2$ , (ii)  $CH_4$ , (iii)  $C_6H_6$  in the gas phase at 25 °C.

**2A.1(b)** Use the equipartition theorem to estimate the molar internal energy relative to  $U(0)$  of (i)  $O_3$ , (ii)  $C_2H_6$ , (iii)  $SO_2$  in the gas phase at 25 °C.

**2A.2(a)** Which of (i) pressure, (ii) temperature, (iii) work, (iv) enthalpy are state functions?

**2A.2(b)** Which of (i) volume, (ii) heat, (iii) internal energy, (iv) density are state functions?

**2A.3(a)** A chemical reaction takes place in a container of cross-sectional area 50 cm<sup>2</sup>. As a result of the reaction, a piston is pushed out through 15 cm against an external pressure of 1.0 atm. Calculate the work done by the system.

**2A.3(b)** A chemical reaction takes place in a container of cross-sectional area 75.0 cm<sup>2</sup>. As a result of the reaction, a piston is pushed out through 25.0 cm against an external pressure of 150 kPa. Calculate the work done by the system.

**2A.4(a)** A sample consisting of 1.00 mol Ar is expanded isothermally at 20 °C from 10.0 dm<sup>3</sup> to 30.0 dm<sup>3</sup> (i) reversibly, (ii) against a constant external pressure equal to the final pressure of the gas, and (iii) freely (against zero external pressure). For the three processes calculate  $q$ ,  $w$ , and  $\Delta U$ .

**2A.4(b)** A sample consisting of 2.00 mol He is expanded isothermally at 0 °C from 5.0 dm<sup>3</sup> to 20.0 dm<sup>3</sup> (i) reversibly, (ii) against a constant external pressure equal to the final pressure of the gas, and (iii) freely (against zero external pressure). For the three processes calculate  $q$ ,  $w$ , and  $\Delta U$ .

**2A.5(a)** A sample consisting of 1.00 mol of perfect gas atoms, for which  $C_{V,m} = \frac{3}{2}R$ , initially at  $p_1 = 1.00$  atm and  $T_1 = 300$  K, is heated reversibly to 400 K at constant volume. Calculate the final pressure,  $\Delta U$ ,  $q$ , and  $w$ .

**2A.5(b)** A sample consisting of 2.00 mol of perfect gas molecules, for which  $C_{V,m} = \frac{5}{2}R$ , initially at  $p_1 = 111$  kPa and  $T_1 = 277$  K, is heated reversibly to 356 K at constant volume. Calculate the final pressure,  $\Delta U$ ,  $q$ , and  $w$ .

**2A.6(a)** A sample of 4.50 g of methane occupies 12.7 dm<sup>3</sup> at 310 K. (i) Calculate the work done when the gas expands isothermally against a constant external pressure of 200 Torr until its volume has increased by 3.3 dm<sup>3</sup>. (ii) Calculate the work that would be done if the same expansion occurred reversibly.

**2A.6(b)** A sample of argon of mass 6.56 g occupies 18.5 dm<sup>3</sup> at 305 K. (i) Calculate the work done when the gas expands isothermally against a constant external pressure of 7.7 kPa until its volume has increased by 2.5 dm<sup>3</sup>. (ii) Calculate the work that would be done if the same expansion occurred reversibly.

### Problems

**2A.1** Calculate the work done during the isothermal reversible expansion of a van der Waals gas (Topic 1C). Plot on the same graph the indicator diagrams (graphs of pressure against volume) for the isothermal reversible expansion of (a) a perfect gas, (b) a van der Waals gas in which  $a=0$  and  $b=5.11 \times 10^{-2}$  dm<sup>3</sup> mol<sup>-1</sup>, and (c)  $a=4.2$  dm<sup>6</sup> atm mol<sup>-2</sup> and  $b=0$ . The values selected exaggerate the imperfections but give rise to significant effects on the indicator diagrams. Take  $V_i = 1.0$  dm<sup>3</sup>,  $n = 1.0$  mol, and  $T = 298$  K.

**2A.2** A sample consisting of 1.0 mol  $CaCO_3(s)$  was heated to 800 °C, when it decomposed. The heating was carried out in a container fitted with a piston that was initially resting on the solid. Calculate the work done during complete decomposition at 1.0 atm. What work would be done if instead of having a piston the container was open to the atmosphere?

**2A.3** Calculate the work done during the isothermal reversible expansion of a gas that satisfies the virial equation of state, eqn 1C.3. Evaluate (a) the work

for 1.0 mol Ar at 273 K (for data, see Table 1C.1) and (b) the same amount of a perfect gas. Let the expansion be from 500 cm<sup>3</sup> to 1000 cm<sup>3</sup> in each case.

**2A.4** Express the work of isothermal reversible expansion of a van der Waals gas in reduced variables (Topic 1C) and find a definition of reduced work that makes the overall expression independent of the identity of the gas. Calculate the work of isothermal reversible expansion along the critical isotherm from  $V_c$  to  $xV_c$ .

**2A.5** Suppose that a DNA molecule resists being extended from an equilibrium, more compact conformation with a restoring force  $F = -k_f x$ , where  $x$  is the difference in the end-to-end distance of the chain from an equilibrium value and  $k_f$  is the force constant. Use this model to write an expression for the work that must be done to extend a DNA molecule by a distance  $x$ . Draw a graph of your conclusion.

**2A.6** A better model of a DNA molecule is the 'one-dimensional freely jointed chain', in which a rigid unit of length  $l$  can only make an angle of  $0^\circ$  or  $180^\circ$  with an adjacent unit. In this case, the restoring force of a chain extended by  $x=nl$  is given by

$$F = \frac{kT}{2l} \ln\left(\frac{1+v}{1-v}\right) \quad v = \frac{n}{N}$$

where  $k$  is Boltzmann's constant. (a) What is the magnitude of the force that must be applied to extend a DNA molecule with  $N=200$  by 90 nm? (b) Plot the restoring force against  $v$ , noting that  $v$  can be either positive or negative. How is the variation of the restoring force with end-to-end distance different from that predicted by Hooke's law? (c) Keep in mind that the difference in

end-to-end distance from an equilibrium value is  $x=nl$  and, consequently,  $dx=ldn=Nldv$ , and write an expression for the work of extending a DNA molecule. (d) Calculate the work of extending a DNA molecule from  $v=0$  to  $v=1.0$ . *Hint:* You must integrate the expression for  $w$ . The task can be accomplished easily with mathematical software.

**2A.7** As a continuation of Problem 2A.6, (a) show that for small extensions of the chain, when  $i \ll 1$ , the restoring force is given by

$$F \approx \frac{vkT}{l} = \frac{nkT}{Nl}$$

(b) Is the variation of the restoring force with extension of the chain given in part (a) different from that predicted by Hooke's law? Explain your answer.

## TOPIC 2B Enthalpy

### Discussion questions

**2B.1** Explain the difference between the change in internal energy and the change in enthalpy accompanying a process.

**2B.2** Why is the heat capacity at constant pressure of a substance normally greater than its heat capacity at constant volume?

### Exercises

**2B.1(a)** When 229 J of energy is supplied as heat to 3.0 mol Ar(g), the temperature of the sample increases by 2.55 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

**2B.1(b)** When 178 J of energy is supplied as heat to 1.9 mol of gas molecules, the temperature of the sample increases by 1.78 K. Calculate the molar heat capacities at constant volume and constant pressure of the gas.

**2B.2(a)** The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression  $C_p/(\text{J K}^{-1}) = 20.17 + 0.3665(T/\text{K})$ . Calculate  $q$ ,  $w$ , and  $\Delta H$  when the temperature is raised from 25 °C to 100 °C (i) at constant pressure, (ii) at constant volume.

**2B.2(b)** The constant-pressure heat capacity of a sample of a perfect gas was found to vary with temperature according to the expression  $C_p/(\text{J K}^{-1}) = 20.17 + 0.4001(T/\text{K})$ . Calculate  $q$ ,  $w$ , and  $\Delta H$  when the temperature is raised from 25 °C to 100 °C (i) at constant pressure, (ii) at constant volume.

**2B.3(a)** When 3.0 mol O<sub>2</sub> is heated at a constant pressure of 3.25 atm, its temperature increases from 260 K to 285 K. Given that the molar heat capacity of O<sub>2</sub> at constant pressure is 29.4 J K<sup>-1</sup> mol<sup>-1</sup>, calculate  $q$ ,  $\Delta H$ , and  $\Delta U$ .

**2B.3(b)** When 2.0 mol CO<sub>2</sub> is heated at a constant pressure of 1.25 atm, its temperature increases from 250 K to 277 K. Given that the molar heat capacity of CO<sub>2</sub> at constant pressure is 37.11 J K<sup>-1</sup> mol<sup>-1</sup>, calculate  $q$ ,  $\Delta H$ , and  $\Delta U$ .

### Problems

**2B.1** The following data show how the standard molar constant-pressure heat capacity of sulfur dioxide varies with temperature. By how much does the standard molar enthalpy of SO<sub>2</sub>(g) increase when the temperature is raised from 298.15 K to 1500 K?

$T/\text{K}$	300	500	700	900	1100	1300	1500
$C_{p,m}^\ominus/(\text{J K}^{-1} \text{mol}^{-1})$	39.909	46.490	50.829	53.407	54.993	56.033	56.759

**2B.2** The following data show how the standard molar constant-pressure heat capacity of ammonia depends on the temperature. Use mathematical software to fit an expression of the form of eqn 2B.8 to the data and determine the values of  $a$ ,  $b$ , and  $c$ . Explore whether it would be better to express the data as  $C_{p,m} = \alpha + \beta T + \gamma T^2$ , and determine the values of these coefficients.

$T/\text{K}$	300	400	500	600	700	800	900	1000
$C_{p,m}^\ominus/(\text{J K}^{-1} \text{mol}^{-1})$	35.678	38.674	41.994	45.229	48.269	51.112	53.769	56.244

**2B.3** A sample consisting of 2.0 mol CO<sub>2</sub> occupies a fixed volume of 15.0 dm<sup>3</sup> at 300 K. When it is supplied with 2.35 kJ of energy as heat its temperature increases to 341 K. Assume that CO<sub>2</sub> is described by the van der Waals equation of state (Topic 1C) and calculate  $w$ ,  $\Delta U$ , and  $\Delta H$ .

**2B.4** (a) Express  $(\partial C_V/\partial V)_T$  as a second derivative of  $U$  and find its relation to  $(\partial U/\partial V)_T$  and  $(\partial C_p/\partial p)_T$  as a second derivative of  $H$  and find its relation to  $(\partial H/\partial p)_T$ . (b) From these relations show that  $(\partial C_V/\partial V)_T=0$  and  $(\partial C_p/\partial p)_T=0$  for a perfect gas.

## TOPIC 2C Thermochemistry

### Discussion questions

**2C.1** Describe two calorimetric methods for the determination of enthalpy changes that accompany chemical processes.

**2C.2** Distinguish between 'standard state' and 'reference state', and indicate their applications.

### Exercises

**2C.1(a)** For tetrachloromethane,  $\Delta_{\text{vap}}H^\ominus = 30.0 \text{ kJ mol}^{-1}$ . Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  when 0.75 mol  $\text{CCl}_4(\text{l})$  is vaporized at 250 K and 750 Torr.

**2C.1(b)** For ethanol,  $\Delta_{\text{vap}}H^\ominus = 43.5 \text{ kJ mol}^{-1}$ . Calculate  $q$ ,  $w$ ,  $\Delta H$ , and  $\Delta U$  when 1.75 mol  $\text{C}_2\text{H}_5\text{OH}(\text{l})$  is vaporized at 260 K and 765 Torr.

**2C.2(a)** The standard enthalpy of formation of ethylbenzene is  $-12.5 \text{ kJ mol}^{-1}$ . Calculate its standard enthalpy of combustion.

**2C.2(b)** The standard enthalpy of formation of phenol is  $-165.0 \text{ kJ mol}^{-1}$ . Calculate its standard enthalpy of combustion.

**2C.3(a)** The standard enthalpy of combustion of cyclopropane is  $-2091 \text{ kJ mol}^{-1}$  at 25°C. From this information and enthalpy of formation data for  $\text{CO}_2(\text{g})$  and  $\text{H}_2\text{O}(\text{g})$ , calculate the enthalpy of formation of cyclopropane. The enthalpy of formation of propene is  $+20.42 \text{ kJ mol}^{-1}$ . Calculate the enthalpy of isomerization of cyclopropane to propene.

**2C.3(b)** From the following data, determine  $\Delta_f H^\ominus$  for diborane,  $\text{B}_2\text{H}_6(\text{g})$ , at 298 K:

**2C.4(a)** Given that the standard enthalpy of formation of  $\text{HCl}(\text{aq})$  is  $-167 \text{ kJ mol}^{-1}$ , what is the value of  $\Delta_f H^\ominus(\text{Cl}^-, \text{aq})$ ?

**2C.4(b)** Given that the standard enthalpy of formation of  $\text{HI}(\text{aq})$  is  $-55 \text{ kJ mol}^{-1}$ , what is the value of  $\Delta_f H^\ominus(\text{I}^-, \text{aq})$ ?

**2C.5(a)** When 120 mg of naphthalene,  $\text{C}_{10}\text{H}_8(\text{s})$ , was burned in a bomb calorimeter the temperature rose by 3.05 K. Calculate the calorimeter constant. By how much will the temperature rise when 150 mg of phenol,  $\text{C}_6\text{H}_5\text{OH}(\text{s})$ , is burned in the calorimeter under the same conditions?

**2C.5(b)** When 225 mg of anthracene,  $\text{C}_{14}\text{H}_{10}(\text{s})$ , was burned in a bomb calorimeter the temperature rose by 1.75 K. Calculate the calorimeter constant. By how much will the temperature rise when 125 mg of phenol,  $\text{C}_6\text{H}_5\text{OH}(\text{s})$ , is burned in the calorimeter under the same conditions? ( $\Delta_f H^\ominus(\text{C}_{14}\text{H}_{10}, \text{s}) = -7061 \text{ kJ mol}^{-1}$ .)

**2C.6(a)** Given the reactions (1) and (2) below, determine (i)  $\Delta_r H^\ominus$  and  $\Delta_r U^\ominus$  for reaction (3), (ii)  $\Delta_f H^\ominus$  for both  $\text{HCl}(\text{g})$  and  $\text{H}_2\text{O}(\text{g})$  all at 298 K.

**2C.6(b)** Given the reactions (1) and (2) below, determine (i)  $\Delta_r H^\ominus$  and  $\Delta_r U^\ominus$  for reaction (3), (ii)  $\Delta_f H^\ominus$  for both  $\text{HI}(\text{g})$  and  $\text{H}_2\text{O}(\text{g})$  all at 298 K.

**2C.7(a)** For the reaction  $\text{C}_2\text{H}_5\text{OH}(\text{l}) + 3 \text{O}_2(\text{g}) \rightarrow 2 \text{CO}_2(\text{g}) + 3 \text{H}_2\text{O}(\text{g})$ ,  $\Delta_r U^\ominus = -1373 \text{ kJ mol}^{-1}$  at 298 K. Calculate  $\Delta_r H^\ominus$ .

**2C.7(b)** For the reaction  $2 \text{C}_6\text{H}_5\text{COOH}(\text{s}) + 15 \text{O}_2(\text{g}) \rightarrow 14 \text{CO}_2(\text{g}) + 6 \text{H}_2\text{O}(\text{g})$ ,  $\Delta_r U^\ominus = -772.7 \text{ kJ mol}^{-1}$  at 298 K. Calculate  $\Delta_r H^\ominus$ .

**2C.8(a)** From the data in Tables 2C.2 and 2C.3, calculate  $\Delta_r H^\ominus$  and  $\Delta_r U^\ominus$  at (i) 298 K, (ii) 478 K for the reaction  $\text{C}(\text{graphite}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{CO}(\text{g}) + \text{H}_2(\text{g})$ . Assume all heat capacities to be constant over the temperature range of interest.

**2C.8(b)** Calculate  $\Delta_r H^\ominus$  and  $\Delta_r U^\ominus$  at 298 K and  $\Delta_r H^\ominus$  at 427 K for the hydrogenation of ethyne (acetylene) to ethene (ethylene) from the enthalpy of combustion and heat capacity data in Tables 2C.5 and 2C.6. Assume the heat capacities to be constant over the temperature range involved.

**2C.9(a)** Estimate  $\Delta_r H^\ominus$  (500 K) for the combustion of methane,  $\text{CH}_4(\text{g}) + 2 \text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g}) + 2 \text{H}_2\text{O}(\text{g})$  by using the data on the temperature dependence of heat capacities in Table 2B.1.

**2C.9(b)** Estimate  $\Delta_r H^\ominus$  (478 K) for the combustion of naphthalene,  $\text{C}_{10}\text{H}_8(\text{l}) + 12 \text{O}_2(\text{g}) \rightarrow 10 \text{CO}_2(\text{g}) + 4 \text{H}_2\text{O}(\text{g})$  by using the data on the temperature dependence of heat capacities in Table 2B.1.

**2C.10(a)** Set up a thermodynamic cycle for determining the enthalpy of hydration of  $\text{Mg}^{2+}$  ions using the following data: enthalpy of sublimation of  $\text{Mg}(\text{s})$ ,  $+167.2 \text{ kJ mol}^{-1}$ ; first and second ionization enthalpies of  $\text{Mg}(\text{g})$ , 7.646 eV and 15.035 eV; dissociation enthalpy of  $\text{Cl}_2(\text{g})$ ,  $+241.6 \text{ kJ mol}^{-1}$ ; electron gain enthalpy of  $\text{Cl}(\text{g})$ ,  $-3.78 \text{ eV}$ ; enthalpy of solution of  $\text{MgCl}_2(\text{s})$ ,  $-150.5 \text{ kJ mol}^{-1}$ ; enthalpy of hydration of  $\text{Cl}^-(\text{g})$ ,  $-383.7 \text{ kJ mol}^{-1}$ .

**2C.10(b)** Set up a thermodynamic cycle for determining the enthalpy of hydration of  $\text{Ca}^{2+}$  ions using the following data: enthalpy of sublimation of  $\text{Ca}(\text{s})$ ,  $+178.2 \text{ kJ mol}^{-1}$ ; first and second ionization enthalpies of  $\text{Ca}(\text{g})$ ,  $589.7 \text{ kJ mol}^{-1}$  and  $1145 \text{ kJ mol}^{-1}$ ; enthalpy of vaporization of bromine,  $+30.91 \text{ kJ mol}^{-1}$ ; dissociation enthalpy of  $\text{Br}_2(\text{g})$ ,  $+192.9 \text{ kJ mol}^{-1}$ ; electron gain enthalpy of  $\text{Br}(\text{g})$ ,  $-331.0 \text{ kJ mol}^{-1}$ ; enthalpy of solution of  $\text{CaBr}_2(\text{s})$ ,  $-103.1 \text{ kJ mol}^{-1}$ ; enthalpy of hydration of  $\text{Br}^-(\text{g})$ ,  $-289 \text{ kJ mol}^{-1}$ .

### Problems

**2C.1** A sample of the sugar D-ribose ( $\text{C}_5\text{H}_{10}\text{O}_5$ ) of mass 0.727 g was placed in a constant-volume bomb calorimeter and then ignited in the presence of excess oxygen. The temperature rose by 0.910 K. In a separate experiment in the same calorimeter, the combustion of 0.825 g of benzoic acid, for which the internal energy of combustion is  $-3251 \text{ kJ mol}^{-1}$ , gave a temperature rise of 1.940 K. Calculate the enthalpy of formation of D-ribose.

**2C.2** The standard enthalpy of formation of bis(benzene)chromium was measured in a calorimeter. It was found for the reaction  $\text{Cr}(\text{C}_6\text{H}_6)_2(\text{s}) \rightarrow \text{Cr}(\text{s}) + 2 \text{C}_6\text{H}_6(\text{g})$  that  $\Delta_r U^\ominus(583 \text{ K}) = +8.0 \text{ kJ mol}^{-1}$ . Find the corresponding reaction enthalpy and estimate the standard enthalpy of formation of the compound at 583 K. The constant-pressure molar heat capacity of benzene is  $136.1 \text{ J K}^{-1} \text{ mol}^{-1}$  in its liquid range and  $81.67 \text{ J K}^{-1} \text{ mol}^{-1}$  as a gas.

**2C.3\*** From the enthalpy of combustion data in Table 2C.1 for the alkanes methane through octane, test the extent to which the relation  $\Delta_c H^\ominus = k\{(M/(g\ mol^{-1}))^n\}$  holds and find the numerical values for  $k$  and  $n$ . Predict  $\Delta_c H^\ominus$  for decane and compare to the known value.

**2C.4\*** Kolesov et al. reported the standard enthalpy of combustion and of formation of crystalline  $C_{60}$  based on calorimetric measurements (V.P. Kolesov et al., *J. Chem. Thermodynamics* **28**, 1121 (1996)). In one of their runs, they found the standard specific internal energy of combustion to be  $-36.0334\ kJ\ g^{-1}$  at 298.15 K. Compute  $\Delta_c H^\ominus$  and  $\Delta_f H^\ominus$  of  $C_{60}$ .

**2C.5\*** A thermodynamic study of  $DyCl_3$  (E.H.P. Cordfunke et al., *J. Chem. Thermodynamics* **28**, 1387 (1996)) determined its standard enthalpy of formation from the following information

- (1)  $DyCl_3(s) \rightarrow DyCl_3(aq, \text{ in } 4.0\ M\ HCl) \quad \Delta_r H^\ominus = -180.06\ kJ\ mol^{-1}$
- (2)  $Dy(s) + 3\ HCl(aq, 4.0\ M) \rightarrow DyCl_3(aq, \text{ in } 4.0\ M\ HCl(aq)) + \frac{3}{2}\ H_2(g) \quad \Delta_r H^\ominus = -699.43\ kJ\ mol^{-1}$
- (3)  $\frac{1}{2}\ H_2(g) + \frac{1}{2}\ Cl_2(g) \rightarrow HCl(aq, 4.0\ M) \quad \Delta_r H^\ominus = -158.31\ kJ\ mol^{-1}$

Determine  $\Delta_f H^\ominus(DyCl_3, s)$  from these data.

**2C.6\*** Silylene ( $SiH_2$ ) is a key intermediate in the thermal decomposition of silicon hydrides such as silane ( $SiH_4$ ) and disilane ( $Si_2H_6$ ). H.K. Moffat et al. (*J. Phys. Chem.* **95**, 145 (1991)) report  $\Delta_f H^\ominus(SiH_2) = +274\ kJ\ mol^{-1}$ . If  $\Delta_f H^\ominus(SiH_4) = +34.3\ kJ\ mol^{-1}$  and  $\Delta_f H^\ominus(Si_2H_6) = +80.3\ kJ\ mol^{-1}$ , compute the standard enthalpies of the following reactions:

- (a)  $SiH_4(g) \rightarrow SiH_2(g) + H_2(g)$
- (b)  $Si_2H_6(g) \rightarrow SiH_2(g) + SiH_4(g)$

**2C.7** As remarked in Problem 2B.2, it is sometimes appropriate to express the temperature dependence of the heat capacity by the empirical expression  $C_{p,m} = \alpha + \beta T + \gamma T^2$ . Use this expression to estimate the standard enthalpy of combustion of methane at 350 K. Use the following data:

	$\alpha/(J\ K^{-1}\ mol^{-1})$	$\beta/(mJ\ K^{-2}\ mol^{-1})$	$\gamma/(\mu J\ K^{-3}\ mol^{-1})$
$CH_4(g)$	14.16	75.5	-17.99
$CO_2(g)$	26.86	6.97	-0.82
$O_2(g)$	25.72	12.98	-3.862
$H_2O(g)$	30.36	9.61	1.184

**2C.8** Figure 2.1 shows the experimental DSC scan of hen white lysozyme (G. Privalov et al., *Anal. Biochem.* **79**, 232 (1995)) converted to joules (from calories). Determine the enthalpy of unfolding of this protein by integration of the curve and the change in heat capacity accompanying the transition.

Figure 2.1 The experimental DSC scan of hen white lysozyme.

**2C.9** An average human produces about 10 MJ of heat each day through metabolic activity. If a human body were an isolated system of mass 65 kg with the heat capacity of water, what temperature rise would the body experience? Human bodies are actually open systems, and the main mechanism of heat loss is through the evaporation of water. What mass of water should be evaporated each day to maintain constant temperature?

**2C.10** In biological cells that have a plentiful supply of oxygen, glucose is oxidized completely to  $CO_2$  and  $H_2O$  by a process called *aerobic oxidation*. Muscle cells may be deprived of  $O_2$  during vigorous exercise and, in that case, one molecule of glucose is converted to two molecules of lactic acid ( $CH_3CH(OH)COOH$ ) by a process called *anaerobic glycolysis*. (a) When 0.3212 g of glucose was burned in a bomb calorimeter of calorimeter constant  $641\ J\ K^{-1}$  the temperature rose by  $7.793\ K$ . Calculate (i) the standard molar enthalpy of combustion, (ii) the standard internal energy of combustion, and (iii) the standard enthalpy of formation of glucose. (b) What is the biological advantage (in kilojoules per mole of energy released as heat) of complete aerobic oxidation compared with anaerobic glycolysis to lactic acid?

## TOPIC 2D State functions and exact differentials

### Discussion questions

**2D.1** Suggest (with explanation) how the internal energy of a van der Waals gas should vary with volume at constant temperature.

**2D.2** Explain why a perfect gas does not have an inversion temperature.

### Exercises

**2D.1(a)** Estimate the internal pressure,  $\pi_T$ , of water vapour at 1.00 bar and 400 K, treating it as a van der Waals gas. *Hint:* Simplify the approach by estimating the molar volume by treating the gas as perfect.

**2D.1(b)** Estimate the internal pressure,  $\pi_T$ , of sulfur dioxide at 1.00 bar and 298 K, treating it as a van der Waals gas. *Hint:* Simplify the approach by estimating the molar volume by treating the gas as perfect.

**2D.2(a)** For a van der Waals gas,  $\pi_T = a/V_m^2$ . Calculate  $\Delta U_m$  for the isothermal expansion of nitrogen gas from an initial volume of  $1.00\ dm^3$  to  $20.00\ dm^3$  at 298 K. What are the values of  $q$  and  $w$ ?

**2D.2(b)** Repeat Exercise 2D.2(a) for argon, from an initial volume of  $1.00\ dm^3$  to  $30.00\ dm^3$  at 298 K.

\* These problems were provided by Charles Trapp and Carmen Giunta.

**2D.3(a)** The volume of a certain liquid varies with temperature as

$$V = V^\ominus \{0.75 + 3.9 \times 10^{-4}(T/K) + 1.48 \times 10^{-6}(T/K)^2\}$$

where  $V^\ominus$  is its volume at 300 K. Calculate its expansion coefficient,  $\alpha$ , at 320 K.

**2D.3(b)** The volume of a certain liquid varies with temperature as

$$V = V^\ominus \{0.77 + 3.7 \times 10^{-4}(T/K) + 1.52 \times 10^{-6}(T/K)^2\}$$

where  $V^\ominus$  is its volume at 298 K. Calculate its expansion coefficient,  $\alpha$ , at 310 K.

**2D.4(a)** The isothermal compressibility of water at 293 K is  $4.96 \times 10^{-5} \text{ atm}^{-1}$ . Calculate the pressure that must be applied in order to increase its density by 0.10 per cent.

**2D.4(b)** The isothermal compressibility of lead at 293 K is  $2.21 \times 10^{-6} \text{ atm}^{-1}$ . Calculate the pressure that must be applied in order to increase its density by 0.10 per cent.

## Problems

**2D.1\*** In 2006, the Intergovernmental Panel on Climate Change (IPCC) considered a global average temperature rise of 1.0–3.5 °C likely by the year 2100, with 2.0 °C its best estimate. Predict the average rise in sea level due to thermal expansion of sea water based on temperature rises of 1.0 °C, 2.0 °C, and 3.5 °C given that the volume of the Earth's oceans is  $1.37 \times 10^9 \text{ km}^3$  and their surface area is  $361 \times 10^6 \text{ km}^2$ , and state the approximations which go into the estimates.

**2D.2** The heat capacity ratio of a gas determines the speed of sound in it through the formula  $c_s = (\gamma RT/M)^{1/2}$ , where  $\gamma = C_p/C_V$  and  $M$  is the molar mass of the gas. Deduce an expression for the speed of sound in a perfect gas of (a) diatomic, (b) linear triatomic, (c) nonlinear triatomic molecules at high temperatures (with translation and rotation active). Estimate the speed of sound in air at 25 °C.

**2D.3** Starting from the expression  $C_p - C_V = T(\partial p/\partial T)_V(\partial V/\partial T)_p$ , use the appropriate relations between partial derivatives to show that

$$C_p - C_V = \frac{T(\partial V/\partial T)_p^2}{(\partial V/\partial p)_T}$$

Evaluate  $C_p - C_V$  for a perfect gas.

**2D.4** (a) Write expressions for  $dV$  and  $dp$  given that  $V$  is a function of  $p$  and  $T$  and  $p$  is a function of  $V$  and  $T$ . (b) Deduce expressions for  $d \ln V$  and  $d \ln p$  in terms of the expansion coefficient and the isothermal compressibility.

**2D.5** Rearrange the van der Waals equation of state,  $p = nRT/(V - nb) - n^2a/V^2$ , to give an expression for  $T$  as a function of  $p$  and  $V$  (with  $n$  constant). Calculate  $(\partial T/\partial p)_V$  and confirm that  $(\partial T/\partial p)_V = 1/(\partial p/\partial T)_V$ . Go on to confirm Euler's chain relation (*Mathematical background 2*).

**2D.6** Calculate the isothermal compressibility and the expansion coefficient of a van der Waals gas (see Problem 2D.5). Show, using Euler's chain relation (*Mathematical background 2*), that  $\kappa_T R = \alpha(V_m - b)$ .

**2D.7** The speed of sound,  $c_s$ , in a gas of molar mass  $M$  is related to the ratio of heat capacities  $\gamma$  by  $c_s = (\gamma RT/M)^{1/2}$ . Show that  $c_s = (\gamma p/\rho)^{1/2}$ , where  $\rho$  is the mass density of the gas. Calculate the speed of sound in argon at 25 °C.

**2D.8\*** A gas obeying the equation of state  $p(V - nb) = nRT$  is subjected to a Joule–Thomson expansion. Will the temperature increase, decrease, or remain the same?

**2D.5(a)** Given that  $\mu = 0.25 \text{ K atm}^{-1}$  for nitrogen, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 10.0 mol  $\text{N}_2$  flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 85 atm.

**2D.5(b)** Given that  $\mu = 1.11 \text{ K atm}^{-1}$  for carbon dioxide, calculate the value of its isothermal Joule–Thomson coefficient. Calculate the energy that must be supplied as heat to maintain constant temperature when 10.0 mol  $\text{CO}_2$  flows through a throttle in an isothermal Joule–Thomson experiment and the pressure drop is 75 atm.

**2D.9** Use the fact that  $(\partial U/\partial V)_T = a/V_m^2$  for a van der Waals gas (Topic 1C) to show that  $\mu C_{p,m} \approx (2a/RT) - b$  by using the definition of  $\mu$  and appropriate relations between partial derivatives. *Hint:* Use the approximation  $pV_m \approx RT$  when it is justifiable to do so.

**2D.10\*** Concerns over the harmful effects of chlorofluorocarbons on stratospheric ozone have motivated a search for new refrigerants. One such alternative is 2,2-dichloro-1,1,1-trifluoroethane (refrigerant 123). Younglove and McLinden published a compendium of thermophysical properties of this substance (B.A. Younglove and M. McLinden, *J. Phys. Chem. Ref. Data* **23**, 7 (1994)), from which properties such as the Joule–Thomson coefficient  $\mu$  can be computed. (a) Compute  $\mu$  at 1.00 bar and 50 °C given that  $(\partial H/\partial p)_T = -3.29 \times 10^3 \text{ J MPa}^{-1} \text{ mol}^{-1}$  and  $C_{p,m} = 110.0 \text{ J K}^{-1} \text{ mol}^{-1}$ . (b) Compute the temperature change which would accompany adiabatic expansion of 2.0 mol of this refrigerant from 1.5 bar to 0.5 bar at 50 °C.

**2D.11\*** Another alternative refrigerant (see preceding problem) is 1,1,1,2-tetrafluoroethane (refrigerant HFC-134a). A compendium of thermophysical properties of this substance has been published (R. Tillner-Roth and H.D. Baehr, *J. Phys. Chem. Ref. Data* **23**, 657 (1994)) from which properties such as the Joule–Thomson coefficient  $\mu$  can be computed. (a) Compute  $\mu$  at 0.100 MPa and 300 K from the following data (all referring to 300 K):

$p/\text{MPa}$	0.080	0.100	0.12
Specific enthalpy/(kJ kg <sup>-1</sup> )	426.48	426.12	425.76

(The specific constant-pressure heat capacity is  $0.7649 \text{ kJ K}^{-1} \text{ kg}^{-1}$ .) (b) Compute  $\mu$  at 1.00 MPa and 350 K from the following data (all referring to 350 K):

$p/\text{MPa}$	0.80	1.00	1.2
Specific enthalpy/(kJ kg <sup>-1</sup> )	461.93	459.12	42B.15

(The specific constant-pressure heat capacity is  $1.0392 \text{ kJ K}^{-1} \text{ kg}^{-1}$ .)

## TOPIC 2E Adiabatic changes

### Discussion questions

2E.1 Why are adiabats steeper than isotherms?

2E.2 Why do heat capacities play a role in the expressions for adiabatic expansion?

### Exercises

2E.1(a) Use the equipartition principle to estimate the values of  $\gamma = C_p/C_v$  for gaseous ammonia and methane. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at 25 °C?

2E.1(b) Use the equipartition principle to estimate the value of  $\gamma = C_p/C_v$  for carbon dioxide. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at 25 °C?

2E.2(a) Calculate the final temperature of a sample of argon of mass 12.0 g that is expanded reversibly and adiabatically from 1.0 dm<sup>3</sup> at 273.15 K to 3.0 dm<sup>3</sup>.

2E.2(b) Calculate the final temperature of a sample of carbon dioxide of mass 16.0 g that is expanded reversibly and adiabatically from 500 cm<sup>3</sup> at 298.15 K to 2.00 dm<sup>3</sup>.

2E.3(a) A sample consisting of 1.0 mol of perfect gas molecules with  $C_v = 20.8 \text{ J K}^{-1}$  is initially at 4.25 atm and 300 K. It undergoes reversible adiabatic expansion until its pressure reaches 2.50 atm. Calculate the final volume and temperature and the work done.

2E.3(b) A sample consisting of 2.5 mol of perfect gas molecules with  $C_{p,m} = 20.8 \text{ J K}^{-1} \text{ mol}^{-1}$  is initially at 240 kPa and 325 K. It undergoes reversible adiabatic expansion until its pressure reaches 150 kPa. Calculate the final volume and temperature and the work done.

2E.4(a) A sample of carbon dioxide of mass 2.45 g at 27.0 °C is allowed to expand reversibly and adiabatically from 500 cm<sup>3</sup> to 3.00 dm<sup>3</sup>. What is the work done by the gas?

2E.4(b) A sample of nitrogen of mass 3.12 g at 23.0 °C is allowed to expand reversibly and adiabatically from 400 cm<sup>3</sup> to 2.00 dm<sup>3</sup>. What is the work done by the gas?

2E.5(a) Calculate the final pressure of a sample of carbon dioxide that expands reversibly and adiabatically from 67.4 kPa and 0.50 dm<sup>3</sup> to a final volume of 2.00 dm<sup>3</sup>. Take  $\gamma = 1.4$ .

2E.5(b) Calculate the final pressure of a sample of water vapour that expands reversibly and adiabatically from 97.3 Torr and 400 cm<sup>3</sup> to a final volume of 5.0 dm<sup>3</sup>. Take  $\gamma = 1.3$ .

### Problem

2E.1 The constant-volume heat capacity of a gas can be measured by observing the decrease in temperature when it expands adiabatically and reversibly. The value of  $\gamma = C_p/C_v$  can be inferred if the decrease in pressure is also measured and the constant-pressure heat capacity deduced by combining the two values.

A fluorocarbon gas was allowed to expand reversibly and adiabatically to twice its volume; as a result, the temperature fell from 298.15 K to 248.44 K and its pressure fell from 202.94 kPa to 81.840 kPa. Evaluate  $C_p$ .

## Integrated activities

2.1 Give examples of state functions and discuss why they play a critical role in thermodynamics.

2.2 The thermochemical properties of hydrocarbons are commonly investigated by using molecular modelling methods. (a) Use software to predict  $\Delta_c H^\ominus$  values for the alkanes methane through pentane. To calculate  $\Delta_c H^\ominus$  values, estimate the standard enthalpy of formation of  $C_n H_{2n+2}(g)$  by performing semi-empirical calculations (for example, AM1 or PM3 methods) and use experimental standard enthalpy of formation values for  $CO_2(g)$  and  $H_2O(l)$ . (b) Compare your estimated values with the experimental values of  $\Delta_c H^\ominus$  (Table 2C.4) and comment on the reliability of the molecular modelling method. (c) Test the extent to which the relation  $\Delta_c H^\ominus = \text{constant} \times \{(M/(\text{g mol}^{-1}))^n\}$  holds and determine the numerical values of the constant and  $n$ .

2.3 Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to:

(a) Calculate the work of isothermal reversible expansion of 1.0 mol  $CO_2(g)$  at 298 K from 1.0 m<sup>3</sup> to 3.0 m<sup>3</sup> on the basis that it obeys the van der Waals equation of state.

(b) Explore how the parameter  $\gamma$  affects the dependence of the pressure on the volume. Does the pressure–volume dependence become stronger or weaker with increasing volume?

## Mathematical background 2 Multivariate calculus

A thermodynamic property of a system typically depends on a number of variables, such as the internal energy depending on the amount, volume, and temperature. To understand how these properties vary with the conditions we need to understand how to manipulate their derivatives. This is the field of **multivariate calculus**, the calculus of several variables.

### MB2.1 Partial derivatives

A **partial derivative** of a function of more than one variable, such as  $f(x,y)$ , is the slope of the function with respect to one of the variables, all the other variables being held constant (Fig. MB2.1). Although a partial derivative shows how a function changes when one variable changes, it may be used to determine how the function changes when more than one variable changes by an infinitesimal amount. Thus, if  $f$  is a function of  $x$  and  $y$ , then when  $x$  and  $y$  change by  $dx$  and  $dy$ , respectively,  $f$  changes by

$$df = \left(\frac{\partial f}{\partial x}\right)_y dx + \left(\frac{\partial f}{\partial y}\right)_x dy \quad (\text{MB2.1})$$

where the symbol  $\partial$  ('curly d') is used (instead of d) to denote a partial derivative and the subscript on the parentheses indicates which variable is being held constant. The quantity  $df$  is also called the **differential** of  $f$ . Successive partial derivatives may be taken in any order:

$$\left(\frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right)_y\right)_x = \left(\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial y}\right)_x\right)_y \quad (\text{MB2.2})$$

**Figure MB2.1** A function of two variables,  $f(x,y)$ , as depicted by the coloured surface and the two partial derivatives,  $(\partial f/\partial x)_y$  and  $(\partial f/\partial y)_x$ , the slope of the function parallel to the  $x$ - and  $y$ -axes, respectively. The function plotted here is  $f(x,y) = ax^3y + by^2$  with  $a=1$  and  $b=-2$ .

#### Brief illustration MB2.1 Partial derivatives

Suppose that  $f(x,y) = ax^3y + by^2$  (the function plotted in Fig. MB2.1) then

$$\left(\frac{\partial f}{\partial x}\right)_y = 3ax^2y \quad \left(\frac{\partial f}{\partial y}\right)_x = ax^3 + 2by$$

Then, when  $x$  and  $y$  undergo infinitesimal changes,  $f$  changes by

$$df = 3ax^2y dx + (ax^3 + 2by) dy$$

To verify that the order of taking the second partial derivative is irrelevant, we form

$$\begin{aligned} \left(\frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right)_y\right)_x &= \left(\frac{\partial(3ax^2y)}{\partial y}\right)_x = 3ax^2 \\ \left(\frac{\partial}{\partial x}\left(\frac{\partial f}{\partial y}\right)_x\right)_y &= \left(\frac{\partial(ax^3 + 2by)}{\partial x}\right)_y = 3ax^2 \end{aligned}$$

In the following,  $z$  is a variable on which  $x$  and  $y$  depend (for example,  $x$ ,  $y$ , and  $z$  might correspond to  $p$ ,  $V$ , and  $T$ ).

*Relation 1.* When  $x$  is changed at constant  $z$ :

$$\left(\frac{\partial f}{\partial x}\right)_z = \left(\frac{\partial f}{\partial x}\right)_y + \left(\frac{\partial f}{\partial y}\right)_x \left(\frac{\partial y}{\partial x}\right)_z \quad (\text{MB2.3a})$$

*Relation 2*

$$\left(\frac{\partial y}{\partial x}\right)_z = \frac{1}{(\partial x/\partial y)_z} \quad (\text{MB2.3b})$$

*Relation 3*

$$\left(\frac{\partial x}{\partial y}\right)_z = -\left(\frac{\partial x}{\partial z}\right)_y \left(\frac{\partial z}{\partial y}\right)_x \quad (\text{MB2.3c})$$

By combining Relations 2 and 3 we obtain the **Euler chain relation**:

$$\left(\frac{\partial y}{\partial x}\right)_z \left(\frac{\partial x}{\partial z}\right)_y \left(\frac{\partial z}{\partial y}\right)_x = -1 \quad \text{Euler chain relation} \quad (\text{MB2.4})$$

### MB2.2 Exact differentials

The relation in eqn MB2.2 is the basis of a test for an **exact differential**; that is, the test of whether

$$df = g(x,y)dx + h(x,y)dy \quad (\text{MB2.5})$$

has the form in eqn MB2.1. If it has that form, then  $g$  can be identified with  $(\partial f/\partial x)_y$  and  $h$  can be identified with  $(\partial f/\partial y)_x$ . Then eqn MB2.2 becomes

$$\left(\frac{\partial g}{\partial y}\right)_x = \left(\frac{\partial h}{\partial x}\right)_y \quad \text{Test for exact differential (MB2.6)}$$

**Brief illustration MB2.2** Exact differentials

Suppose, instead of the form  $df = 3ax^2y dx + (ax^3 + 2by) dy$  in the previous *Brief illustration*, we were presented with the expression

$$df = \overbrace{3ax^2y}^{g(x,y)} dx + \overbrace{(ax^2 + 2by)}^{h(x,y)} dy$$

with  $ax^2$  in place of  $ax^3$  inside the second parentheses. To test whether this is an exact differential, we form

$$\left(\frac{\partial g}{\partial y}\right)_x = \left(\frac{\partial(3ax^2y)}{\partial y}\right)_x = 3ax^2$$

$$\left(\frac{\partial h}{\partial x}\right)_y = \left(\frac{\partial(ax^2 + 2by)}{\partial x}\right)_y = 2ax$$

These two expressions are not equal, so this form of  $df$  is not an exact differential and there is not a corresponding integrated function of the form  $f(x,y)$ .

If  $df$  is exact, then we can do two things:

- From a knowledge of the functions  $g$  and  $h$  we can reconstruct the function  $f$ .
- Be confident that the integral of  $df$  between specified limits is independent of the path between those limits.

The first conclusion is best demonstrated with a specific example.

**Brief illustration MB2.3** The reconstruction of an equation

We consider the differential  $df = 3ax^2y dx + (ax^3 + 2by) dy$ , which we know to be exact. Because  $(\partial f/\partial x)_y = 3ax^2y$ , we can integrate with respect to  $x$  with  $y$  held constant, to obtain

$$f = \int df = \int 3ax^2y dx = 3ay \int x^2 dx = ax^3y + k$$

where the ‘constant’ of integration  $k$  may depend on  $y$  (which has been treated as a constant in the integration), but not on  $x$ . To find  $k(y)$ , we note that  $(\partial f/\partial y)_x = ax^3 + 2by$ , and therefore

$$\left(\frac{\partial f}{\partial y}\right)_x = \left(\frac{\partial(ax^3y + k)}{\partial y}\right)_x = ax^3 + \frac{dk}{dy} = ax^3 + 2by$$

Therefore

$$\frac{dk}{dy} = 2by$$

from which it follows that  $k = by^2 + \text{constant}$ . We have found, therefore, that

$$f(x,y) = ax^3y + by^2 + \text{constant}$$

which, apart from the constant, is the original function in the *Brief illustration* MB2.1. The value of the constant is pinned down by stating the boundary conditions; thus, if it is known that  $f(0,0) = 0$ , then the constant is zero.

To demonstrate that the integral of  $df$  is independent of the path is now straight forward. Because  $df$  is a differential, its integral between the limits  $a$  and  $b$  is

$$\int_a^b df = f(b) - f(a)$$

The value of the integral depends only on the values at the end points and is independent of the path between them. If  $df$  is not an exact differential, the function  $f$  does not exist, and this argument no longer holds. In such cases, the integral of  $df$  does depend on the path.

**Brief illustration MB2.4** Path-dependent integration

Consider the inexact differential (the expression with  $ax^2$  in place of  $ax^3$  inside the second parentheses):

$$df = 3ax^2y dx + (ax^2 + 2by) dy$$

Suppose we integrate  $df$  from  $(0,0)$  to  $(2,2)$  along the two paths shown in Fig. MB2.2. Along Path 1,

**Figure MB2.2** The two integration paths referred to in *Brief illustration* MB2.4.

$$\begin{aligned}\int_{\text{Path 1}} df &= \int_{0,0}^{2,0} 3ax^2y \, dx + \int_{2,0}^{2,2} (ax^2 + 2by) \, dy \\ &= 0 + 4a \int_0^2 dy + 2b \int_0^2 y \, dy = 8a + 4b\end{aligned}$$

whereas along Path 2,

$$\begin{aligned}\int_{\text{Path 2}} df &= \int_{0,2}^{2,2} 3ax^2y \, dx + \int_{0,0}^{0,2} (ax^2 + 2by) \, dy \\ &= 6a \int_0^2 x^2 \, dx + 0 + 2b \int_0^2 y \, dy = 16a + 4b\end{aligned}$$

The two integrals are not the same.

An inexact differential may sometimes be converted into an exact differential by multiplication by a factor known as an *integrating factor*. A physical example is the integrating factor  $1/T$  that converts the inexact differential  $dq_{\text{rev}}$  into the exact differential  $dS$  in thermodynamics (Topic 3A).

#### Brief illustration MB2.5 An integrating factor

We have seen that the differential  $df = 3ax^2y \, dx + (ax^2 + 2by) \, dy$  is inexact; the same is true when we set  $b=0$  and consider  $df = 3ax^2y \, dx + ax^2 \, dy$  instead. Suppose we multiply this  $df$  by  $x^m y^n$  and write  $x^m y^n df = df'$ , then we obtain

$$df' = \overbrace{3ax^{m+2}y^{n+1}}^{g(x,y)} \, dx + \overbrace{ax^{m+2}y^n}_{h(x,y)} \, dy$$

We evaluate the following two partial derivatives:

$$\begin{aligned}\left(\frac{\partial g}{\partial y}\right)_x &= \left(\frac{\partial(3ax^{m+2}y^{n+1})}{\partial y}\right)_x = 3a(n+1)x^{m+2}y^n \\ \left(\frac{\partial h}{\partial x}\right)_y &= \left(\frac{\partial(ax^{m+2}y^n)}{\partial x}\right)_y = a(m+2)x^{m+1}y^n\end{aligned}$$

For the new differential to be exact, these two partial derivatives must be equal, so we write

$$3a(n+1)x^{m+2}y^n = a(m+2)x^{m+1}y^n$$

which simplifies to

$$3(n+1)x = m+2$$

The only solution that is independent of  $x$  is  $n = -1$  and  $m = -2$ . It follows that

$$df' = 3a \, dx + (a/y) \, dy$$

is an exact differential. By the procedure already illustrated, its integrated form is  $f'(x,y) = 3ax + a \ln y + \text{constant}$ .

# CHAPTER 3

## The Second and Third Laws

Some things happen naturally, some things don't. Some aspect of the world determines the **spontaneous** direction of change, the direction of change that does not require work to bring it about. An important point, though, is that throughout this text 'spontaneous' must be interpreted as a natural *tendency* that may or may not be realized in practice. Thermodynamics is silent on the rate at which a spontaneous change in fact occurs, and some spontaneous processes (such as the conversion of diamond to graphite) may be so slow that the tendency is never realized in practice whereas others (such as the expansion of a gas into a vacuum) are almost instantaneous.

### 3A Entropy

The direction of change is related to the *distribution of energy and matter*, and spontaneous changes are always accompanied by a dispersal of energy or matter. To quantify this concept we introduce the property called 'entropy', which is central to the formulation of the 'Second Law of thermodynamics'. That law governs all spontaneous change.

### 3B The measurement of entropy

To make the Second Law quantitative, it is necessary to measure the entropy of a substance. We see that measurement, perhaps with calorimetric methods, of the energy transferred as heat during a physical process or chemical reaction leads to determination of the entropy change and, consequently, the direction of spontaneous change. The discussion in this Topic also leads to the 'Third Law of thermodynamics', which helps us to understand the properties of matter at very low temperatures and to set up an absolute measure of the entropy of a substance.

### 3C Concentrating on the system

One problem with dealing with the entropy is that it requires separate calculations of the changes taking place in the system and the surroundings. Providing we are willing to impose certain restrictions on the system, that problem can be overcome by introducing the 'Gibbs energy'. Indeed, most thermodynamic calculations in chemistry focus on the change in Gibbs energy, not the direct measurement of the entropy change.

### 3D Combining the First and Second Laws

Finally, we bring the First and Second Laws together and begin to see the considerable power of thermodynamics for accounting for the properties of matter.

### What is the impact of this material?

The Second Law is at the heart of the operation of engines of all types, including devices resembling engines that are used to cool objects. See *Impact* I3.1 for an application to the technology of refrigeration. Entropy considerations are also important in modern electronic materials for it permits a quantitative discussion of the concentration of impurities. See *Impact* I3.2 for a note about how measurement of the entropy at low temperatures gives insight into the purity of materials used as superconductors.

### ► Why do you need to know this material?

Entropy is the concept on which almost all applications of thermodynamics in chemistry are based: it explains why some reactions take place and others do not.

### ► What is the key idea?

The change in entropy of a system can be calculated from the heat transferred to it reversibly.

### ► What do you need to know already?

You need to be familiar with the First-Law concepts of work, heat, and internal energy (Topic 2A). The Topic draws on the expression for work of expansion of a perfect gas (Topic 2A) and on the changes in volume and temperature that accompany the reversible adiabatic expansion of a perfect gas (Topic 2D).

What determines the direction of spontaneous change? It is not the total energy of the isolated system. The First Law of thermodynamics states that energy is conserved in any process, and we cannot disregard that law now and say that everything tends towards a state of lower energy. When a change occurs, the total energy of an isolated system remains constant but it is parcelled out in different ways. Can it be, therefore, that the direction of change is related to the *distribution* of energy? We shall see that this idea is the key, and that spontaneous changes are always accompanied by a dispersal of energy or matter.

## 3A.1 The Second Law

We can begin to understand the role of the dispersal of energy and matter by thinking about a ball (the system) bouncing on a floor (the surroundings). The ball does not rise as high after each bounce because there are inelastic losses in the materials of the ball and floor. The kinetic energy of the ball's overall motion is spread out into the energy of thermal motion of its particles and those of the floor that it hits. The direction of spontaneous change is towards a state in which the ball is at rest with all its energy dispersed into disorderly thermal motion of molecules in the air and of the atoms of the virtually infinite floor (Fig. 3A.1).

A ball resting on a warm floor has never been observed to start bouncing. For bouncing to begin, something rather special would need to happen. In the first place, some of the thermal motion of the atoms in the floor would have to accumulate in a single, small object, the ball. This accumulation requires a spontaneous localization of energy from the myriad vibrations of the atoms of the floor into the much smaller number of atoms that constitute the ball (Fig. 3A.2). Furthermore, whereas the thermal motion is random, for the ball to move upwards its

**Figure 3A.1** The direction of spontaneous change for a ball bouncing on a floor. On each bounce some of its energy is degraded into the thermal motion of the atoms of the floor, and that energy disperses. The reverse has never been observed to take place on a macroscopic scale.

**Figure 3A.2** The molecular interpretation of the irreversibility expressed by the Second Law. (a) A ball resting on a warm surface; the atoms are undergoing thermal motion (vibration, in this instance), as indicated by the arrows. (b) For the ball to fly upwards, some of the random vibrational motion would have to change into coordinated, directed motion. Such a conversion is highly improbable.

atoms must all move in the same direction. The localization of random, disorderly motion as concerted, ordered motion is so unlikely that we can dismiss it as virtually impossible.<sup>1</sup>

We appear to have found the signpost of spontaneous change: *we look for the direction of change that leads to dispersal of the total energy of the isolated system.* This principle accounts for the direction of change of the bouncing ball, because its energy is spread out as thermal motion of the atoms of the floor. The reverse process is not spontaneous because it is highly improbable that energy will become localized, leading to uniform motion of the ball's atoms.

Matter also has a tendency to disperse in disorder. A gas does not contract spontaneously because to do so the random motion of its molecules, which spreads out the distribution of

<sup>1</sup> Concerted motion, but on a much smaller scale, is observed as *Brownian motion*, the jittering motion of small particles suspended in a liquid or gas.

molecules throughout the container, would have to take them all into the same region of the container. The opposite change, spontaneous expansion, is a natural consequence of matter becoming more dispersed as the gas molecules occupy a larger volume.

The recognition of two classes of process, spontaneous and non-spontaneous, is summarized by the **Second Law of thermodynamics**. This law may be expressed in a variety of equivalent ways. One statement was formulated by Kelvin:

No process is possible in which the sole result is the absorption of heat from a reservoir and its complete conversion into work.

For example, it has proved impossible to construct an engine like that shown in Fig. 3A.3, in which heat is drawn from a hot reservoir and completely converted into work. All real heat engines have both a hot source and a cold sink; some energy is always discarded into the cold sink as heat and not converted into work. The Kelvin statement is a generalization of the everyday observation that we have already discussed, that a ball at rest on a surface has never been observed to leap spontaneously upwards. An upward leap of the ball would be equivalent to the conversion of heat from the surface into work. Another statement of the Second Law is due to Rudolf Clausius (Fig. 3A.4):

Heat does not flow spontaneously from a cool body to a hotter body.

To achieve the transfer of heat to a hotter body, it is necessary to do work on the system, as in a refrigerator.

These two empirical observations turn out to be aspects of a single statement in which the Second Law is expressed in terms of a new state function, the **entropy**,  $S$ . We shall see that the entropy (which we shall define shortly, but is a measure of the energy and matter dispersed in a process) lets us assess whether one state is accessible from another by a spontaneous change:

The entropy of an isolated system increases in the course of a spontaneous change:  $\Delta S_{\text{tot}} > 0$

**Figure 3A.3** The Kelvin statement of the Second Law denies the possibility of the process illustrated here, in which heat is changed completely into work, there being no other change. The process is not in conflict with the First Law because energy is conserved.

**Figure 3A.4** The Clausius statement of the Second Law denies the possibility of the process illustrated here, in which energy as heat migrates from a cool source to a hot sink, there being no other change. The process is not in conflict with the First Law because energy is conserved.

where  $S_{\text{tot}}$  is the total entropy of the system and its surroundings. Thermodynamically irreversible processes (like cooling to the temperature of the surroundings and the free expansion of gases) are spontaneous processes, and hence must be accompanied by an increase in total entropy.

In summary, the First Law uses the internal energy to identify *permissible* changes; the Second Law uses the entropy to identify the *spontaneous changes* among those permissible changes.

## 3A.2 The definition of entropy

To make progress, and to turn the Second Law into a quantitatively useful expression, we need to define and then calculate the entropy change accompanying various processes. There are two approaches, one classical and one molecular. They turn out to be equivalent, but each one enriches the other.

### (a) The thermodynamic definition of entropy

The thermodynamic definition of entropy concentrates on the change in entropy,  $dS$ , that occurs as a result of a physical or chemical change (in general, as a result of a ‘process’). The definition is motivated by the idea that a change in the extent to which energy is dispersed depends on how much energy is transferred as heat. As explained in Topic 2A, heat stimulates random motion in the surroundings. On the other hand, work stimulates uniform motion of atoms in the surroundings and so does not change their entropy.

The thermodynamic definition of entropy is based on the expression

$$dS = \frac{dq_{\text{rev}}}{T} \quad \text{Definition Entropy change} \quad (3A.1)$$

For a measurable change between two states  $i$  and  $f$ ,

$$\Delta S = \int_i^f \frac{dq_{\text{rev}}}{T} \quad (3A.2)$$

That is, to calculate the difference in entropy between any two states of a system, we find a *reversible* path between them, and integrate the energy supplied as heat at each stage of the path divided by the temperature at which heating occurs.

*A note on good practice* According to eqn 3A.1, when the energy transferred as heat is expressed in joules and the temperature is in kelvins, the units of entropy are joules per kelvin ( $\text{J K}^{-1}$ ). Entropy is an extensive property. Molar entropy, the entropy divided by the amount of substance,  $S_{\text{m}} = S/n$ , is expressed in joules per kelvin per mole ( $\text{J K}^{-1} \text{mol}^{-1}$ ). The units of entropy are the same as those of the gas constant,  $R$ , and molar heat capacities. Molar entropy is an intensive property.

### Example 3A.1 Calculating the entropy change for the isothermal expansion of a perfect gas

Calculate the entropy change of a sample of perfect gas when it expands isothermally from a volume  $V_i$  to a volume  $V_f$ .

**Method** The definition of entropy instructs us to find the energy supplied as heat for a reversible path between the stated initial and final states regardless of the actual manner in which the process takes place. A simplification is that the expansion is isothermal, so the temperature is a constant and may be taken outside the integral in eqn 3A.2. The energy absorbed as heat during a reversible isothermal expansion of a perfect gas can be calculated from  $\Delta U = q + w$  and  $\Delta U = 0$ , which implies that  $q = -w$  in general and therefore that  $q_{\text{rev}} = -w_{\text{rev}}$  for a reversible change. The work of reversible isothermal expansion is calculated in Topic 2A. The change in molar entropy is calculated from  $\Delta S_{\text{m}} = \Delta S/n$ .

**Answer** Because the temperature is constant, eqn 3A.2 becomes

$$\Delta S = \frac{1}{T} \int_i^f dq_{\text{rev}} = \frac{q_{\text{rev}}}{T}$$

From Topic 2A we know that

$$q_{\text{rev}} = -w_{\text{rev}} = nRT \ln \frac{V_f}{V_i}$$

It follows that

$$\Delta S = nR \ln \frac{V_f}{V_i} \quad \text{and} \quad \Delta S_{\text{m}} = R \ln \frac{V_f}{V_i}$$

**Self-test 3A.1** Calculate the change in entropy when the pressure of a fixed amount of perfect gas is changed isothermally from  $p_i$  to  $p_f$ . What is this change due to?

Answer:  $\Delta S = nR \ln(p_i/p_f)$ ; the change in volume when the gas is compressed or expands

The definition in eqn 3A.1 is used to formulate an expression for the change in entropy of the surroundings,  $\Delta S_{\text{sur}}$ . Consider an infinitesimal transfer of heat  $dq_{\text{sur}}$  to the surroundings. The surroundings consist of a reservoir of constant volume, so the energy supplied to them by heating can be identified with the change in the internal energy of the surroundings,  $dU_{\text{sur}}$ .<sup>2</sup> The internal energy is a state function, and  $dU_{\text{sur}}$  is an exact differential. These properties imply that  $dU_{\text{sur}}$  is independent of how the change is brought about and in particular is independent of whether the process is reversible or irreversible. The same remarks therefore apply to  $dq_{\text{sur}}$ , to which  $dU_{\text{sur}}$  is equal. Therefore, we can adapt the definition in eqn 3A.1, delete the constraint ‘reversible’, and write

$$dS = \frac{dq_{\text{rev,sur}}}{T_{\text{sur}}} = \frac{dq_{\text{sur}}}{T_{\text{sur}}} \quad \text{Entropy change of the surroundings} \quad (3A.3a)$$

Furthermore, because the temperature of the surroundings is constant whatever the change, for a measurable change

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T_{\text{sur}}} \quad (3A.3b)$$

That is, regardless of how the change is brought about in the system, reversibly or irreversibly, we can calculate the change of entropy of the surroundings by dividing the heat transferred by the temperature at which the transfer takes place.

Equation 3A.3 makes it very simple to calculate the changes in entropy of the surroundings that accompany any process. For instance, for any adiabatic change,  $q_{\text{sur}} = 0$ , so

$$\Delta S_{\text{sur}} = 0 \quad \text{Adiabatic change} \quad (3A.4)$$

This expression is true however the change takes place, reversibly or irreversibly, provided no local hot spots are formed in the surroundings. That is, it is true so long as the surroundings remain in internal equilibrium. If hot spots do form, then the localized energy may subsequently disperse spontaneously and hence generate more entropy.

### Brief illustration 3A.1 The entropy change of the surroundings

To calculate the entropy change in the surroundings when 1.00 mol  $\text{H}_2\text{O}(\text{l})$  is formed from its elements under standard conditions at 298 K, we use  $\Delta H^\ominus = -286 \text{ kJ}$  from Table 2C.2. The energy released as heat is supplied to the surroundings, now regarded as being at constant pressure, so  $q_{\text{sur}} = +286 \text{ kJ}$ . Therefore,

$$\Delta S_{\text{sur}} = \frac{2.86 \times 10^5 \text{ J mol}^{-1}}{298 \text{ K}} = +960 \text{ J K}^{-1}$$

<sup>2</sup> Alternatively, the surroundings can be regarded as being at constant pressure, in which case we could equate  $dq_{\text{sur}}$  to  $dH_{\text{sur}}$ .

This strongly exothermic reaction results in an increase in the entropy of the surroundings as energy is released as heat into them.

**Self-test 3A.2** Calculate the entropy change in the surroundings when 1.00 mol  $\text{N}_2\text{O}_4(\text{g})$  is formed from 2.00 mol  $\text{NO}_2(\text{g})$  under standard conditions at 298 K.

Answer:  $-192 \text{ J K}^{-1}$

We are now in a position to see how the definition of entropy is consistent with Kelvin’s and Clausius’s statements of the Second Law. In the arrangement shown in Fig. 3A.3, the entropy of the hot source is reduced as energy leaves it as heat, but no other change in entropy occurs (the transfer of energy as work does not result in the production of entropy); consequently the arrangement does not produce work. In Clausius version, the entropy of the cold source in Fig 3A.4 decreases when a certain quantity of energy leaves it as heat, but when that heat enters the hot sink the rise in entropy is not as great. Therefore, overall there is a decrease in entropy: the process is not spontaneous.

## (b) The statistical definition of entropy

The entry point into the molecular interpretation of the Second Law of thermodynamics is Boltzmann’s insight, first mentioned in *Foundations* B, that an atom or molecule can possess only certain values of the energy, called its ‘energy levels’. The continuous thermal agitation that molecules experience at  $T > 0$  ensures that they are distributed over the available energy levels. Boltzmann also made the link between the distribution of molecules over energy levels and the entropy. He proposed that the entropy of a system is given by

$$S = k \ln \mathcal{W} \quad \text{Boltzmann formula for the entropy} \quad (3A.5)$$

where  $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$  and  $\mathcal{W}$  is the number of **microstates**, the number of ways in which the molecules of a system can be arranged while keeping the total energy constant. Each microstate lasts only for an instant and corresponds to a certain distribution of molecules over the available energy levels. When we measure the properties of a system, we are measuring an average taken over the many microstates the system can occupy under the conditions of the experiment. The concept of the number of microstates makes quantitative the ill-defined qualitative concepts of ‘disorder’ and ‘the dispersal of matter and energy’ that are used widely to introduce the concept of entropy: a more disorderly distribution of matter and a greater dispersal of energy corresponds to a greater number of microstates associated with the same total energy. This point is discussed in much greater detail in Topic 15E.

Equation 3A.5 is known as the **Boltzmann formula** and the entropy calculated from it is sometimes called the **statistical**

**entropy.** We see that if  $\mathcal{W}=1$ , which corresponds to one microstate (only one way of achieving a given energy, all molecules in exactly the same state), then  $S=0$  because  $\ln 1=0$ . However, if the system can exist in more than one microstate, then  $\mathcal{W}>1$  and  $S>0$ . If the molecules in the system have access to a greater number of energy levels, then there may be more ways of achieving a given total energy; that is, there are more microstates for a given total energy,  $\mathcal{W}$  is greater, and the entropy is greater than when fewer states are accessible. Therefore, the statistical view of entropy summarized by the Boltzmann formula is consistent with our previous statement that the entropy is related to the dispersal of energy and matter. In particular, for a gas of particles in a container, the energy levels become closer together as the container expands (Fig. 3A.5; this is a conclusion from quantum theory that is verified in Topic 8A). As a result, more microstates become possible,  $\mathcal{W}$  increases, and the entropy increases, exactly as we inferred from the thermodynamic definition of entropy.

### Brief illustration 3A.2 The Boltzmann formula

Suppose that each diatomic molecule in a solid sample can be arranged in either of two orientations and that there are  $N=6.022 \times 10^{23}$  molecules in the sample (that is, 1 mol of molecules). Then  $\mathcal{W}=2^N$  and the entropy of the sample is

$$S = k \ln 2^N = Nk \ln 2 = (6.022 \times 10^{23}) \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \ln 2 = 5.76 \text{ J K}^{-1}$$

**Self-test 3A.3** What is the molar entropy of a similar system in which each molecule can be arranged in four different orientations?

Answer:  $11.5 \text{ J K}^{-1} \text{ mol}^{-1}$

The molecular interpretation of entropy advanced by Boltzmann also suggests the thermodynamic definition given

**Figure 3A.5** When a box expands, the energy levels move closer together and more become accessible to the molecules. As a result the number of ways of achieving the same energy (the value of  $\mathcal{W}$ ) increases, and so therefore does the entropy.

by eqn 3A.1. To appreciate this point, consider that molecules in a system at high temperature can occupy a large number of the available energy levels, so a small additional transfer of energy as heat will lead to a relatively small change in the number of accessible energy levels. Consequently, the number of microstates does not increase appreciably and neither does the entropy of the system. In contrast, the molecules in a system at low temperature have access to far fewer energy levels (at  $T=0$ , only the lowest level is accessible), and the transfer of the same quantity of energy by heating will increase the number of accessible energy levels and the number of microstates significantly. Hence, the change in entropy upon heating will be greater when the energy is transferred to a cold body than when it is transferred to a hot body. This argument suggests that the change in entropy for a given transfer of energy as heat should be greater at low temperatures than at high, as in eqn 3A.1.

### 3A.3 The entropy as a state function

Entropy is a state function. To prove this assertion, we need to show that the integral of  $dS$  is independent of path. To do so, it is sufficient to prove that the integral of eqn 3A.1 around an arbitrary cycle is zero, for that guarantees that the entropy is the same at the initial and final states of the system regardless of the path taken between them (Fig. 3A.6). That is, we need to show that

$$\oint dS = \oint \frac{dq_{\text{rev}}}{T} = 0 \quad (3A.6)$$

where the symbol  $\oint$  denotes integration around a closed path. There are three steps in the argument:

1. First, to show that eqn 3A.6 is true for a special cycle (a 'Carnot cycle') involving a perfect gas.

**Figure 3A.6** In a thermodynamic cycle, the overall change in a state function (from the initial state to the final state and then back to the initial state again) is zero.

- Then to show that the result is true whatever the working substance.
- Finally, to show that the result is true for any cycle.

### (a) The Carnot cycle

A **Carnot cycle**, which is named after the French engineer Sadi Carnot, consists of four reversible stages (Fig. 3A.7):

- Reversible isothermal expansion from A to B at  $T_h$ ; the entropy change is  $q_h/T_h$ , where  $q_h$  is the energy supplied to the system as heat from the hot source.
- Reversible adiabatic expansion from B to C. No energy leaves the system as heat, so the change in entropy is zero. In the course of this expansion, the temperature falls from  $T_h$  to  $T_c$ , the temperature of the cold sink.
- Reversible isothermal compression from C to D at  $T_c$ . Energy is released as heat to the cold sink; the change in entropy of the system is  $q_c/T_c$ ; in this expression  $q_c$  is negative.
- Reversible adiabatic compression from D to A. No energy enters the system as heat, so the change in entropy is zero. The temperature rises from  $T_c$  to  $T_h$ .

The total change in entropy around the cycle is the sum of the changes in each of these four steps:

$$\oint dS = \frac{q_h}{T_h} + \frac{q_c}{T_c}$$

However, we show in the following *Justification* that for a perfect gas

**Figure 3A.7** The basic structure of a Carnot cycle. In Step 1, there is isothermal reversible expansion at the temperature  $T_h$ . Step 2 is a reversible adiabatic expansion in which the temperature falls from  $T_h$  to  $T_c$ . In Step 3 there is an isothermal reversible compression at  $T_c$ , and that isothermal step is followed by an adiabatic reversible compression, which restores the system to its initial state.

$$\frac{q_h}{q_c} = -\frac{T_h}{T_c} \quad (3A.7)$$

Substitution of this relation into the preceding equation gives zero on the right, which is what we wanted to prove.

#### Justification 3A.1 Heating accompanying reversible adiabatic expansion

This *Justification* is based on two features of the cycle. One feature is that the two temperatures  $T_h$  and  $T_c$  in eqn 3A.7 lie on the same adiabat in Fig. 3A.7. The second feature is that the energy transferred as heat during the two isothermal stages are

$$q_h = nRT_h \ln \frac{V_B}{V_A} \quad q_c = nRT_c \ln \frac{V_D}{V_C}$$

We now show that the two volume ratios are related in a very simple way. From the relation between temperature and volume for reversible adiabatic processes ( $VT^\gamma = \text{constant}$ , Topic 2D):

$$V_A T_h^\gamma = V_D T_c^\gamma \quad V_C T_c^\gamma = V_B T_h^\gamma$$

Multiplication of the first of these expressions by the second gives

$$V_A V_C T_h^\gamma T_c^\gamma = V_D V_B T_h^\gamma T_c^\gamma$$

which, on cancellation of the temperatures, simplifies to

$$\frac{V_D}{V_C} = \frac{V_A}{V_B}$$

With this relation established, we can write

$$q_c = nRT_c \ln \frac{V_D}{V_C} = nRT_c \ln \frac{V_A}{V_B} = -nRT_c \ln \frac{V_B}{V_A}$$

and therefore

$$\frac{q_h}{q_c} = \frac{nRT_h \ln(V_B/V_A)}{-nRT_c \ln(V_B/V_A)} = -\frac{T_h}{T_c}$$

as in eqn 3A.7. For clarification, note that  $q_h$  is negative (heat is withdrawn from the hot source) and  $q_c$  is positive (heat is deposited in the cold sink), so their ratio is negative.

#### Brief illustration 3A.3 The Carnot cycle

The Carnot cycle can be regarded as a representation of the changes taking place in an actual idealized engine, where heat is converted into work. (However, other cycles are closer approximations to real engines.) In an engine running in accord with the Carnot cycle, 100 J of energy is withdrawn

from the hot source ( $q_h = -100$  J) at 500 K and some is used to do work, with the remainder deposited in the cold sink at 300 K. According to eqn 3A.7, the amount of heat deposited is

$$q_c = -q_h \times \frac{T_c}{T_h} = -(-100 \text{ J}) \times \frac{300 \text{ K}}{500 \text{ K}} = +60 \text{ J}$$

That means that 40 J was used to do work.

**Self-test 3A.4** How much work can be extracted when the temperature of the hot source is increased to 800 K?

Answer: 62 J

In the second step we need to show that eqn 3A.6 applies to any material, not just a perfect gas (which is why, in anticipation, we have not labelled it in blue). We begin this step of the argument by introducing the **efficiency**,  $\eta$  (eta), of a heat engine:

$$\eta = \frac{\text{work performed}}{\text{heat absorbed from hot source}} = \frac{|w|}{|q_h|} \quad \text{Definition of efficiency} \quad (3A.8)$$

We are using modulus signs to avoid complications with signs: all efficiencies are positive numbers. The definition implies that the greater the work output for a given supply of heat from the hot reservoir, the greater is the efficiency of the engine. We can express the definition in terms of the heat transactions alone, because (as shown in Fig. 3A.8), the energy supplied as work by the engine is the difference between the energy supplied as heat by the hot reservoir and returned to the cold reservoir:

$$\eta = \frac{|q_h| - |q_c|}{|q_h|} = 1 - \frac{|q_c|}{|q_h|} \quad (3A.9)$$

**Figure 3A.8** Suppose an energy  $q_h$  (for example, 20 kJ) is supplied to the engine and  $q_c$  is lost from the engine (for example,  $q_c = -15$  kJ) and discarded into the cold reservoir. The work done by the engine is equal to  $q_h + q_c$  (for example,  $20 \text{ kJ} + (-15 \text{ kJ}) = 5 \text{ kJ}$ ). The efficiency is the work done divided by the energy supplied as heat from the hot source.

It then follows from eqn 3A.7 written as  $|q_c|/|q_h| = T_c/T_h$  (see the concluding remark in *Justification 3A.1*) that

$$\eta = 1 - \frac{T_c}{T_h} \quad \text{Carnot efficiency} \quad (3A.10)$$

#### Brief illustration 3A.4 Thermal efficiency

A certain power station operates with superheated steam at 300 °C ( $T_h = 573$  K) and discharges the waste heat into the environment at 20 °C ( $T_c = 293$  K). The theoretical efficiency is therefore

$$\eta = 1 - \frac{293 \text{ K}}{573 \text{ K}} = 0.489, \text{ or } 48.9 \text{ per cent}$$

In practice, there are other losses due to mechanical friction and the fact that the turbines do not operate reversibly.

**Self-test 3A.5** At what temperature of the hot source would the theoretical efficiency reach 80 per cent?

Answer: 1465 K

Now we are ready to generalize this conclusion. The Second Law of thermodynamics implies that *all reversible engines have the same efficiency regardless of their construction*. To see the truth of this statement, suppose two reversible engines are coupled together and run between the same two reservoirs (Fig. 3A.9). The working substances and details of construction of the two engines are entirely arbitrary. Initially, suppose that engine A is more efficient than engine B, and that we choose a setting of the controls that causes engine B to acquire energy as heat  $q_c$  from the cold reservoir and to release a certain

**Figure 3A.9** (a) The demonstration of the equivalence of the efficiencies of all reversible engines working between the same thermal reservoirs is based on the flow of energy represented in this diagram. (b) The net effect of the processes is the conversion of heat into work without there being a need for a cold sink: this is contrary to the Kelvin statement of the Second Law.

quantity of energy as heat into the hot reservoir. However, because engine A is more efficient than engine B, not all the work that A produces is needed for this process, and the difference can be used to do work. The net result is that the cold reservoir is unchanged, work has been done, and the hot reservoir has lost a certain amount of energy. This outcome is contrary to the Kelvin statement of the Second Law, because some heat has been converted directly into work. In molecular terms, the random thermal motion of the hot reservoir has been converted into ordered motion characteristic of work. Because the conclusion is contrary to experience, the initial assumption that engines A and B can have different efficiencies must be false. It follows that the relation between the heat transfers and the temperatures must also be independent of the working material, and therefore that eqn 3A.10 is always true for any substance involved in a Carnot cycle.

For the final step in the argument, we note that any reversible cycle can be approximated as a collection of Carnot cycles and the integral around an arbitrary path is the sum of the integrals around each of the Carnot cycles (Fig. 3A.10). This approximation becomes exact as the individual cycles are allowed to become infinitesimal. The entropy change around each individual cycle is zero (as demonstrated above), so the sum of entropy changes for all the cycles is zero. However, in the sum, the entropy change along any individual path is cancelled by the entropy change along the path it shares with the neighbouring cycle. Therefore, all the entropy changes cancel except for those along the perimeter of the overall cycle. That is,

$$\sum_{\text{all}} \frac{q_{\text{rev}}}{T} = \sum_{\text{perimeter}} \frac{q_{\text{rev}}}{T} = 0$$

In the limit of infinitesimal cycles, the non-cancelling edges of the Carnot cycles match the overall cycle exactly, and the sum

**Figure 3A.10** A general cycle can be divided into small Carnot cycles. The match is exact in the limit of infinitesimally small cycles. Paths cancel in the interior of the collection, and only the perimeter, an increasingly good approximation to the true cycle as the number of cycles increases, survives. Because the entropy change around every individual cycle is zero, the integral of the entropy around the perimeter is zero too.

becomes an integral. Equation 3A.6 then follows immediately. This result implies that  $dS$  is an exact differential and therefore that  $S$  is a state function.

### (b) The thermodynamic temperature

Suppose we have an engine that is working reversibly between a hot source at a temperature  $T_h$  and a cold sink at a temperature  $T$ , then we know from eqn 3A.10 that

$$T = (1 - \eta)T_h \quad (3A.11)$$

This expression enabled Kelvin to define the **thermodynamic temperature scale** in terms of the efficiency of a heat engine: we construct an engine in which the hot source is at a known temperature and the cold sink is the object of interest. The temperature of the latter can then be inferred from the measured efficiency of the engine. The **Kelvin scale** (which is a special case of the thermodynamic temperature scale) is currently defined by using water at its triple point as the notional hot source and defining that temperature as 273.16 K exactly.<sup>3</sup>

#### Brief illustration 3A.5 The thermodynamic temperature

A heat engine was constructed that used a hot source at the triple point temperature of water and used as a cold source a cooled liquid. The efficiency of the engine was measured as 0.400. The temperature of the liquid is therefore

$$T = (1 - 0.400) \times (273.16 \text{ K}) = 164 \text{ K}$$

**Self-test 3A.6** What temperature would be reported for the hot source if a thermodynamic efficiency of 0.500 was measured when the cold sink was at 273.16 K?

Answer: 546 K

### (c) The Clausius inequality

We now show that the definition of entropy is consistent with the Second Law. To begin, we recall that more work is done when a change is reversible than when it is irreversible. That is,  $|dw_{\text{rev}}| \geq |dw|$ . Because  $dw$  and  $dw_{\text{rev}}$  are negative when energy leaves the system as work, this expression is the same as  $-dw_{\text{rev}} \geq -dw$ , and hence  $dw - dw_{\text{rev}} \geq 0$ . Because the internal energy is a state function, its change is the same for irreversible and reversible paths between the same two states, so we can also write:

$$dU = dq + dw = dq_{\text{rev}} + dw_{\text{rev}}$$

<sup>3</sup> Discussions are in progress to replace this definition by another that is independent of the specification of a particular substance.

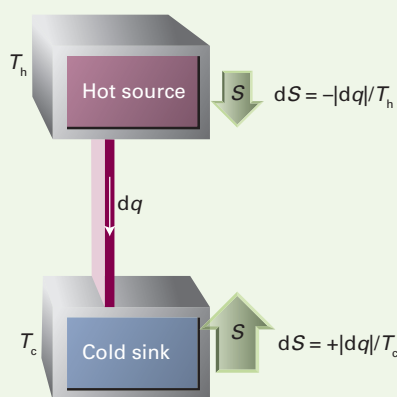

It follows that  $dq_{\text{rev}} - dq = dw - dw_{\text{rev}} \geq 0$ , or  $dq_{\text{rev}} \geq dq$ , and therefore that  $dq_{\text{rev}}/T \geq dq/T$ . Now we use the thermodynamic definition of the entropy (eqn 3A.1;  $dS = dq_{\text{rev}}/T$ ) to write

$$dS \geq \frac{dq}{T} \quad \text{Clausius inequality} \quad (3A.12)$$

This expression is the **Clausius inequality**. It proves to be of great importance for the discussion of the spontaneity of chemical reactions, as is shown in Topic 3C.

### Brief illustration 3A.6 The Clausius inequality

Consider the transfer of energy as heat from one system—the hot source—at a temperature  $T_h$  to another system—the cold sink—at a temperature  $T_c$  (Fig. 3A.11).

**Figure 3A.11** When energy leaves a hot reservoir as heat, the entropy of the reservoir decreases. When the same quantity of energy enters a cooler reservoir, the entropy increases by a larger amount. Hence, overall there is an increase in entropy and the process is spontaneous. Relative changes in entropy are indicated by the sizes of the arrows.

When  $|dq|$  leaves the hot source (so  $dq_h < 0$ ), the Clausius inequality implies that  $dS \geq dq_h/T_h$ . When  $|dq|$  enters the cold sink the Clausius inequality implies that  $dS \geq dq_c/T_c$  (with  $dq_c > 0$ ). Overall, therefore,

$$dS \geq \frac{dq_h}{T_h} + \frac{dq_c}{T_c}$$

However,  $dq_h = -dq_c$ , so

$$dS \geq -\frac{dq_c}{T_h} + \frac{dq_c}{T_c} = \left( \frac{1}{T_c} - \frac{1}{T_h} \right) dq_c$$

which is positive (because  $dq_c > 0$  and  $T_h \geq T_c$ ). Hence, cooling (the transfer of heat from hot to cold) is spontaneous, as we know from experience.

**Self-test 3A.7** What is the change in entropy when 1.0 J of energy as heat transfers from a large block of iron at 30 °C to another large block at 20 °C?

Answer: +0.1 mJ K<sup>-1</sup>

We now suppose that the system is isolated from its surroundings, so that  $dq = 0$ . The Clausius inequality implies that

$$dS \geq 0 \quad (3A.13)$$

and we conclude that *in an isolated system the entropy cannot decrease when a spontaneous change occurs*. This statement captures the content of the Second Law.

## 3A.4 Entropy changes accompanying specific processes

We now see how to calculate the entropy changes that accompany a variety of basic processes.

### (a) Expansion

We established in *Example 3A.1* that the change in entropy of a perfect gas that expands isothermally from  $V_i$  to  $V_f$  is

$$\Delta S = nR \ln \frac{V_f}{V_i} \quad \text{Entropy change for the isothermal expansion of a perfect gas} \quad (3A.14)$$

Because  $S$  is a state function, the value of  $\Delta S$  of the system is independent of the path between the initial and final states, so this expression applies whether the change of state occurs reversibly or irreversibly. The logarithmic dependence of entropy on volume is illustrated in Fig. 3A.12.

The *total* change in entropy, however, does depend on how the expansion takes place. For any process the energy lost as heat from the system is acquired by the surroundings, so  $dq_{\text{sur}} = -dq$ . For a reversible change we use the expression in *Example 3A.1* ( $q_{\text{rev}} = nRT \ln(V_f/V_i)$ ); consequently, from eqn 3A.3b

$$\Delta S_{\text{sur}} = \frac{q_{\text{sur}}}{T} = -\frac{q_{\text{rev}}}{T} = -nR \ln \frac{V_f}{V_i} \quad (3A.15)$$

**Figure 3A.12** The logarithmic increase in entropy of a perfect gas as it expands isothermally.

This change is the negative of the change in the system, so we can conclude that  $\Delta S_{\text{tot}}=0$ , which is what we should expect for a reversible process. If, on the other hand, the isothermal expansion occurs freely ( $w=0$ ), then  $q=0$  (because  $\Delta U=0$ ). Consequently,  $\Delta S_{\text{surr}}=0$ , and the total entropy change is given by eqn 3A.17 itself:

$$\Delta S_{\text{tot}} = nR \ln \frac{V_f}{V_i} \quad (3A.16)$$

In this case,  $\Delta S_{\text{tot}} > 0$ , as we expect for an irreversible process.

### Brief illustration 3A.7 Entropy of expansion

When the volume of any perfect gas is doubled at any constant temperature,  $V_f/V_i=2$  and the change in molar entropy of the system is

$$\Delta S_m = (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times \ln 2 = +5.76 \text{ J K}^{-1} \text{ mol}^{-1}$$

If the change is carried out reversibly, the change in entropy of the surroundings is  $-5.76 \text{ J K}^{-1} \text{ mol}^{-1}$  (the ‘per mole’ meaning per mole of gas molecules in the sample). The total change in entropy is 0. If the expansion is free, the change in molar entropy of the gas is still  $+5.76 \text{ J K}^{-1} \text{ mol}^{-1}$ , but that of the surroundings is 0, and the total change is  $+5.76 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Self-test 3A.8** Calculate the change in entropy when a perfect gas expands isothermally to 10 times its initial volume (a) reversibly, (b) irreversibly against zero pressure.

Answer: (a)  $\Delta S_m = +19 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $\Delta S_{\text{surr}} = -19 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $\Delta S_{\text{tot}} = 0$ ;  
(b)  $\Delta S_m = +19 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $\Delta S_{\text{surr}} = 0$ ,  $\Delta S_{\text{tot}} = +19 \text{ J K}^{-1} \text{ mol}^{-1}$

## (b) Phase transitions

The degree of dispersal of matter and energy changes when a substance freezes or boils as a result of changes in the order with which the molecules pack together and the extent to which the energy is localized or dispersed. Therefore, we should expect the transition to be accompanied by a change in entropy. For example, when a substance vaporizes, a compact condensed phase changes into a widely dispersed gas and we can expect the entropy of the substance to increase considerably. The entropy of a solid also increases when it melts to a liquid and when that liquid turns into a gas.

Consider a system and its surroundings at the **normal transition temperature**,  $T_{\text{trs}}$ , the temperature at which two phases are in equilibrium at 1 atm. This temperature is  $0^\circ\text{C}$  (273 K) for ice in equilibrium with liquid water at 1 atm, and  $100^\circ\text{C}$  (373 K) for water in equilibrium with its vapour at 1 atm. At the transition temperature, any transfer of energy as heat between the system and its surroundings is reversible because the two phases in the system are in equilibrium. Because at

constant pressure  $q = \Delta_{\text{trs}}H$ , the change in molar entropy of the system is<sup>4</sup>

$$\Delta_{\text{trs}}S = \frac{\Delta_{\text{trs}}H}{T_{\text{trs}}} \quad \begin{array}{l} \text{At the} \\ \text{transition} \\ \text{temperature} \end{array} \quad \begin{array}{l} \text{Entropy} \\ \text{of phase} \\ \text{transition} \end{array} \quad (3A.17)$$

If the phase transition is exothermic ( $\Delta_{\text{trs}}H < 0$ , as in freezing or condensing), then the entropy change of the system is negative. This decrease in entropy is consistent with the increased order of a solid compared with a liquid and with the increased order of a liquid compared with a gas. The change in entropy of the surroundings, however, is positive because energy is released as heat into them, and at the transition temperature the total change in entropy is zero. If the transition is endothermic ( $\Delta_{\text{trs}}H > 0$ , as in melting and vaporization), then the entropy change of the system is positive, which is consistent with dispersal of matter in the system. The entropy of the surroundings decreases by the same amount, and overall the total change in entropy is zero.

Table 3A.1 lists some experimental entropies of transition. Table 3A.2 lists in more detail the standard entropies of vaporization of several liquids at their boiling points. An interesting feature of the data is that a wide range of liquids give approximately the same standard entropy of vaporization (about  $85 \text{ J K}^{-1} \text{ mol}^{-1}$ ): this empirical observation is called

**Table 3A.1\*** Standard entropies (and temperatures) of phase transitions,  $\Delta_{\text{trs}}S^\ominus / (\text{J K}^{-1} \text{ mol}^{-1})$

	Fusion (at $T_f$ )	Vaporization (at $T_b$ )
Argon, Ar	14.17 (at 83.8 K)	74.53 (at 87.3 K)
Benzene, C <sub>6</sub> H <sub>6</sub>	38.00 (at 279 K)	87.19 (at 353 K)
Water, H <sub>2</sub> O	22.00 (at 273.15 K)	109.0 (at 373.15 K)
Helium, He	4.8 (at 8 K and 30 bar)	19.9 (at 4.22 K)

\* More values are given in the *Resource section*.

**Table 3A.2\*** The standard enthalpies and entropies of vaporization of liquids at their normal boiling points

	$\Delta_{\text{vap}}H^\ominus / (\text{kJ mol}^{-1})$	$\theta_b / ^\circ\text{C}$	$\Delta_{\text{vap}}S^\ominus / (\text{J K}^{-1} \text{ mol}^{-1})$
Benzene	30.8	80.1	87.2
Carbon tetrachloride	30	76.7	85.8
Cyclohexane	30.1	80.7	85.1
Hydrogen sulfide	18.7	-60.4	87.9
Methane	8.18	-161.5	73.2
Water	40.7	100.0	109.1

\* More values are given in the *Resource section*.

<sup>4</sup> According to Topic 2C,  $\Delta_{\text{trs}}H$  is an enthalpy change per mole of substance; so  $\Delta_{\text{trs}}S$  is also a molar quantity.

**Trouton's rule.** The explanation of Trouton's rule is that a comparable change in volume occurs when any liquid evaporates and becomes a gas. Hence, all liquids can be expected to have similar standard entropies of vaporization. Liquids that show significant deviations from Trouton's rule do so on account of strong molecular interactions that result in a partial ordering of their molecules. As a result, there is a greater change in disorder when the liquid turns into a vapour than for a fully disordered liquid. An example is water, where the large entropy of vaporization reflects the presence of structure arising from hydrogen-bonding in the liquid. Hydrogen bonds tend to organize the molecules in the liquid so that they are less random than, for example, the molecules in liquid hydrogen sulfide (in which there is no hydrogen bonding). Methane has an unusually low entropy of vaporization. A part of the reason is that the entropy of the gas itself is slightly low ( $186 \text{ J K}^{-1} \text{ mol}^{-1}$  at  $298 \text{ K}$ ); the entropy of  $\text{N}_2$  under the same conditions is  $192 \text{ J K}^{-1} \text{ mol}^{-1}$ . As explained in Topic 12B, fewer rotational states are accessible at room temperature for molecules with low moments of inertia (like  $\text{CH}_4$ ) than for molecules with relatively high moments of inertia (like  $\text{N}_2$ ), so their molar entropy is slightly lower.

#### Brief illustration 3A.8 Trouton's rule

There is no hydrogen bonding in liquid bromine and  $\text{Br}_2$  is a heavy molecule that is unlikely to display unusual behaviour in the gas phase, so it is safe to use Trouton's rule. To predict the standard molar enthalpy of vaporization of bromine given that it boils at  $59.2^\circ\text{C}$ , we use the rule in the form

$$\Delta_{\text{vap}}H^\ominus = T_b \times (85 \text{ J K}^{-1} \text{ mol}^{-1})$$

Substitution of the data then gives

$$\begin{aligned} \Delta_{\text{vap}}H^\ominus &= (332.4 \text{ K}) \times (85 \text{ J K}^{-1} \text{ mol}^{-1}) = +2.8 \times 10^3 \text{ J mol}^{-1} \\ &= +28 \text{ kJ mol}^{-1} \end{aligned}$$

The experimental value is  $+29.45 \text{ kJ mol}^{-1}$ .

**Self-test 3A.9** Predict the enthalpy of vaporization of ethane from its boiling point,  $-88.6^\circ\text{C}$ .

Answer:  $16 \text{ kJ mol}^{-1}$

### (c) Heating

Equation 3A.2 can be used to calculate the entropy of a system at a temperature  $T_f$  from a knowledge of its entropy at another temperature  $T_i$  and the heat supplied to change its temperature from one value to the other:

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{dq_{\text{rev}}}{T} \quad (3A.18)$$

We shall be particularly interested in the entropy change when the system is subjected to constant pressure (such as from the atmosphere) during the heating. Then, from the definition of constant-pressure heat capacity (eqn 2B.5,  $C_p = (\partial H/\partial T)_p$ , written as  $dq_{\text{rev}} = C_p dT$ ):

$$S(T_f) = S(T_i) + \int_{T_i}^{T_f} \frac{C_p dT}{T} \quad \begin{array}{l} \text{Constant} \\ \text{pressure} \end{array} \quad \begin{array}{l} \text{Entropy variation} \\ \text{with temperature} \end{array} \quad (3A.19)$$

The same expression applies at constant volume, but with  $C_p$  replaced by  $C_v$ . When  $C_p$  is independent of temperature in the temperature range of interest, it can be taken outside the integral and we obtain

$$S(T_f) = S(T_i) + C_p \int_{T_i}^{T_f} \frac{dT}{T} = S(T_i) + C_p \ln \frac{T_f}{T_i} \quad (3A.20)$$

with a similar expression for heating at constant volume. The logarithmic dependence of entropy on temperature is illustrated in Fig. 3A.13.

#### Brief illustration 3A.9 Entropy change on heating

The molar constant-volume heat capacity of water at  $298 \text{ K}$  is  $75.3 \text{ J K}^{-1} \text{ mol}^{-1}$ . The change in molar entropy when it is heated from  $20^\circ\text{C}$  ( $293 \text{ K}$ ) to  $50^\circ\text{C}$  ( $323 \text{ K}$ ), supposing the heat capacity to be constant in that range, is therefore

$$\begin{aligned} \Delta S_m &= S_m(323 \text{ K}) - S_m(293 \text{ K}) = (75.3 \text{ J K}^{-1} \text{ mol}^{-1}) \times \ln \frac{323 \text{ K}}{293 \text{ K}} \\ &= +7.34 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

**Self-test 3A.10** What is the change when further heating takes the temperature from  $50^\circ\text{C}$  to  $80^\circ\text{C}$ ?

Answer:  $+5.99 \text{ J K}^{-1} \text{ mol}^{-1}$

**Figure 3A.13** The logarithmic increase in entropy of a substance as it is heated at constant volume. Different curves correspond to different values of the heat capacity (which is assumed constant over the temperature range) expressed as  $C_m/R$ .

**(d) Composite processes**

In many cases, more than one parameter changes. For instance, it might be the case that both the volume and the temperature of a gas are different in the initial and final states. Because  $S$  is a state function, we are free to choose the most convenient path from the initial state to the final state, such as reversible isothermal expansion to the final volume, followed by reversible heating at constant volume to the final temperature. Then the total entropy change is the sum of the two contributions.

**Example 3A.2** Calculating the entropy change for a composite process

Calculate the entropy change when argon at 25 °C and 1.00 bar in a container of volume 0.500 dm<sup>3</sup> is allowed to expand to 1.000 dm<sup>3</sup> and is simultaneously heated to 100 °C.

**Method** As remarked in the text, use reversible isothermal expansion to the final volume, followed by reversible heating at constant volume to the final temperature. The entropy change in the first step is given by eqn 3A.16 and that of the second step, provided  $C_V$  is independent of temperature, by eqn 3A.20 (with  $C_V$  in place of  $C_p$ ). In each case we need to know  $n$ , the amount of gas molecules, and can calculate it from the perfect gas equation and the data for the initial state from  $n = p_i V_i / RT_i$ . The molar heat capacity at constant volume is given by the equipartition theorem as  $\frac{3}{2}R$ . (The equipartition theorem is reliable for monatomic gases; for others and in general use experimental data like that in Tables 2C.1 and 2C.2 of the *Resource section*, converting to the value at constant volume by using the relation  $C_{p,m} - C_{v,m} = R$ .)

**Answer** From eqn 3A.16 the entropy change in the isothermal expansion from  $V_i$  to  $V_f$  is

$$\Delta S(\text{Step 1}) = nR \ln \frac{V_f}{V_i}$$

From eqn 3A.20, the entropy change in the second step, from  $T_i$  to  $T_f$  at constant volume, is

$$\Delta S(\text{Step 2}) = nC_{V,m} \ln \frac{T_f}{T_i} = \frac{3}{2} nR \ln \frac{T_f}{T_i} = nR \ln \left( \frac{T_f}{T_i} \right)^{3/2}$$

The overall entropy change of the system, the sum of these two changes, is

$$\Delta S = nR \ln \frac{V_f}{V_i} + nR \ln \left( \frac{T_f}{T_i} \right)^{3/2} = nR \ln \frac{V_f}{V_i} \left( \frac{T_f}{T_i} \right)^{3/2}$$

(We have used  $\ln x + \ln y = \ln xy$ .) Now we substitute  $n = p_i V_i / RT_i$  and obtain

$$\Delta S = \frac{p_i V_i}{T_i} \ln \frac{V_f}{V_i} \left( \frac{T_f}{T_i} \right)^{3/2}$$

At this point we substitute the data:

$$\begin{aligned} \Delta S &= \frac{(1.00 \times 10^5 \text{ Pa}) \times (0.500 \times 10^{-3} \text{ m}^3)}{298 \text{ K}} \times \ln \frac{1.000}{0.500} \left( \frac{373}{298} \right)^{3/2} \\ &= +0.173 \text{ J K}^{-1} \end{aligned}$$

*A note on good practice* It is sensible to proceed as generally as possible before inserting numerical data so that, if required, the formula can be used for other data and to avoid rounding errors.

**Self-test 3A.11** Calculate the entropy change when the same initial sample is compressed to 0.0500 dm<sup>3</sup> and cooled to -25 °C.

Answer: -0.44 J K<sup>-1</sup>

## Checklist of concepts

- 1. The **entropy** acts as a signpost of spontaneous change.
- 2. Entropy change is defined in terms of heat transactions (the **Clausius definition**).
- 3. The **Boltzmann formula** defines absolute entropies in terms of the number of ways of achieving a configuration.
- 4. The **Carnot cycle** is used to prove that entropy is a state function.
- 5. The **efficiency** of a heat engine is the basis of the definition of the thermodynamic temperature scale and one realization, the Kelvin scale.
- 6. The **Clausius inequality** is used to show that the entropy increases in a spontaneous change and therefore that the Clausius definition is consistent with the Second Law.
- 7. The entropy of a perfect gas increases when it expands isothermally.
- 8. The change in entropy of a substance accompanying a change of state at its transition temperature is calculated from its enthalpy of transition.
- 9. The increase in entropy when a substance is heated is expressed in terms of its heat capacity.

## Checklist of equations

Property	Equation	Comment	Equation number
Thermodynamic entropy	$dS = dq_{\text{rev}}/T$	Definition	3A.1
Entropy change of surroundings	$\Delta S_{\text{sur}} = q_{\text{sur}}/T_{\text{sur}}$		3A.3b
Boltzmann formula	$S = k \ln \mathcal{W}$	Definition	3A.5
Carnot efficiency	$\eta = 1 - T_c/T_h$	Reversible processes	3A.10
Thermodynamic temperature	$T = (1 - \eta)T_h$		3A.11
Clausius inequality	$dS \geq dq/T$		3A.12
Entropy of isothermal expansion	$\Delta S = nR \ln(V_f/V_i)$	Perfect gas	3A.14
Entropy of transition	$\Delta_{\text{trs}}S = \Delta_{\text{trs}}H/T_{\text{trs}}$	At the transition temperature	3A.17
Variation of the entropy with temperature	$S(T_f) = S(T_i) + C \ln(T_f/T_i)$	The heat capacity, $C$ , is independent of temperature and no phase transitions occur	3A.20

### ► Why do you need to know this material?

For entropy to be a quantitatively useful concept it is important to be able to measure it: the calorimetric procedure is described here. The discussion also introduces the Third Law of thermodynamics, which has important implications for the measurement of entropies and (as shown in later Topics) the attainment of absolute zero.

### ► What is the key idea?

The entropy of a perfectly crystalline solid is zero at  $T=0$ .

### ► What do you need to know already?

You need to be familiar with the expression for the temperature dependence of entropy and how entropies of transition are calculated (Topic 3A). The discussion of residual entropy draws on the Boltzmann formula for the entropy (Topic 3A).

The entropy of a substance can be determined in two ways. One, which is the subject of this Topic, is to make calorimetric measurements of the heat required to raise the temperature of a sample from  $T=0$  to the temperature of interest. The other,

which is described in Topic 15E, is to use calculated parameters or spectroscopic data and to calculate the entropy by using Boltzmann's statistical definition.

## 3B.1 The calorimetric measurement of entropy

It is established in Topic 3A that the entropy of a system at a temperature  $T$  is related to its entropy at  $T=0$  by measuring its heat capacity  $C_p$  at different temperatures and evaluating the integral in eqn 3A.19 ( $S(T_f) = S(T_i) + \int_{T_i}^{T_f} C_p dT/T$ ). The entropy of transition ( $\Delta_{\text{trs}}H/T_{\text{trs}}$ ) for each phase transition between  $T=0$  and the temperature of interest must then be included in the overall sum. For example, if a substance melts at  $T_f$  and boils at  $T_b$ , then its molar entropy above its boiling temperature is given by

$$\begin{aligned}
 S_{\text{m}}(T) = S_{\text{m}}(0) &+ \int_0^{T_f} \frac{C_{p,\text{m}}(\text{s}, T)}{T} dT + \frac{\Delta_{\text{fus}}H}{T_f} \\
 &+ \int_{T_f}^{T_b} \frac{C_{p,\text{m}}(\text{l}, T)}{T} dT + \frac{\Delta_{\text{vap}}H}{T_b} \\
 &+ \int_{T_b}^T \frac{C_{p,\text{m}}(\text{g}, T)}{T} dT
 \end{aligned}
 \tag{3B.1}$$

All the properties required, except  $S_{\text{m}}(0)$ , can be measured calorimetrically, and the integrals can be evaluated either graphically or, as is now more usual, by fitting a polynomial to the data and integrating the polynomial analytically. The former procedure is illustrated in Fig. 3B.1: the area under the curve of  $C_{p,\text{m}}/T$  against  $T$  is the integral required. Provided all measurements are made at 1 bar on a pure material, the final value is the **standard entropy**,  $S^{\ominus}(T)$  and, on division by the amount of substance  $n$ , its **standard molar entropy**,  $S_{\text{m}}^{\ominus}(T) = S^{\ominus}(T)/n$ . Because  $dT/T = d \ln T$ , an alternative procedure is to evaluate the area under a plot of  $C_{p,\text{m}}$  against  $\ln T$ .

**Figure 3B.1** The variation of  $C_p/T$  with the temperature for a sample is used to evaluate the entropy, which is equal to the area beneath the upper curve up to the corresponding temperature, plus the entropy of each phase transition passed.

### Brief illustration 3B.1 The standard molar entropy

The standard molar entropy of nitrogen gas at 25 °C has been calculated from the following data:

	$S_m^\ominus/(\text{JK}^{-1}\text{mol}^{-1})$
Debye extrapolation*	1.92
Integration, from 10 K to 35.61 K	25.25
Phase transition at 35.61 K	6.43
Integration, from 35.61 K to 63.14 K	23.38
Fusion at 63.14 K	11.42
Integration, from 63.14 K to 77.32 K	11.41
Vaporization at 77.32 K	72.13
Integration, from 77.32 K to 298.15 K	39.20
Correction for gas imperfection	0.92
Total	192.06

Therefore,  $S_m^\ominus(298.15\text{ K}) = S_m(0) + 192.1\text{ JK}^{-1}\text{ mol}^{-1}$ .

\*This extrapolation is explained immediately following.

One problem with the determination of entropy is the difficulty of measuring heat capacities near  $T=0$ . There are good theoretical grounds for assuming that the heat capacity of a non-metallic solid is proportional to  $T^3$  when  $T$  is low (see Topic 7A), and this dependence is the basis of the **Debye extrapolation**. In this method,  $C_p$  is measured down to as low a temperature as possible and a curve of the form  $aT^3$  is fitted to the data. That fit determines the value of  $a$ , and the expression  $C_{p,m} = aT^3$  is assumed valid down to  $T=0$ .

### Example 3B.1 Calculating the entropy at low temperatures

The molar constant-pressure heat capacity of a certain solid at 4.2 K is  $0.43\text{ JK}^{-1}\text{ mol}^{-1}$ . What is its molar entropy at that temperature?

**Method** Because the temperature is so low, we can assume that the heat capacity varies with temperature as  $aT^3$ , in which case we can use eqn 3A.19 (quoted in the opening paragraph of 3B.1) to calculate the entropy at a temperature  $T$  in terms of the entropy at  $T=0$  and the constant  $a$ . When the integration is carried out, it turns out that the result can be expressed in terms of the heat capacity at the temperature  $T$ , so the data can be used directly to calculate the entropy.

**Answer** The integration required is

$$\begin{aligned} S_m(T) &= S_m(0) + \int_0^T \frac{aT^3}{T} dT = S_m(0) + a \int_0^T T^2 dT \\ &= S_m(0) + \frac{1}{3} aT^3 = S_m(0) + \frac{1}{3} C_{p,m}(T) \end{aligned}$$

from which it follows that

$$S_m(4.2\text{ K}) = S_m(0) + 0.14\text{ JK}^{-1}\text{ mol}^{-1}$$

**Self-test 3B.1** For metals, there is also a contribution to the heat capacity from the electrons which is linearly proportional to  $T$  when the temperature is low. Find its contribution to the entropy at low temperatures.

Answer:  $S(T) = S(0) + C_p(T)$

## 3B.2 The Third Law

We now address the problem of the value of  $S(0)$ . At  $T=0$ , all energy of thermal motion has been quenched, and in a perfect crystal all the atoms or ions are in a regular, uniform array. The localization of matter and the absence of thermal motion suggest that such materials also have zero entropy. This conclusion is consistent with the molecular interpretation of entropy, because  $S=0$  if there is only one way of arranging the molecules and only one microstate is accessible (all molecules occupy the ground state,  $\mathcal{W}=1$ ).

### (a) The Nernst heat theorem

The experimental observation that turns out to be consistent with the view that the entropy of a regular array of molecules is zero at  $T=0$  is summarized by the **Nernst heat theorem**:

The entropy change accompanying any physical or chemical transformation approaches zero as the temperature approaches zero:  $\Delta S \rightarrow 0$  as  $T \rightarrow 0$  provided all the substances involved are perfectly ordered.

Nernst heat theorem

**Brief illustration 3B.2** The Nernst heat theorem

Consider the entropy of the transition between orthorhombic sulfur,  $\alpha$ , and monoclinic sulfur,  $\beta$ , which can be calculated from the transition enthalpy ( $-402 \text{ J mol}^{-1}$ ) at the transition temperature (369 K):

$$\begin{aligned}\Delta_{\text{trs}}S &= S_{\text{m}}(\beta) - S_{\text{m}}(\alpha) = \frac{-402 \text{ J mol}^{-1}}{369 \text{ K}} \\ &= -1.09 \text{ J K}^{-1} \text{ mol}^{-1}\end{aligned}$$

The two individual entropies can also be determined by measuring the heat capacities from  $T=0$  up to  $T=369 \text{ K}$ . It is found that  $S_{\text{m}}(\alpha) = S_{\text{m}}(\alpha, 0) + 37 \text{ J K}^{-1} \text{ mol}^{-1}$  and  $S_{\text{m}}(\beta) = S_{\text{m}}(\beta, 0) + 38 \text{ J K}^{-1} \text{ mol}^{-1}$ . These two values imply that at the transition temperature

$$\Delta_{\text{trs}}S = S_{\text{m}}(\alpha, 0) - S_{\text{m}}(\beta, 0) = -1 \text{ J K}^{-1} \text{ mol}^{-1}$$

On comparing this value with the one above, we conclude that  $S_{\text{m}}(\alpha, 0) - S_{\text{m}}(\beta, 0) \approx 0$ , in accord with the theorem.

**Self-test 3B.2** Two forms of a metallic solid (see *Self-test 3B.1*) undergo a phase transition at  $T_{\text{trs}}$ , which is close to  $T=0$ . What is the enthalpy of transition at  $T_{\text{trs}}$  in terms of the heat capacities of the two polymorphs?

Answer:  $\Delta_{\text{trs}}H(T_{\text{trs}}) = T_{\text{trs}}\Delta C_p(T_{\text{trs}})$

It follows from the Nernst theorem, that if we arbitrarily ascribe the value zero to the entropies of elements in their perfect crystalline form at  $T=0$ , then all perfect crystalline compounds also have zero entropy at  $T=0$  (because the change in entropy that accompanies the formation of the compounds, like the entropy of all transformations at that temperature, is zero). This conclusion is summarized by the **Third Law of thermodynamics**:

The entropy of all perfect crystalline substances is zero at  $T=0$ .

Third Law of thermodynamics

As far as thermodynamics is concerned, choosing this common value as zero is a matter of convenience. The molecular interpretation of entropy, however, justifies the value  $S=0$  at  $T=0$  because then, as we have remarked,  $\mathcal{W}=1$ .

In certain cases  $\mathcal{W}>1$  at  $T=0$  and therefore  $S(0)>0$ . This is the case if there is no energy advantage in adopting a particular orientation even at absolute zero. For instance, for a diatomic molecule AB there may be almost no energy difference between the arrangements ...AB AB AB... and ...BA AB BA..., so  $\mathcal{W}>1$  even at  $T=0$ . If  $S(0)>0$  we say that the substance has a **residual entropy**. Ice has a residual entropy of  $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$ . It stems from the arrangement of the hydrogen bonds between neighbouring water molecules: a given O atom has two short O—H bonds and

two long O··H bonds to its neighbours, but there is a degree of randomness in which two bonds are short and which two are long.

**Example 3B.2** Estimating a residual entropy

Estimate the residual entropy of ice by taking into account the distribution of hydrogen bonds and chemical bonds about the oxygen atom of one  $\text{H}_2\text{O}$  molecule. The experimental value is  $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Method** Focus on the O atom, and consider the number of ways that that O atom can have two short (chemical) bonds and two long hydrogen bonds to its four neighbours. Refer to Fig. 3B.2.

**Figure 3B.2** The model of ice showing (a) the local structure of an oxygen atom and (b) the array of chemical and hydrogen bonds used to calculate the residual entropy of ice.

**Answer** Suppose each H atom can lie either close to or far from its 'parent' O atom, as depicted in Fig. 3B.2. The total number of these conceivable arrangements in a sample that contains  $N \text{ H}_2\text{O}$  molecules and therefore  $2N \text{ H}$  atoms is  $2^{2N}$ . Now consider a single central O atom. The total number of possible arrangements of locations of H atoms around the central O atom of one  $\text{H}_2\text{O}$  molecule is  $2^4 = 16$ . Of these 16 possibilities, only 6 correspond to two short and two long bonds. That is, only  $\frac{6}{16} = \frac{3}{8}$  of all possible arrangements are possible, and for  $N$  such molecules only  $(3/8)^N$  of all possible arrangements are possible. Therefore, the total number of allowed arrangements in the crystal is  $2^{2N}(3/8)^N = 4^N(3/8)^N = (3/2)^N$ . If we suppose that all these arrangements are energetically identical, the residual entropy is

$$S(0) = k \ln \left( \frac{3}{2} \right)^N = Nk \ln \frac{3}{2} = nN_A k \ln \frac{3}{2} = nR \ln \frac{3}{2}$$

and the residual molar entropy would be

$$S_m(0) = R \ln \frac{3}{2} = 3.4 \text{ J K}^{-1} \text{ mol}^{-1}$$

in accord with the experimental value.

**Self-test 3B.3** What would be the residual molar entropy of  $\text{HCF}_3$  on the assumption that each molecule could take up one of four tetrahedral orientations in a crystal?

Answer:  $11.5 \text{ J K}^{-1} \text{ mol}^{-1}$

### (b) Third-Law entropies

Entropies reported on the basis that  $S(0)=0$  are called **Third-Law entropies** (and commonly just ‘entropies’). When the substance is in its standard state at the temperature  $T$ , the **standard (Third-Law) entropy** is denoted  $S^\ominus(T)$ . A list of values at 298 K is given in Table 3B.1.

The **standard reaction entropy**,  $\Delta_r S^\ominus$ , is defined, like the standard reaction enthalpy in Topic 2C, as the difference between the molar entropies of the pure, separated products and the pure, separated reactants, all substances being in their standard states at the specified temperature:

$$\Delta_r S^\ominus = \sum_{\text{Products}} \nu S_m^\ominus - \sum_{\text{Reactants}} \nu S_m^\ominus \quad \text{Definition} \quad \text{Standard reaction entropy} \quad (3B.2a)$$

In this expression, each term is weighted by the appropriate stoichiometric coefficient. A more sophisticated approach is to adopt the notation introduced in Topic 2C and to write

**Table 3B.1\*** Standard Third-Law entropies at 298 K,  $S_m^\ominus / (\text{J K}^{-1} \text{ mol}^{-1})$

	$S_m^\ominus / (\text{J K}^{-1} \text{ mol}^{-1})$
<i>Solids</i>	
Graphite, C(s)	5.7
Diamond, C(s)	2.4
Sucrose, $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ (s)	360.2
Iodine, $\text{I}_2$ (s)	116.1
<i>Liquids</i>	
Benzene, $\text{C}_6\text{H}_6$ (l)	173.3
Water, $\text{H}_2\text{O}$ (l)	69.9
Mercury, Hg(l)	76.0
<i>Gases</i>	
Methane, $\text{CH}_4$ (g)	186.3
Carbon dioxide, $\text{CO}_2$ (g)	213.7
Hydrogen, $\text{H}_2$ (g)	130.7
Helium, He(g)	126.2
Ammonia, $\text{NH}_3$ (g)	192.4

\* More values are given in the *Resource section*.

### Brief illustration 3B.3 The standard reaction entropy

To calculate the standard reaction entropy of  $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$  at 298 K, we use the data in Table 2C.5 of the *Resource section* to write

$$\begin{aligned} \Delta_r S^\ominus &= S_m^\ominus(\text{H}_2\text{O}, \text{l}) - \{S_m^\ominus(\text{H}_2, \text{g}) + \frac{1}{2}S_m^\ominus(\text{O}_2, \text{g})\} \\ &= 69.9 \text{ J K}^{-1} \text{ mol}^{-1} - \left\{130.7 + \frac{1}{2}(205.1)\right\} \text{ J K}^{-1} \text{ mol}^{-1} \\ &= -163.4 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

The negative value is consistent with the conversion of two gases to a compact liquid.

*A note on good practice* Do not make the mistake of setting the standard molar entropies of elements equal to zero: they have nonzero values (provided  $T > 0$ ), as we have already discussed.

**Self-test 3B.4** Calculate the standard reaction entropy for the combustion of methane to carbon dioxide and liquid water at 298 K.

Answer:  $-243 \text{ J K}^{-1} \text{ mol}^{-1}$

$$\Delta_r S^\ominus = \sum_j \nu_j S_m^\ominus(j) \quad (3B.2b)$$

where the  $\nu_j$  are signed (+ for products, – for reactants) stoichiometric numbers. Standard reaction entropies are likely to be positive if there is a net formation of gas in a reaction, and are likely to be negative if there is a net consumption of gas.

Just as in the discussion of enthalpies in Topic 2C, where it is acknowledged that solutions of cations cannot be prepared in the absence of anions, the standard molar entropies of ions in solution are reported on a scale in which the standard entropy of the  $\text{H}^+$  ions in water is taken as zero at all temperatures:

$$S^\ominus(\text{H}^+, \text{aq}) = 0 \quad \text{Convention} \quad \text{Ions in solution} \quad (3B.3)$$

The values based on this choice are listed in Table 2C.5 in the *Resource section*.<sup>1</sup> Because the entropies of ions in water are values relative to the hydrogen ion in water, they may be either positive or negative. A positive entropy means that an ion has a higher molar entropy than  $\text{H}^+$  in water and a negative entropy means that the ion has a lower molar entropy than  $\text{H}^+$  in water. Ion entropies vary as expected on the basis that they are related to the degree to which the ions order the water molecules around them in the solution. Small, highly charged ions induce local structure in the surrounding water, and the disorder of

<sup>1</sup> In terms of the language introduced in Topic 5A, the entropies of ions in solution are actually *partial molar entropies*, for their values include the consequences of their presence on the organization of the solvent molecules around them.

the solution is decreased more than in the case of large, singly charged ions. The absolute, Third-Law standard molar entropy of the proton in water can be estimated by proposing a model of the structure it induces, and there is some agreement on the value  $-21 \text{ J K}^{-1} \text{ mol}^{-1}$ . The negative value indicates that the proton induces order in the solvent.

#### Brief illustration 3B.4 Absolute and relative ion entropies

The standard molar entropy of  $\text{Cl}^{-}(\text{aq})$  is  $+57 \text{ J K}^{-1} \text{ mol}^{-1}$  and that of  $\text{Mg}^{2+}(\text{aq})$  is  $-128 \text{ J K}^{-1} \text{ mol}^{-1}$ . That is, the partial molar

entropy of  $\text{Cl}^{-}(\text{aq})$  is  $57 \text{ J K}^{-1} \text{ mol}^{-1}$  higher than that of the proton in water (presumably because it induces less local structure in the surrounding water), whereas that of  $\text{Mg}^{2+}(\text{aq})$  is  $128 \text{ J K}^{-1} \text{ mol}^{-1}$  lower (presumably because its higher charge induces more local structure in the surrounding water).

**Self-test 3B.5** Estimate the absolute values of the partial molar entropies of these ions.

Answer:  $+36 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $-149 \text{ J K}^{-1} \text{ mol}^{-1}$

## Checklist of concepts

- 1. Entropies are determined calorimetrically by measuring the heat capacity of a substance from low temperatures up to the temperature of interest.
- 2. The **Debye- $T^3$  law** is used to estimate heat capacities of non-metallic solids close to  $T=0$ .
- 3. The **Nernst heat theorem** states that the entropy change accompanying any physical or chemical transformation approaches zero as the temperature approaches zero:  $\Delta S \rightarrow 0$  as  $T \rightarrow 0$  provided all the substances involved are perfectly ordered.
- 4. The **Third Law of thermodynamics** states that the entropy of all perfect crystalline substances is zero at  $T=0$ .
- 5. The **residual entropy** of a solid is the entropy arising from disorder that persists at  $T=0$ .
- 6. **Third-Law entropies** are entropies based on  $S(0)=0$ .
- 7. The **standard entropies of ions in solution** are based on setting  $S^{\ominus}(\text{H}^{+}, \text{aq})=0$  at all temperatures.
- 8. The **standard reaction entropy**,  $\Delta_r S^{\ominus}$ , is the difference between the molar entropies of the pure, separated products and the pure, separated reactants, all substances being in their standard states.

### ► Why do you need to know this material?

Most processes of interest in chemistry occur at constant temperature and pressure. Under these conditions, thermodynamic processes are discussed in terms of the Gibbs energy, which is introduced in this Topic. The Gibbs energy is the foundation of the discussion of phase equilibria, chemical equilibrium, and bioenergetics.

### ► What is the key idea?

The Gibbs energy is a signpost of spontaneous change at constant temperature and pressure, and is equal to the maximum non-expansion work that a system can do.

### ► What do you need to know already?

This Topic develops the Clausius inequality (Topic 3A) and draws on information about standard states and reaction enthalpy introduced in Topic 2C. The derivation of the Born equation uses information about the energy of one electric charge in the field of another (*Foundations B*).

Entropy is the basic concept for discussing the direction of natural change, but to use it we have to analyse changes in both the system and its surroundings. In Topic 3A it is shown that it is always very simple to calculate the entropy change in the surroundings (from  $\Delta S_{\text{sur}} = q_{\text{sur}}/T_{\text{sur}}$ ); here we see that it is possible to devise a simple method for taking that contribution into account automatically. This approach focuses our attention on the system and simplifies discussions. Moreover, it is the foundation of all the applications of chemical thermodynamics that follow.

## 3C.1 The Helmholtz and Gibbs energies

Consider a system in thermal equilibrium with its surroundings at a temperature  $T$ . When a change in the system occurs and there is a transfer of energy as heat between the system and the surroundings, the Clausius inequality (eqn 3A.12,  $dS \geq dq/T$ ) reads

$$dS - \frac{dq}{T} \geq 0 \quad (3C.1)$$

We can develop this inequality in two ways according to the conditions (of constant volume or constant pressure) under which the process occurs.

### (a) Criteria of spontaneity

First, consider heating at constant volume. Then, in the absence of additional (non-expansion) work, we can write  $dq_v = dU$ ; consequently

$$dS - \frac{dU}{T} \geq 0 \quad (3C.2)$$

The importance of the inequality in this form is that it expresses the criterion for spontaneous change solely in terms of the state functions of the system. The inequality is easily rearranged into

$$TdS \geq dU \quad (\text{constant } V, \text{ no additional work}) \quad (3C.3)$$

Because  $T > 0$ , at either constant internal energy ( $dU=0$ ) or constant entropy ( $dS=0$ ) this expression becomes, respectively,

$$dS_{U,V} \geq 0 \quad dU_{S,V} \leq 0 \quad (3C.4)$$

where the subscripts indicate the constant conditions.

Equation 3C.4 expresses the criteria for spontaneous change in terms of properties relating to the system. The first inequality states that, in a system at constant volume and constant internal energy (such as an isolated system), the entropy increases in a spontaneous change. That statement is essentially the content of the Second Law. The second inequality is less obvious, for it says that if the entropy and volume of the system are constant, then the internal energy must decrease in a spontaneous change. Do not interpret this criterion as a tendency of the system to sink to lower energy. It is a disguised statement about entropy and should be interpreted as implying that if the entropy of the system is unchanged, then there must be an increase in entropy of the surroundings, which can be achieved only if the energy of the system decreases as energy flows out as heat.

When energy is transferred as heat at constant pressure, and there is no work other than expansion work, we can write  $dq_p = dH$  and obtain

$$TdS \geq dH \quad (\text{constant } p, \text{ no additional work}) \quad (3C.5)$$

At either constant enthalpy or constant entropy this inequality becomes, respectively,

$$dS_{H,p} \geq 0 \quad dH_{S,p} \leq 0 \quad (3C.6)$$

The interpretations of these inequalities are similar to those of eqn 3C.4. The entropy of the system at constant pressure must increase if its enthalpy remains constant (for there can then be no change in entropy of the surroundings). Alternatively, the enthalpy must decrease if the entropy of the system is constant, for then it is essential to have an increase in entropy of the surroundings.

#### Brief illustration 3C.1 Spontaneous changes at constant volume

A concrete example of the criterion  $dS_{U,V} \geq 0$  is the diffusion of a solute B through a solvent A that form an ideal solution (in the sense of Topic 5B, in which AA, BB, and AB interactions are identical). There is no change in internal energy or volume

of the system or the surroundings as B spreads into A, but the process is spontaneous.

**Self-test 3C.1** Invent an example of the criterion  $dU_{S,V} \leq 0$ .

Answer: A phase change in which one perfectly ordered phase changes into another of lower energy and equal density at  $T=0$

Because eqns 3C.4 and 3C.6 have the forms  $dU - TdS \leq 0$  and  $dH - TdS \leq 0$ , respectively, they can be expressed more simply by introducing two more thermodynamic quantities. One is the **Helmholtz energy**,  $A$ , which is defined as

$$A = U - TS \quad \text{Definition} \quad \text{Helmholtz energy} \quad (3C.7)$$

The other is the **Gibbs energy**,  $G$ :

$$G = H - TS \quad \text{Definition} \quad \text{Gibbs energy} \quad (3C.8)$$

All the symbols in these two definitions refer to the system.

When the state of the system changes at constant temperature, the two properties change as follows:

$$(a) dA = dU - TdS \quad (b) dG = dH - TdS \quad (3C.9)$$

When we introduce eqns 3C.4 and 3C.6, respectively, we obtain the criteria of spontaneous change as

$$(a) dA_{T,V} \leq 0 \quad (b) dG_{T,p} \leq 0 \quad \text{Criteria of spontaneous change} \quad (3C.10)$$

These inequalities, especially the second, are the most important conclusions from thermodynamics for chemistry. They are developed in subsequent sections, Topics, and chapters.

#### Brief illustration 3C.2 The spontaneity of endothermic reactions

The existence of spontaneous endothermic reactions provides an illustration of the role of  $G$ . In such reactions,  $H$  increases, the system rises spontaneously to states of higher enthalpy, and  $dH > 0$ . Because the reaction is spontaneous we know that  $dG < 0$  despite  $dH > 0$ ; it follows that the entropy of the system increases so much that  $TdS$  outweighs  $dH$  in  $dG = dH - TdS$ . Endothermic reactions are therefore driven by the increase of entropy of the system, and this entropy change overcomes the reduction of entropy brought about in the surroundings by the inflow of heat into the system ( $dS_{\text{sur}} = -dH/T$  at constant pressure).

**Self-test 3C.2** Why are so many exothermic reactions spontaneous?

Answer: With  $dH < 0$ , it is common for  $dG < 0$  unless  $TdS$  is strongly negative.

### (b) Some remarks on the Helmholtz energy

A change in a system at constant temperature and volume is spontaneous if  $dA_{T,V} \leq 0$ . That is, a change under these conditions is spontaneous if it corresponds to a decrease in the Helmholtz energy. Such systems move spontaneously towards states of lower  $A$  if a path is available. The criterion of equilibrium, when neither the forward nor reverse process has a tendency to occur, is

$$dA_{T,V} = 0 \quad (3C.11)$$

The expressions  $dA = dU - TdS$  and  $dA < 0$  are sometimes interpreted as follows. A negative value of  $dA$  is favoured by a negative value of  $dU$  and a positive value of  $TdS$ . This observation suggests that the tendency of a system to move to lower  $A$  is due to its tendency to move towards states of lower internal energy and higher entropy. However, this interpretation is false because the tendency to lower  $A$  is solely a tendency towards states of greater overall entropy. *Systems change spontaneously if in doing so the total entropy of the system and its surroundings increases, not because they tend to lower internal energy.* The form of  $dA$  may give the impression that systems favour lower energy, but that is misleading:  $dS$  is the entropy change of the system,  $-dU/T$  is the entropy change of the surroundings (when the volume of the system is constant), and their total tends to a maximum.

#### Brief illustration 3C.3 Spontaneous change at constant volume

A bouncing ball comes to rest. The spontaneous direction of change is one in which the energy of the ball (potential at the top of its bounce, kinetic when it strikes the floor) spreads out into the surroundings on each bounce. When the ball is still, the energy of the universe is the same as initially, but the energy of the ball is dispersed over the surroundings.

**Self-test 3C.3** What other spontaneous similar mechanical processes have a similar explanation?

Answer: One example: A pendulum coming to rest through friction.

### (c) Maximum work

It turns out, as we show in the following *Justification*, that  $A$  carries a greater significance than being simply a signpost of spontaneous change: *the change in the Helmholtz function is equal to the maximum work accompanying a process at constant temperature:*

$$dw_{\max} = dA \quad \text{Constant temperature} \quad \text{Maximum work} \quad (3C.12)$$

As a result,  $A$  is sometimes called the ‘maximum work function’, or the ‘work function’.<sup>1</sup>

#### Justification 3C.1 Maximum work

To demonstrate that maximum work can be expressed in terms of the changes in Helmholtz energy, we combine the Clausius inequality  $dS \geq dq/T$  in the form  $TdS \geq dq$  with the First Law,  $dU = dq + dw$ , and obtain

$$dU \leq TdS + dw$$

$dU$  is smaller than the term of the right because  $dq$  has been replaced by  $TdS$ , which in general is larger than  $dq$ . This expression rearranges to

$$dw \geq dU - TdS$$

It follows that the most negative value of  $dw$ , and therefore the maximum energy that can be obtained from the system as work, is given by

$$dw_{\max} = dU - TdS$$

and that this work is done only when the path is traversed reversibly (because then the equality applies). Because at constant temperature  $dA = dU - TdS$ , we conclude that  $dw_{\max} = dA$ .

When a macroscopic isothermal change takes place in the system, eqn 3C.12 becomes

$$w_{\max} = \Delta A \quad \text{Constant temperature} \quad \text{Maximum work} \quad (3C.13)$$

with

$$\Delta A = \Delta U - T\Delta S \quad \text{Constant temperature} \quad (3C.14)$$

This expression shows that, depending on the sign of  $T\Delta S$ , not all the change in internal energy may be available for doing work. If the change occurs with a decrease in entropy (of the system), in which case  $T\Delta S < 0$ , then the right-hand side of this equation is not as negative as  $\Delta U$  itself, and consequently the maximum work is less than  $\Delta U$ . For the change to be spontaneous, some of the energy must escape as heat in order to generate enough entropy in the surroundings to overcome the reduction in entropy in the system (Fig. 3C.1). In this case, Nature is demanding a tax on the internal energy as it is converted into work. This is the origin of the alternative name ‘Helmholtz free energy’ for  $A$ , because  $\Delta A$  is that part of the change in internal energy that we are free to use to do work.

Further insight into the relation between the work that a system can do and the Helmholtz energy is to recall that work is

<sup>1</sup> *Arbeit* is the German word for work; hence the symbol  $A$ .

**Figure 3C.1** In a system not isolated from its surroundings, the work done may be different from the change in internal energy. Moreover, the process is spontaneous if overall the entropy of the global, isolated system increases. In the process depicted here, the entropy of the system decreases, so that of the surroundings must increase in order for the process to be spontaneous, which means that energy must pass from the system to the surroundings as heat. Therefore, less work than  $\Delta U$  can be obtained.

energy transferred to the surroundings as the uniform motion of atoms. We can interpret the expression  $A = U - TS$  as showing that  $A$  is the total internal energy of the system,  $U$ , less a contribution that is stored as energy of thermal motion (the quantity  $TS$ ). Because energy stored in random thermal motion cannot be used to achieve uniform motion in the surroundings, only the part of  $U$  that is not stored in that way, the quantity  $U - TS$ , is available for conversion into work.

If the change occurs with an increase of entropy of the system (in which case  $T\Delta S > 0$ ), the right-hand side of the equation is more negative than  $\Delta U$ . In this case, the maximum work that can be obtained from the system is greater than  $\Delta U$ . The explanation of this apparent paradox is that the system is not isolated and energy may flow in as heat as work is done. Because the entropy of the system increases, we can afford a reduction of

**Figure 3C.2** In this process, the entropy of the system increases; hence we can afford to lose some entropy of the surroundings. That is, some of their energy may be lost as heat to the system. This energy can be returned to them as work. Hence the work done can exceed  $\Delta U$ .

the entropy of the surroundings yet still have, overall, a spontaneous process. Therefore, some energy (no more than the value of  $T\Delta S$ ) may leave the surroundings as heat and contribute to the work the change is generating (Fig. 3C.2). Nature is now providing a tax refund.

### Example 3C.1 Calculating the maximum available work

When 1.000 mol  $C_6H_{12}O_6$  (glucose) is oxidized to carbon dioxide and water at 25 °C according to the equation  $C_6H_{12}O_6(s) + 6 O_2(g) \rightarrow 6 CO_2(g) + 6 H_2O(l)$  calorimetric measurements give  $\Delta_r U^\ominus = -2808 \text{ kJ mol}^{-1}$  and  $\Delta_r S^\ominus = +182.4 \text{ J K}^{-1} \text{ mol}^{-1}$  at 25 °C. How much of this energy change can be extracted as (a) heat at constant pressure, (b) work?

**Method** We know that the heat released at constant pressure is equal to the value of  $\Delta H$ , so we need to relate  $\Delta_r H^\ominus$  to  $\Delta_r U^\ominus$ , which is given. To do so, we suppose that all the gases involved are perfect, and use eqn 2B.4 ( $\Delta H = \Delta U + \Delta n_g RT$ ) in the form  $\Delta_r H = \Delta_r U + \Delta v_g RT$ . For the maximum work available from the process we use eqn 3C.13.

**Answer** (a) Because  $\Delta v_g = 0$ , we know that  $\Delta_r H^\ominus = \Delta_r U^\ominus = -2808 \text{ kJ mol}^{-1}$ . Therefore, at constant pressure, the energy available as heat is  $2808 \text{ kJ mol}^{-1}$ . (b) Because  $T = 298 \text{ K}$ , the value of  $\Delta_r A^\ominus$  is

$$\Delta_r A^\ominus = \Delta_r U^\ominus - T\Delta_r S^\ominus = -2862 \text{ kJ mol}^{-1}$$

Therefore, the combustion of 1.000 mol  $C_6H_{12}O_6$  can be used to produce up to 2862 kJ of work. The maximum work available is greater than the change in internal energy on account of the positive entropy of reaction (which is partly due to the generation of a large number of small molecules from one big one). The system can therefore draw in energy from the surroundings (so reducing their entropy) and make it available for doing work.

**Self-test 3C.4** Repeat the calculation for the combustion of 1.000 mol  $CH_4(g)$  under the same conditions, using data from Table 2C.4.

Answer:  $|q_p| = 890 \text{ kJ}$ ,  $|w_{\max}| = 813 \text{ kJ}$

### (d) Some remarks on the Gibbs energy

The Gibbs energy (the ‘free energy’) is more common in chemistry than the Helmholtz energy because, at least in laboratory chemistry, we are usually more interested in changes occurring at constant pressure than at constant volume. The criterion  $dG_{T,p} \leq 0$  carries over into chemistry as the observation that, *at constant temperature and pressure, chemical reactions are spontaneous in the direction of decreasing Gibbs energy*. Therefore, if we want to know whether a reaction is

spontaneous, the pressure and temperature being constant, we assess the change in the Gibbs energy. If  $G$  decreases as the reaction proceeds, then the reaction has a spontaneous tendency to convert the reactants into products. If  $G$  increases, then the reverse reaction is spontaneous. The criterion for equilibrium, when neither the forward nor reverse process is spontaneous, under conditions of constant temperature and pressure is

$$dG_{T,p} = 0 \quad (3C.15)$$

The existence of spontaneous endothermic reactions provides an illustration of the role of  $G$ . In such reactions,  $H$  increases, the system rises spontaneously to states of higher enthalpy, and  $dH > 0$ . Because the reaction is spontaneous we know that  $dG < 0$  despite  $dH > 0$ ; it follows that the entropy of the system increases so much that  $TdS$  outweighs  $dH$  in  $dG = dH - TdS$ . Endothermic reactions are therefore driven by the increase of entropy of the system, and this entropy change overcomes the reduction of entropy brought about in the surroundings by the inflow of heat into the system ( $dS_{\text{sur}} = -dH/T$  at constant pressure).

### (e) Maximum non-expansion work

The analogue of the maximum work interpretation of  $\Delta A$ , and the origin of the name 'free energy', can be found for  $\Delta G$ . In the following *Justification*, we show that at constant temperature and pressure, the maximum additional (non-expansion) work,  $w_{\text{add,max}}$ , is given by the change in Gibbs energy:

$$dw_{\text{add,max}} = dG \quad \begin{array}{l} \text{Constant} \\ \text{temperature} \\ \text{and pressure} \end{array} \quad \begin{array}{l} \text{Maximum} \\ \text{non-expansion} \\ \text{work} \end{array} \quad (3C.16a)$$

The corresponding expression for a measurable change is

$$w_{\text{add,max}} = \Delta G \quad \begin{array}{l} \text{Constant} \\ \text{temperature} \\ \text{and pressure} \end{array} \quad \begin{array}{l} \text{Maximum} \\ \text{non-expansion} \\ \text{work} \end{array} \quad (3C.16b)$$

This expression is particularly useful for assessing the electrical work that may be produced by fuel cells and electrochemical cells, and we shall see many applications of it.

#### Justification 3C.2 Maximum non-expansion work

Because  $H = U + pV$ , the change in enthalpy for a general change in conditions is

$$dH = dq + dw + d(pV)$$

The corresponding change in Gibbs energy ( $G = H - TS$ ) is

$$dG = dH - TdS - SdT = dq + dw + d(pV) - TdS - SdT$$

When the change is isothermal we can set  $dT = 0$ ; then

$$dG = dq + dw + d(pV) - TdS$$

When the change is reversible,  $dw = dw_{\text{rev}}$  and  $dq = dq_{\text{rev}} = TdS$ , so for a reversible, isothermal process

$$dG = TdS + dw_{\text{rev}} + d(pV) - TdS = dw_{\text{rev}} + d(pV)$$

The work consists of expansion work, which for a reversible change is given by  $-pdV$ , and possibly some other kind of work (for instance, the electrical work of pushing electrons through a circuit or of raising a column of liquid); this additional work we denote  $dw_{\text{add}}$ . Therefore, with  $d(pV) = pdV + Vdp$ ,

$$dG = (-pdV + dw_{\text{add,rev}}) + pdV + Vdp = dw_{\text{add,rev}} + Vdp$$

If the change occurs at constant pressure (as well as constant temperature), we can set  $dp = 0$  and obtain  $dG = dw_{\text{add,rev}}$ . Therefore, at constant temperature and pressure,  $dw_{\text{add,rev}} = dG$ . However, because the process is reversible, the work done must now have its maximum value, so eqn 3C.16 follows.

#### Example 3C.2 Calculating the maximum non-expansion work of a reaction

How much energy is available for sustaining muscular and nervous activity from the combustion of 1.00 mol of glucose molecules under standard conditions at 37 °C (blood temperature)? The standard entropy of reaction is  $+182.4 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Method** The non-expansion work available from the reaction is equal to the change in standard Gibbs energy for the reaction ( $\Delta_r G^\ominus$ , a quantity defined more fully below). To calculate this quantity, it is legitimate to ignore the temperature-dependence of the reaction enthalpy, to obtain  $\Delta_r H^\ominus$  from Table 2C.5, and to substitute the data into  $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$ .

**Answer** Because the standard reaction enthalpy is  $-2808 \text{ kJ mol}^{-1}$ , it follows that the standard reaction Gibbs energy is

$$\begin{aligned} \Delta_r G^\ominus &= -2808 \text{ kJ mol}^{-1} - (310 \text{ K}) \times (182.4 \text{ J K}^{-1} \text{ mol}^{-1}) \\ &= -2865 \text{ kJ mol}^{-1} \end{aligned}$$

Therefore,  $w_{\text{add,max}} = -2865 \text{ kJ}$  for the combustion of 1 mol glucose molecules, and the reaction can be used to do up to 2865 kJ of non-expansion work. To place this result in perspective, consider that a person of mass 70 kg needs to do 2.1 kJ of work to climb vertically through 3.0 m; therefore, at least 0.13 g of glucose is needed to complete the task (and in practice significantly more).

**Self-test 3C.5** How much non-expansion work can be obtained from the combustion of 1.00 mol  $\text{CH}_4(\text{g})$  under standard conditions at 298 K? Use  $\Delta_r S^\ominus = -243 \text{ J K}^{-1} \text{ mol}^{-1}$ .

Answer: 818 kJ

## 3C.2 Standard molar Gibbs energies

Standard entropies and enthalpies of reaction can be combined to obtain the **standard Gibbs energy of reaction** (or 'standard reaction Gibbs energy'),  $\Delta_r G^\ominus$ :

$$\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus \quad \text{Definition} \quad \text{Standard Gibbs energy of reaction} \quad (3C.17)$$

The standard Gibbs energy of reaction is the difference in standard molar Gibbs energies of the products and reactants in their standard states at the temperature specified for the reaction as written.

### (a) Gibbs energies of formation

As in the case of standard reaction enthalpies, it is convenient to define the **standard Gibbs energies of formation**,  $\Delta_f G^\ominus$ , the standard reaction Gibbs energy for the formation of a compound from its elements in their reference states.<sup>2</sup> Standard Gibbs energies of formation of the elements in their reference states are zero, because their formation is a 'null' reaction. A selection of values for compounds is given in Table 3C.1. From the values there, it is a simple matter to obtain the standard Gibbs energy of reaction by taking the appropriate combination:

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G_m^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G_m^\ominus \quad \text{Practical implementation} \quad \text{Standard Gibbs energy of reaction} \quad (3C.18a)$$

In the notation introduced in Topic 2C,

$$\Delta_r G^\ominus = \sum_j \nu_j \Delta_f G_m^\ominus (j) \quad (3C.18b)$$

**Table 3C.1\*** Standard Gibbs energies of formation at 298 K,  $\Delta_f G^\ominus / (\text{kJ mol}^{-1})$

	$\Delta_f G^\ominus / (\text{kJ mol}^{-1})$
Diamond, C(s)	+2.9
Benzene, C <sub>6</sub> H <sub>6</sub> (l)	+124.3
Methane, CH <sub>4</sub> (g)	-50.7
Carbon dioxide, CO <sub>2</sub> (g)	-394.4
Water, H <sub>2</sub> O(l)	-237.1
Ammonia, NH <sub>3</sub> (g)	-16.5
Sodium chloride, NaCl(s)	-384.1

\* More values are given in the *Resource section*.

<sup>2</sup> The reference state of an element is defined in Topic 2C.

### Brief illustration 3C.4 The standard reaction Gibbs energy

To calculate the standard Gibbs energy of the reaction  $\text{CO(g)} + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{CO}_2(\text{g})$  at 25 °C, we write

$$\begin{aligned} \Delta_r G^\ominus &= \Delta_f G^\ominus(\text{CO}_2, \text{g}) - \{\Delta_f G^\ominus(\text{CO}, \text{g}) + \frac{1}{2}\Delta_f G^\ominus(\text{O}_2, \text{g})\} \\ &= -394.4 \text{ kJ mol}^{-1} - \{-137.2 + \frac{1}{2}(0)\} \text{ kJ mol}^{-1} \\ &= -257.2 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test 3C.6** Calculate the standard reaction Gibbs energy for the combustion of CH<sub>4</sub>(g) at 298 K.

Answer: -818 kJ mol<sup>-1</sup>

Just as is done in Topics 2C and 3B, where it is acknowledged that solutions of cations cannot be prepared without their accompanying anions, we define one ion, conventionally the hydrogen ion, to have zero standard Gibbs energy of formation at all temperatures:

$$\Delta_f G^\ominus(\text{H}^+, \text{aq}) = 0 \quad \text{Convention} \quad \text{Ions in solution} \quad (3C.19)$$

In essence, this definition adjusts the actual values of the Gibbs energies of formation of ions by a fixed amount, which is chosen so that the standard value for one of them, H<sup>+</sup>(aq), has the value zero.

### Brief illustration 3C.5 Gibbs energies of formation of ions

For the reaction

we can write

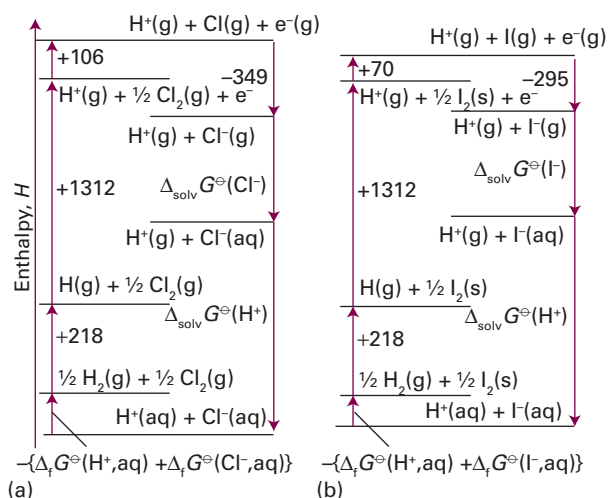

$$\Delta_r G^\ominus = \Delta_f G^\ominus(\text{H}^+, \text{aq}) + \Delta_f G^\ominus(\text{Cl}^-, \text{aq}) = \Delta_f G^\ominus(\text{Cl}^-, \text{aq})$$

and hence identify  $\Delta_f G^\ominus(\text{Cl}^-, \text{aq})$  as -131.23 kJ mol<sup>-1</sup>.

**Self-test 3C.7** Evaluate  $\Delta_f G^\ominus(\text{Ag}^+, \text{aq})$  from  $\text{Ag(s)} + \frac{1}{2}\text{Cl}_2(\text{g}) \rightarrow \text{Ag}^+(\text{aq}) + \text{Cl}^-(\text{aq})$ ,  $\Delta_r G^\ominus = -54.12 \text{ kJ mol}^{-1}$

Answer: +77.11 kJ mol<sup>-1</sup>

The factors responsible for the magnitude of the Gibbs energy of formation of an ion in solution can be identified by analysing it in terms of a thermodynamic cycle. As an illustration, we consider the standard Gibbs energy of formation of Cl<sup>-</sup> in water, which is -131 kJ mol<sup>-1</sup>. We do so by treating the formation reaction

**Figure 3C.3** The thermodynamic cycles for the discussion of the Gibbs energies of solvation (hydration) and formation of (a) chloride ions, (b) iodide ions in aqueous solution. The changes in Gibbs energies around the cycle sum to zero because  $G$  is a state function.

as the outcome of the sequence of steps shown in Fig. 3C.3 (with values taken from the *Resource section*). The sum of the Gibbs energies for all the steps around a closed cycle is zero, so

$$\Delta_f G^\ominus(\text{Cl}^-, \text{aq}) = 1287 \text{ kJ mol}^{-1} + \Delta_{\text{solv}} G^\ominus(\text{H}^+) + \Delta_{\text{solv}} G^\ominus(\text{Cl}^-)$$

The standard Gibbs energies of formation of the gas-phase ions are unknown. We have therefore used ionization energies and electron affinities and have assumed that any differences from the Gibbs energies arising from conversion to enthalpy and the inclusion of entropies to obtain Gibbs energies in the formation of  $\text{H}^+$  are cancelled by the corresponding terms in the electron gain of  $\text{X}$ . The conclusions from the cycles are therefore only approximate. An important point to note is that the value of  $\Delta_f G^\ominus$  of an ion  $\text{X}$  is not determined by the properties of  $\text{X}$  alone but includes contributions from the dissociation, ionization, and hydration of hydrogen.

### (b) The Born equation

Gibbs energies of solvation of individual ions may be estimated from an equation derived by Max Born, who identified  $\Delta_{\text{solv}} G^\ominus$  with the electrical work of transferring an ion from a vacuum into the solvent treated as a continuous dielectric of relative permittivity  $\epsilon_r$ . The resulting **Born equation**, which is derived in the following *Justification*, is

$$\Delta_{\text{solv}} G^\ominus = -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right) \quad \text{Born equation} \quad (3\text{C.20a})$$

where  $z_i$  is the charge number of the ion and  $r_i$  its radius ( $N_A$  is Avogadro's constant). Note that  $\Delta_{\text{solv}} G^\ominus < 0$ , and that  $\Delta_{\text{solv}} G^\ominus$  is strongly negative for small, highly charged ions in media of high relative permittivity. For water, for which  $\epsilon_r = 78.54$  at  $25^\circ\text{C}$ ,

$$\Delta_{\text{solv}} G^\ominus = -\frac{z_i^2}{r_i / \text{pm}} \times 6.86 \times 10^4 \text{ kJ mol}^{-1} \quad (3\text{C.20b})$$

#### Brief illustration 3C.6 The Born equation

To see how closely the Born equation reproduces the experimental data, we calculate the difference in the values of  $\Delta_f G^\ominus$  for  $\text{Cl}^-$  and  $\text{I}^-$  in water at  $25^\circ\text{C}$ , given their radii as 181 pm and 220 pm, respectively, is

$$\begin{aligned} \Delta_{\text{solv}} G^\ominus(\text{Cl}^-) - \Delta_{\text{solv}} G^\ominus(\text{I}^-) &= -\left(\frac{1}{181} - \frac{1}{220}\right) \times 6.86 \times 10^4 \text{ kJ mol}^{-1} \\ &= -67 \text{ kJ mol}^{-1} \end{aligned}$$

This estimated difference is in good agreement with the experimental difference, which is  $-61 \text{ kJ mol}^{-1}$ .

**Self-test 3C.8** Estimate the value of  $\Delta_{\text{solv}} G^\ominus(\text{Cl}^-) - \Delta_{\text{solv}} G^\ominus(\text{Br}^-)$  in water from experimental data and from the Born equation.

Answer:  $-26 \text{ kJ mol}^{-1}$  experimental;  $-29 \text{ kJ mol}^{-1}$  calculated

#### Justification 3C.3 The Born equation

The strategy of the calculation is to identify the Gibbs energy of solvation with the work of transferring an ion from a vacuum into the solvent. That work is calculated by taking the difference of the work of charging an ion when it is in the solution and the work of charging the same ion when it is in a vacuum.

The Coulomb interaction between two charges  $Q_1$  and  $Q_2$  separated by a distance  $r$  is described by the Coulombic potential energy:

$$V(r) = \frac{Q_1 Q_2}{4\pi\epsilon r}$$

where  $\epsilon$  is the medium's permittivity. The relative permittivity (formerly called the 'dielectric constant') of a substance is defined as  $\epsilon_r = \epsilon/\epsilon_0$ . Ions do not interact as strongly in a solvent of high relative permittivity (such as water, with  $\epsilon_r = 80$  at  $293 \text{ K}$ ) as they do in a solvent of lower relative permittivity (such as ethanol, with  $\epsilon_r = 25$  at  $293 \text{ K}$ ). See Topic 16A for more details. The potential energy of a charge  $Q_1$  in the presence of a charge  $Q_2$  can be expressed in terms of the Coulomb potential,  $\phi$ :

$$V(r) = Q_1 \phi(r) \quad \phi(r) = \frac{Q_2}{4\pi\epsilon r}$$

We model an ion as a sphere of radius  $r_i$  immersed in a medium of permittivity  $\epsilon$ . The charge of the sphere is  $Q$ , the electric potential,  $\phi$ , at its surface is the same as the potential due to

a point charge at its centre, so we can use the last expression and write

$$\phi(r_i) = \frac{Q}{4\pi\epsilon r_i}$$

The work of bringing up a charge  $dQ$  to the sphere is  $\phi(r_i)dQ$ . Therefore, the total work of charging the sphere from 0 to  $z_i e$  is

$$w = \int_0^{z_i e} \phi(r_i) dQ = \frac{1}{4\pi\epsilon r_i} \int_0^{z_i e} Q dQ = \frac{z_i^2 e^2}{8\pi\epsilon r_i}$$

This electrical work of charging, when multiplied by Avogadro's constant, is the molar Gibbs energy for charging the ions.

The work of charging an ion in a vacuum is obtained by setting  $\epsilon = \epsilon_0$ , the vacuum permittivity. The corresponding value for charging the ion in a medium is obtained by setting  $\epsilon = \epsilon_r \epsilon_0$ , where  $\epsilon_r$  is the relative permittivity of the medium. It follows

that the change in molar Gibbs energy that accompanies the transfer of ions from a vacuum to a solvent is the difference of these two quantities:

$$\begin{aligned} \Delta_{\text{solv}} G^\ominus &= \frac{z_i^2 e^2 N_A}{8\pi\epsilon r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} = \frac{z_i^2 e^2 N_A}{8\pi\epsilon_r \epsilon_0 r_i} - \frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \\ &= -\frac{z_i^2 e^2 N_A}{8\pi\epsilon_0 r_i} \left(1 - \frac{1}{\epsilon_r}\right) \end{aligned}$$

which is eqn 3B.20.

Calorimetry (for  $\Delta H$  directly, and for  $S$  via heat capacities) is only one of the ways of determining Gibbs energies. They may also be obtained from equilibrium constants (Topic 6A) and electrochemical measurements (Topic 6D), and for gases they may be calculated using data from spectroscopic observations (Topic 15F).

## Checklist of concepts

- 1. The **Clausius inequality** implies a number of criteria for spontaneous change under a variety of conditions that may be expressed in terms of the properties of the system alone; they are summarized by introducing the Helmholtz and Gibbs energies.
- 2. A **spontaneous process** at constant temperature and volume is accompanied by a decrease in the Helmholtz energy.
- 3. The change in the Helmholtz function is equal to the **maximum work** accompanying a process at constant temperature.
- 4. A spontaneous process at constant temperature and pressure is accompanied by a decrease in the Gibbs energy.
- 5. The change in the Gibbs function is equal to the **maximum non-expansion work** accompanying a process at constant temperature and pressure.
- 6. **Standard Gibbs energies of formation** are used to calculate the standard Gibbs energies of reactions.
- 7. The standard Gibbs energies of formation of ions may be estimated from a thermodynamic cycle and the **Born equation**.

### ► Why do you need to know this material?

The First and Second Laws of thermodynamics are both relevant to the behaviour of bulk matter, and we can bring the whole force of thermodynamics to bear on a problem by setting up a formulation that combines them.

### ► What is the key idea?

The fact that infinitesimal changes in thermodynamic functions are exact differentials leads to relations between a variety of properties.

### ► What do you need to know already?

You need to be aware of the definitions of the state functions  $U$  (Topic 2A),  $H$  (Topic 2B),  $S$  (Topic 3A), and  $A$  and  $G$  (Topic 3C). The mathematical derivations in this Topic draw frequently on the properties of partial derivatives and exact differentials, which are described in *Mathematical background 2*.

The First Law of thermodynamics may be written  $dU = dq + dw$ . For a reversible change in a closed system of constant composition, and in the absence of any additional (non-expansion) work, we may set  $dw_{\text{rev}} = -pdV$  and (from the definition of entropy)  $dq_{\text{rev}} = TdS$ , where  $p$  is the pressure of the system and  $T$  its temperature. Therefore, for a reversible change in a closed system,

$$dU = TdS - pdV \quad \text{The fundamental equation} \quad (3D.1)$$

However, because  $dU$  is an exact differential, its value is independent of path. Therefore, the same value of  $dU$  is obtained whether the change is brought about irreversibly or reversibly. Consequently, *eqn 3D.1 applies to any change—reversible or irreversible—of a closed system that does no additional (non-expansion) work*. We shall call this combination of the First and Second Laws the **fundamental equation**.

The fact that the fundamental equation applies to both reversible and irreversible changes may be puzzling at first sight. The reason is that only in the case of a reversible change may  $TdS$  be identified with  $dq$  and  $-pdV$  with  $dw$ . When the change is irreversible,  $TdS > dq$  (the Clausius inequality) and  $-pdV > dw$ . The sum of  $dw$  and  $dq$  remains equal to the sum of  $TdS$  and  $-pdV$ , provided the composition is constant.

## 3D.1 Properties of the internal energy

Equation 3D.1 shows that the internal energy of a closed system changes in a simple way when either  $S$  or  $V$  is changed ( $dU \propto dS$  and  $dU \propto dV$ ). These simple proportionalities suggest that  $U$  is best regarded as a function of  $S$  and  $V$ . We could regard  $U$  as a function of other variables, such as  $S$  and  $p$  or  $T$  and  $V$ , because they are all interrelated; but the simplicity of the fundamental equation suggests that  $U(S, V)$  is the best choice.

The *mathematical* consequence of  $U$  being a function of  $S$  and  $V$  is that we can express an infinitesimal change  $dU$  in terms of changes  $dS$  and  $dV$  by

$$dU = \left( \frac{\partial U}{\partial S} \right)_V dS + \left( \frac{\partial U}{\partial V} \right)_S dV \quad (3D.2)$$

The two partial derivatives are the slopes of the plots of  $U$  against  $S$  and  $V$ , respectively. When this expression is compared

term-by-term to the *thermodynamic* relation, eqn 3D.1, we see that for systems of constant composition,

$$\left(\frac{\partial U}{\partial S}\right)_V = T \quad \left(\frac{\partial U}{\partial V}\right)_S = -p \quad (3D.3)$$

The first of these two equations is a purely thermodynamic definition of temperature as the ratio of the changes in the internal energy (a First-Law concept) and entropy (a Second-Law concept) of a constant-volume, closed, constant-composition system. We are beginning to generate relations between the properties of a system and to discover the power of thermodynamics for establishing unexpected relations.

### (a) The Maxwell relations

An infinitesimal change in a function  $f(x,y)$  can be written  $df=gdx+hdy$ , where  $g$  and  $h$  may be functions of  $x$  and  $y$ . The mathematical criterion for  $df$  being an exact differential (in the sense that its integral is independent of path) is that

$$\left(\frac{\partial g}{\partial y}\right)_x = \left(\frac{\partial h}{\partial x}\right)_y \quad (3D.4)$$

This criterion is discussed in *Mathematical background 2*. Because the fundamental equation, eqn 3D.1, is an expression for an exact differential, the functions multiplying  $dS$  and  $dV$  (namely  $T$  and  $-p$ ) must pass this test. Therefore, it must be the case that

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V \quad \text{A Maxwell relation} \quad (3D.5)$$

We have generated a relation between quantities which, at first sight, would not seem to be related.

Equation 3D.5 is an example of a **Maxwell relation**. However, apart from being unexpected, it does not look particularly interesting. Nevertheless, it does suggest that there might be other similar relations that are more useful. Indeed, we can use the fact that  $H$ ,  $G$ , and  $A$  are all state functions to derive three more Maxwell relations. The argument to obtain them runs in the same way in each case: because  $H$ ,  $G$ , and  $A$  are state functions, the expressions for  $dH$ ,  $dG$ , and  $dA$  satisfy relations like eqn 3D.4. All four relations are listed in Table 3D.1.

#### Example 3D.1 Using the Maxwell relations

Use the Maxwell relations in Table 3D.1 to show that the entropy of a perfect gas is proportional to  $\ln V$ .

**Method** The natural place to start, given that you are invited to use the Maxwell relations, is by considering the relation for  $(\partial S/\partial V)_T$ , as that differential coefficient shows how the entropy

varies with volume at constant temperature. Be alert for an opportunity to use the perfect gas equation of state.

**Answer** From Table 3D.1,

$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial p}{\partial T}\right)_V$$

Now use the perfect gas equation of state to write

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial(nRT/V)}{\partial T}\right)_V = \frac{nR}{V}$$

At this point, we can write

$$\left(\frac{\partial S}{\partial V}\right)_T = \frac{nR}{V}$$

and therefore, at constant temperature

$$\int dS = nR \int \frac{dV}{V} = nR \ln V + \text{constant}$$

The integral of the left is  $S + \text{constant}$ , which completes the demonstration.

**Self-test 3D.1** How does the entropy depend on the volume of a van der Waals gas? Discuss.

Answer:  $S$  varies as  $nR \ln(V-nb)$ ; molecules in a smaller available volume

Table 3D.1 The Maxwell relations

State function	Exact differential	Maxwell relation
$U$	$dU = TdS - pdV$	$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial p}{\partial S}\right)_V$
$H$	$dH = TdS + Vdp$	$\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{\partial V}{\partial S}\right)_p$
$A$	$dA = -pdV - SdT$	$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial S}{\partial V}\right)_T$
$G$	$dG = Vdp - SdT$	$\left(\frac{\partial V}{\partial T}\right)_p = -\left(\frac{\partial S}{\partial p}\right)_T$

### (b) The variation of internal energy with volume

The quantity  $\pi_T = (\partial U/\partial V)_T$ , which represents how the internal energy changes as the volume of a system is changed isothermally, plays a central role in the manipulation of the First Law, and in Topic 2D we use the relation

$$\pi_T = T \left(\frac{\partial p}{\partial T}\right)_V - p \quad \text{A thermodynamic equation of state} \quad (3D.6)$$

This relation is called a **thermodynamic equation of state** because it is an expression for pressure in terms of a variety of thermodynamic properties of the system. We are now ready to derive it by using a Maxwell relation.

### Justification 3D.1 The thermodynamic equation of state

We obtain an expression for the coefficient  $\pi_T$  by dividing both sides of eqn 3D.1 by  $dV$ , imposing the constraint of constant temperature, which gives

$$\left(\frac{\partial U}{\partial V}\right)_T = \left(\frac{\partial U}{\partial S}\right)_V \left(\frac{\partial S}{\partial V}\right)_T + \left(\frac{\partial U}{\partial V}\right)_S$$

Next, we introduce the two relations in eqn 3D.3 (as indicated by the annotations) and the definition of  $\pi_T$  to obtain

$$\pi_T = T \left(\frac{\partial S}{\partial V}\right)_T - p$$

The third Maxwell relation in Table 3D.1 turns  $(\partial S/\partial V)_T$  into  $(\partial p/\partial T)_V$ , which completes the derivation of eqn 3D.6.

### Example 3D.2 Deriving a thermodynamic relation

Show thermodynamically that  $\pi_T = 0$  for a perfect gas, and compute its value for a van der Waals gas.

**Method** Proving a result ‘thermodynamically’ means basing it entirely on general thermodynamic relations and equations of state, without drawing on molecular arguments (such as the existence of intermolecular forces). We know that for a perfect gas,  $p = nRT/V$ , so this relation should be used in eqn 3D.6. Similarly, the van der Waals equation is given in Table 1C.3, and for the second part of the question it should be used in eqn 3D.6.

**Answer** For a perfect gas we write

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial nRT/V}{\partial T}\right)_V = \frac{nR}{V}$$

Then, eqn 3D.6 becomes

$$\pi_T = \frac{nRT}{V} - p = 0$$

The equation of state of a van der Waals gas is

$$p = \frac{nRT}{V-nb} - a\frac{n^2}{V^2}$$

Because  $a$  and  $b$  are independent of temperature,

$$\left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{\partial nRT/(V-nb)}{\partial T}\right)_V = \frac{nR}{V-nb}$$

Therefore, from eqn 3D.6,

$$\pi_T = \frac{nRT}{V-nb} - p = \frac{nRT}{V-nb} - \left(\frac{nRT}{V-nb} - a\frac{n^2}{V^2}\right) = a\frac{n^2}{V^2}$$

This result for  $\pi_T$  implies that the internal energy of a van der Waals gas increases when it expands isothermally (that is,  $(\partial U/\partial V)_T > 0$ ), and that the increase is related to the parameter  $a$ , which models the attractive interactions between the particles. A larger molar volume, corresponding to a greater average separation between molecules, implies weaker mean intermolecular attractions, so the total energy is greater.

**Self-test 3D.2** Calculate  $\pi_T$  for a gas that obeys the virial equation of state (Table 1C.3).

Answer:  $\pi_T = RT^2(\partial B/\partial T)_V/V_m^2 + \dots$

## 3D.2 Properties of the Gibbs energy

The same arguments that we have used for  $U$  can be used for the Gibbs energy  $G = H - TS$ . They lead to expressions showing how  $G$  varies with pressure and temperature that are important for discussing phase transitions and chemical reactions.

### (a) General considerations

When the system undergoes a change of state,  $G$  may change because  $H$ ,  $T$ , and  $S$  all change and

$$dG = dH - d(TS) = dH - TdS - SdT$$

Because  $H = U + pV$ , we know that

$$dH = dU + d(pV) = dU + pdV + Vdp$$

and therefore

$$dG = dU + pdV + Vdp - TdS - SdT$$

For a closed system doing no non-expansion work, we can replace  $dU$  by the fundamental equation  $dU = TdS - pdV$  and obtain

$$dG = TdS - pdV + pdV + Vdp - TdS - SdT$$

Four terms now cancel on the right, and we conclude that for a closed system in the absence of non-expansion work and at constant composition

$$dG = Vdp - SdT$$

The fundamental equation of chemical thermodynamics (3D.7)

This expression, which shows that a change in  $G$  is proportional to a change in  $p$  or  $T$ , suggests that  $G$  may be best regarded as a function of  $p$  and  $T$ . It may be regarded as the **fundamental equation of chemical thermodynamics** as it is so central to the application of thermodynamics to chemistry: it suggests that  $G$  is an important quantity in chemistry because the pressure and temperature are usually the variables under our control. In other words,  $G$  carries around the combined consequences of the First and Second Laws in a way that makes it particularly suitable for chemical applications.

The same argument that led to eqn 3D.3, when applied to the exact differential  $dG = Vdp - SdT$ , now gives

$$\left(\frac{\partial G}{\partial T}\right)_p = -S \quad \left(\frac{\partial G}{\partial p}\right)_T = V \quad \text{The variation of } G \text{ with } T \text{ and } p \quad (3D.8)$$

These relations show how the Gibbs energy varies with temperature and pressure (Fig. 3D.1). The first implies that:

- Because  $S > 0$  for all substances,  $G$  always *decreases* when the temperature is raised (at constant pressure and composition).
- Because  $(\partial G/\partial T)_p$  becomes more negative as  $S$  increases,  $G$  decreases most sharply with increasing temperature when the entropy of the system is large.

Physical interpretation

Therefore, the Gibbs energy of the gaseous phase of a substance, which has a high molar entropy, is more sensitive to temperature than its liquid and solid phases (Fig. 3D.2). Similarly, the second relation implies that:

- Because  $V > 0$  for all substances,  $G$  always *increases* when the pressure of the system is increased (at constant temperature and composition).

Physical interpretation

**Figure 3D.1** The variation of the Gibbs energy of a system with (a) temperature at constant pressure and (b) pressure at constant temperature. The slope of the former is equal to the negative of the entropy of the system and that of the latter is equal to the volume.

**Figure 3D.2** The variation of the Gibbs energy with the temperature is determined by the entropy. Because the entropy of the gaseous phase of a substance is greater than that of the liquid phase, and the entropy of the solid phase is smallest, the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance.

**Figure 3D.3** The variation of the Gibbs energy with the pressure is determined by the volume of the sample. Because the volume of the gaseous phase of a substance is greater than that of the same amount of liquid phase, and the entropy of the solid phase is smallest (for most substances), the Gibbs energy changes most steeply for the gas phase, followed by the liquid phase, and then the solid phase of the substance. Because the volumes of the solid and liquid phases of a substance are similar, their molar Gibbs energies vary by similar amounts as the pressure is changed.

- Because  $(\partial G/\partial p)_T$  increases with  $V$ ,  $G$  is more sensitive to pressure when the volume of the system is large.

Because the molar volume of the gaseous phase of a substance is greater than that of its condensed phases, the molar Gibbs energy of a gas is more sensitive to pressure than its liquid and solid phases (Fig. 3D.3).

#### Brief illustration 3D.1 The variation of molar Gibbs energy

The standard molar entropy of liquid water at 298 K is  $69.91 \text{ J K}^{-1} \text{ mol}^{-1}$ . It follows that when the temperature is increased by 5.0 K, the molar Gibbs energy changes by

$$\begin{aligned}\delta G_m &\approx \left(\frac{\partial G_m}{\partial T}\right)_p \delta T = -S_m \delta T = -(69.91 \text{ J K}^{-1} \text{ mol}^{-1}) \times (5.0 \text{ K}) \\ &= -0.35 \text{ kJ mol}^{-1}\end{aligned}$$

**Self-test 3D.3** The mass density of liquid water is  $0.9970 \text{ g cm}^{-3}$  at 298 K. By how much does its molar Gibbs energy change when the pressure is increased by 0.10 bar?

Answer:  $+0.18 \text{ J mol}^{-1}$

### (b) The variation of the Gibbs energy with temperature

Because the equilibrium composition of a system depends on the Gibbs energy, to discuss the response of the composition to temperature we need to know how  $G$  varies with temperature.

The first relation in eqn 3D.8,  $(\partial G/\partial T)_p = -S$ , is our starting point for this discussion. Although it expresses the variation of  $G$  in terms of the entropy, we can express it in terms of the enthalpy by using the definition of  $G$  to write  $S = (H - G)/T$ . Then

$$\left(\frac{\partial G}{\partial T}\right)_p = \frac{G - H}{T} \quad (3D.9)$$

In Topic 6A it is shown that the equilibrium constant of a reaction is related to  $G/T$  rather than to  $G$  itself, and it is easy to deduce from the last equation (see the following *Justification*) that

$$\left(\frac{\partial G/T}{\partial T}\right)_p = -\frac{H}{T^2} \quad \text{Gibbs-Helmholtz equation} \quad (3D.10)$$

This expression is called the **Gibbs-Helmholtz equation**. It shows that if we know the enthalpy of the system, then we know how  $G/T$  varies with temperature.

#### Justification 3D.2 The Gibbs-Helmholtz equation

First, we note that

$$\begin{aligned}\left(\frac{\partial G/T}{\partial T}\right)_p &= \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p + G \frac{d(1/T)}{dT} = \frac{1}{T} \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T^2} \\ &= \frac{1}{T} \left\{ \left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} \right\}\end{aligned}$$

Then we use eqn 3D.9 to write

$$\left(\frac{\partial G}{\partial T}\right)_p - \frac{G}{T} = \frac{G - H}{T} - \frac{G}{T} = -\frac{H}{T}$$

When this expression is substituted in the preceding one, we obtain eqn 3D.10.

The Gibbs-Helmholtz equation is most useful when it is applied to changes, including changes of physical state and chemical reactions at constant pressure. Then, because  $\Delta G = G_f - G_i$  for the change of Gibbs energy between the final and initial states and because the equation applies to both  $G_f$  and  $G_i$ , we can write

$$\left(\frac{\partial \Delta G/T}{\partial T}\right)_p = -\frac{\Delta H}{T^2} \quad (3D.11)$$

This equation shows that if we know the change in enthalpy of a system that is undergoing some kind of transformation (such as vaporization or reaction), then we know how the corresponding change in Gibbs energy varies with temperature. As we shall see, this is a crucial piece of information in chemistry.

### (c) The variation of the Gibbs energy with pressure

To find the Gibbs energy at one pressure in terms of its value at another pressure, the temperature being constant, we set  $dT = 0$  in eqn 3D.7, which gives  $dG = V dp$ , and integrate:

$$G(p_f) = G(p_i) + \int_{p_i}^{p_f} V dp \quad (3D.12a)$$

For molar quantities,

$$G_m(p_f) = G_m(p_i) + \int_{p_i}^{p_f} V_m dp \quad (3D.12b)$$

This expression is applicable to any phase of matter, but to evaluate it we need to know how the molar volume,  $V_m$ , depends on the pressure.

The molar volume of a condensed phase changes only slightly as the pressure changes (Fig. 3D.4), so we can treat  $V_m$  as a constant and take it outside the integral:

$$G_m(p_f) = G_m(p_i) + V_m \int_{p_i}^{p_f} dp$$

That is,

$$G_m(p_f) = G_m(p_i) + (p_f - p_i) V_m \quad \begin{array}{l} \text{Incompressible} \\ \text{solid or liquid} \end{array} \quad \begin{array}{l} \text{Molar} \\ \text{Gibbs} \\ \text{energy} \end{array} \quad (3D.13)$$

Under normal laboratory conditions  $(p_f - p_i)V_m$  is very small and may be neglected. Hence, we may usually suppose that the Gibbs energies of solids and liquids are independent of pressure. However, if we are interested in geophysical problems, then because pressures in the Earth's interior are huge, their effect on the Gibbs energy cannot be ignored. If the pressures are so great that there are substantial volume changes over the range of integration, then we must use the complete expression, eqn 3D.12.

**Figure 3D.4** The difference in Gibbs energy of a solid or liquid at two pressures is equal to the rectangular area shown. We have assumed that the variation of volume with pressure is negligible.

### Example 3D.3 Evaluating the pressure dependence of a Gibbs energy of transition

Suppose that for a certain phase transition of a solid  $\Delta_{\text{trs}}V = +1.0 \text{ cm}^3 \text{ mol}^{-1}$  is independent of pressure. By how much does that Gibbs energy of transition change when the pressure is increased from 1.0 bar ( $1.0 \times 10^5 \text{ Pa}$ ) to 3.0 Mbar ( $3.0 \times 10^{11} \text{ Pa}$ )?

**Method** Start with eqn 3D.12b to obtain expressions for the Gibbs energy of each of the phases 1 and 2 of the solid

$$G_{\text{m},1}(p_f) = G_{\text{m},1}(p_i) + \int_{p_i}^{p_f} V_{\text{m},1} dp$$

$$G_{\text{m},2}(p_f) = G_{\text{m},2}(p_i) + \int_{p_i}^{p_f} V_{\text{m},2} dp$$

Now subtract the second expression from the first, noting that  $G_{\text{m},2} - G_{\text{m},1} = \Delta_{\text{trs}}G$  and  $V_{\text{m},2} - V_{\text{m},1} = \Delta_{\text{trs}}V$ :

$$\Delta_{\text{trs}}G_{\text{m}}(p_f) = \Delta_{\text{trs}}G_{\text{m}}(p_i) + \int_{p_i}^{p_f} \Delta_{\text{trs}}V_{\text{m}} dp$$

Use the data to complete the calculation.

**Answer** Because  $\Delta_{\text{trs}}V$  is independent of pressure, the expression above simplifies to

$$\begin{aligned} \Delta_{\text{trs}}G_{\text{m}}(p_f) &= \Delta_{\text{trs}}G_{\text{m}}(p_i) + \Delta_{\text{trs}}V_{\text{m}} \int_{p_i}^{p_f} dp \\ &= \Delta_{\text{trs}}G_{\text{m}}(p_i) + \Delta_{\text{trs}}V_{\text{m}}(p_f - p_i) \end{aligned}$$

Inserting the data gives

$$\begin{aligned} \Delta_{\text{trs}}G(3 \text{ Mbar}) &= \Delta_{\text{trs}}G(1 \text{ bar}) + (1.0 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}) \times \\ &\quad (3.0 \times 10^{11} \text{ Pa} - 1.0 \times 10^5 \text{ Pa}) \\ &= \Delta_{\text{trs}}G(1 \text{ bar}) + 3.0 \times 10^2 \text{ kJ mol}^{-1} \end{aligned}$$

where we have used  $1 \text{ Pa m}^3 = 1 \text{ J}$ .

**Self-test 3D.4** Calculate the change in  $G_{\text{m}}$  for ice at  $-10^\circ\text{C}$ , with density  $917 \text{ kg m}^{-3}$ , when the pressure is increased from 1.0 bar to 2.0 bar.

Answer:  $+2.0 \text{ J mol}^{-1}$

**Figure 3D.5** The difference in Gibbs energy for a perfect gas at two pressures is equal to the area shown below the perfect-gas isotherm.

The molar volumes of gases are large, so the Gibbs energy of a gas depends strongly on the pressure. Furthermore, because the volume also varies markedly with the pressure, we cannot treat it as a constant in the integral in eqn 3D.12b (Fig. 3D.5). For a perfect gas we substitute  $V_{\text{m}} = RT/p$  into the integral, treat  $RT$  as a constant, and find

$$G_{\text{m}}(p_f) = G_{\text{m}}(p_i) + RT \int_{p_i}^{p_f} \frac{1}{p} dp = G_{\text{m}}(p_i) + RT \ln \frac{p_f}{p_i} \quad (3D.14)$$

This expression shows that when the pressure is increased ten-fold at room temperature, the molar Gibbs energy increases by  $RT \ln 10 \approx 6 \text{ kJ mol}^{-1}$ . It also follows from this equation that if we set  $p_i = p^\ominus$  (the standard pressure of 1 bar), then the molar Gibbs energy of a perfect gas at a pressure  $p$  (set  $p_i = p$ ) is related to its standard value by

$$G_{\text{m}}(p) = G_{\text{m}}^\ominus + RT \ln \frac{p}{p^\ominus} \quad \text{Perfect gas Molar Gibbs energy} \quad (3D.15)$$

### Brief illustration 3D.2 The pressure dependence of the Gibbs energy of a gas

Suppose we are interested in the molar Gibbs energy of water vapour (treated as a perfect gas) when the pressure is increased isothermally from 1.0 bar to 2.0 bar at 298 K. According to eqn 3D.14

$$\begin{aligned} G_{\text{m}}(2.0 \text{ bar}) &= G_{\text{m}}^\ominus(1.0 \text{ bar}) + (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \times \\ &\quad \ln \left( \frac{2.0 \text{ bar}}{1.0 \text{ bar}} \right) = G_{\text{m}}^\ominus(1.0 \text{ bar}) + 1.7 \text{ kJ mol}^{-1} \end{aligned}$$

Note that whereas the change in molar Gibbs energy for a condensed phase is a few joules per mole, for a gas the change is of the order of kilojoules per mole

**Self-test 3D.5** By how much does the molar Gibbs energy of a perfect gas differ from its standard value at 298 K when its pressure is 0.10 bar?

Answer:  $-5.7 \text{ kJ mol}^{-1}$

**Figure 3D.6** The molar Gibbs energy of a perfect gas varies as  $\ln p$ , and the standard state is reached at  $p^\ominus$ . Note that, as  $p \rightarrow 0$ , the molar Gibbs energy becomes negatively infinite.

The logarithmic dependence of the molar Gibbs energy on the pressure predicted by eqn 3D.15 is illustrated in Fig. 3D.6. This very important expression, the consequences of which we unfold in the following chapters, applies to perfect gases (which is usually a good enough approximation). The following section shows how to accommodate imperfections.

#### (d) The fugacity

At various stages in the development of physical chemistry it is necessary to switch from a consideration of idealized systems to real systems. In many cases it is desirable to preserve the form of the expressions that have been derived for an idealized system. Then deviations from the idealized behaviour can be expressed most simply. For instance, the pressure-dependence of the molar Gibbs energy of a real gas might resemble that shown in Fig. 3D.7. To adapt eqn 3D.14 to this case, we replace the true pressure,  $p$ , by an effective pressure, called the **fugacity**,<sup>1</sup>  $f$ , and write

$$G_m = G_m^\ominus + RT \ln(f/p^\ominus) \quad \text{Definition Fugacity} \quad (3D.16)$$

The fugacity, a function of the pressure and temperature, is defined so that this relation is exactly true. A very similar approach is taken in the discussion of real solutions (Topic 5E),

<sup>1</sup> The name 'fugacity' comes from the Latin for 'fleetness' in the sense of 'escaping tendency'; fugacity has the same dimensions as pressure.

**Figure 3D.7** The molar Gibbs energy of a real gas. As  $p \rightarrow 0$ , the molar Gibbs energy coincides with the value for a perfect gas (shown by the purple line). When attractive forces are dominant (at intermediate pressures), the molar Gibbs energy is less than that of a perfect gas and the molecules have a lower 'escaping tendency'. At high pressures, when repulsive forces are dominant, the molar Gibbs energy of a real gas is greater than that of a perfect gas. Then the 'escaping tendency' is increased.

where 'activities' are effective concentrations. Indeed,  $f/p^\ominus$  may be regarded as a gas-phase activity.

Although thermodynamic expressions in terms of fugacities derived from this expression are exact, they are useful only if we know how to interpret fugacities in terms of actual pressures. To develop this relation we write the fugacity as

$$f = \phi p \quad \text{Definition Fugacity coefficient} \quad (3D.17)$$

where  $\phi$  is the dimensionless **fugacity coefficient**, which in general depends on the temperature, the pressure, and the identity of the gas. We show in the following *Justification* that the fugacity coefficient is related to the compression factor,  $Z$ , of a gas (Topic 1C) by

$$\ln \phi = \int_0^p \frac{Z-1}{p} dp \quad (3D.18)$$

Provided we know how  $Z$  varies with pressure up to the pressure of interest, this expression enable us to determine the fugacity coefficient and hence, through eqn 3D.17, to relate the fugacity to the pressure of the gas.

#### Justification 3D.3 The fugacity coefficient

Equation 3D.12a is true for all gases whether real or perfect. Expressing it in terms of the fugacity by using eqn 3D.16 turns it into

$$\int_{p'}^p V_m dp = G_m(p) - G_m(p') = \left\{ G_m^\ominus + RT \ln \frac{f}{p^\ominus} \right\} - \left\{ G_m^\ominus + RT \ln \frac{f'}{p^\ominus} \right\} = RT \ln \frac{f}{f'}$$

In this expression,  $f$  is the fugacity when the pressure is  $p$  and  $f'$  is the fugacity when the pressure is  $p'$ . If the gas were perfect, we would write

$$\int_{p'}^p \overbrace{V_{\text{perfect,m}}^{RT/p}} d p = RT \int_{p'}^p \frac{1}{p'} d p = RT \ln \frac{p}{p'}$$

The difference between the two equations is

$$\begin{aligned} \int_{p'}^p (V_m - V_{\text{perfect,m}}) d p &= RT \left( \ln \frac{f}{f'} - \ln \frac{p}{p'} \right) = RT \ln \frac{f/f'}{p/p'} \\ &= RT \ln \frac{f/p}{f'/p'} \end{aligned}$$

which can be rearranged into

$$\ln \frac{f/p}{f'/p'} = \frac{1}{RT} \int_{p'}^p (V_m - V_{\text{perfect,m}}) d p$$

When  $p' \rightarrow 0$ , the gas behaves perfectly and  $f'$  becomes equal to the pressure,  $p'$ . Therefore,  $f'/p' \rightarrow 1$  as  $p' \rightarrow 0$ . If we take this limit, which means setting  $f'/p' = 1$  on the left and  $p' = 0$  on the right, the last equation becomes

$$\ln \frac{f}{p} = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect,m}}) d p$$

Then, with  $\phi = f/p$ ,

$$\ln \phi = \frac{1}{RT} \int_0^p (V_m - V_{\text{perfect,m}}) d p$$

For a perfect gas,  $V_{\text{perfect,m}} = RT/p$ . For a real gas,  $V_m = RTZ/p$ , where  $Z$  is the compression factor of the gas (Topic 1C). With these two substitutions, we obtain eqn 3D.18.

For a perfect gas,  $\phi = 1$  at all pressures and temperatures. We know from Fig. 1C.9 that for most gases  $Z < 1$  up to moderate pressures, but that  $Z > 1$  at higher pressures. If  $Z < 1$  throughout the range of integration, then the integrand in eqn 3D.18 is negative and  $\phi < 1$ . This value implies that  $f < p$  (the molecules tend to stick together) and that the molar Gibbs energy of the gas is less than that of a perfect gas. At higher pressures, the range over which  $Z > 1$  may dominate the range over which  $Z < 1$ . The integral is then positive,  $\phi > 1$ , and  $f > p$  (the repulsive interactions are dominant and tend to drive the particles apart). Now the molar Gibbs energy of the gas is greater than that of the perfect gas at the same pressure.

Figure 3D.8, which has been calculated using the full van der Waals equation of state, shows how the fugacity coefficient depends on the pressure in terms of the reduced variables

Figure 3D.8 The fugacity coefficient of a van der Waals gas plotted using the reduced variables of the gas. The curves are labelled with the reduced temperature  $T_r = T/T_c$ .

Table 3D.2\* The fugacity of nitrogen at 273 K,  $f/\text{atm}$

$p/\text{atm}$	$f/\text{atm}$
1	0.999 55
10	9.9560
100	97.03
1000	1839

\* More values are given in the Resource section.

(Topic 1C). Because critical constants are available in Table 1C.2, the graphs can be used for quick estimates of the fugacities of a wide range of gases. Table 3D.2 gives some explicit values for nitrogen.

### Brief illustration 3D.3 The fugacity of a real gas

To use Fig. 3D.8 to estimate the fugacity of carbon dioxide at 400 K and 400 atm, we note from Table 1C.2 that its critical constants are  $p_c = 72.85$  atm and  $T_c = 304.2$  K. In terms of reduced variables, the gas has  $p_r = (400 \text{ atm})/(72.85 \text{ atm}) = 5.5$  and  $T_r = (400 \text{ K})/(304.2 \text{ K}) = 1.31$ . From Fig. 3D.8 (interpolating by eye), these conditions correspond to  $\phi \approx 0.4$  and therefore to  $f \approx 160$  atm.

**Self-test 3D.6** At what temperature would carbon dioxide have a fugacity of 400 atm when its pressure is 400 atm?

Answer: At about  $T_r = 2.5$ , corresponding to  $T = 760$  K

## Checklist of concepts

- 1. The **fundamental equation**, a combination of the First and Second Laws, is an expression for the change in internal energy that accompanies changes in the volume and entropy of a system.
- 2. Relations between thermodynamic properties are generated by combining thermodynamic and mathematical expressions for changes in their values.
- 3. The **Maxwell relations** are a series of relations between derivatives of thermodynamic properties based on criteria for changes in the properties being exact differentials.
- 4. The Maxwell relations are used to derive the **thermodynamic equation of state** and to determine how the internal energy of a substance varies with volume.
- 5. The variation of the Gibbs energy of a system suggests that it is best regarded as a function of pressure and temperature.
- 6. The Gibbs energy of a substance decreases with temperature and increases with pressure.
- 7. The variation of Gibbs energy with temperature is related to the enthalpy by the **Gibbs–Helmholtz equation**.
- 8. The Gibbs energies of solids and liquids are almost independent of pressure; those of gases vary linearly with the logarithm of the pressure.
- 9. The **fugacity** is a kind of effective pressure of a real gas.

## Checklist of equations

Property	Equation	Comment	Equation number
Fundamental equation	$dU = TdS - pdV$	No additional work	3D.1
Fundamental equation of chemical thermodynamics	$dG = Vdp - SdT$	No additional work	3D.7
Variation of $G$	$(\partial G/\partial p)_T = V$ and $(\partial G/\partial T)_p = -S$	Composition constant	3D.8
Gibbs–Helmholtz equation	$(\partial(G/T)/\partial T)_p = -H/T^2$	Composition constant	3D.10
Pressure dependence of $G$	$G_m(p_f) = G_m(p_i) + (p_f - p_i)V_m$	Incompressible substance	3D.13
	$G_m(p_f) = G_m(p_i) + RT \ln(p_f/p_i)$	Perfect gas	3D.14
	$G_m = G_m^\ominus + RT \ln(p/p^\ominus)$	Perfect gas	3D.15
Fugacity	$G_m = G_m^\ominus + RT \ln(f/p^\ominus)$	Definition	3D.16
Fugacity coefficient	$f = \phi p$	Definition	3D.17
	$\ln \phi = \int_0^p \{(Z-1)/p\} dp$	Determination	3D.18

# CHAPTER 3 The Second and Third Laws

Assume that all gases are perfect and that data refer to 298.15 K unless otherwise stated.

## TOPIC 3A Entropy

### Discussion questions

**3A.1** The evolution of life requires the organization of a very large number of molecules into biological cells. Does the formation of living organisms violate the Second Law of thermodynamics? State your conclusion clearly and present detailed arguments to support it.

**3A.2** Discuss the significance of the terms 'dispersal' and 'disorder' in the context of the Second Law.

**3A.3** Discuss the relationships between the various formulations of the Second Law of thermodynamics.

**3A.4** Account for deviations from Trouton's rule for liquids such as water and ethanol. Is their entropy of vaporization larger or smaller than  $85 \text{ J K}^{-1} \text{ mol}^{-1}$ ? Why?

### Exercises

**3A.1(a)** During a hypothetical process, the entropy of a system increases by  $125 \text{ J K}^{-1}$  while the entropy of the surroundings decreases by  $125 \text{ J K}^{-1}$ . Is the process spontaneous?

**3A.1(b)** During a hypothetical process, the entropy of a system increases by  $105 \text{ J K}^{-1}$  while the entropy of the surroundings decreases by  $95 \text{ J K}^{-1}$ . Is the process spontaneous?

**3A.2(a)** A certain ideal heat engine uses water at the triple point as the hot source and an organic liquid as the cold sink. It withdraws  $10.00 \text{ kJ}$  of heat from the hot source and generates  $3.00 \text{ kJ}$  of work. What is the temperature of the organic liquid?

**3A.2(b)** A certain ideal heat engine uses water at the triple point as the hot source and an organic liquid as the cold sink. It withdraws  $2.71 \text{ kJ}$  of heat from the hot source and generates  $0.71 \text{ kJ}$  of work. What is the temperature of the organic liquid?

**3A.3(a)** Calculate the change in entropy when  $100 \text{ kJ}$  of energy is transferred reversibly and isothermally as heat to a large block of copper at (i)  $0^\circ\text{C}$ , (ii)  $50^\circ\text{C}$ .

**3A.3(b)** Calculate the change in entropy when  $250 \text{ kJ}$  of energy is transferred reversibly and isothermally as heat to a large block of lead at (i)  $20^\circ\text{C}$ , (ii)  $100^\circ\text{C}$ .

**3A.4(a)** Which of  $\text{F}_2(\text{g})$  and  $\text{I}_2(\text{g})$  is likely to have the higher standard molar entropy at  $298 \text{ K}$ ?

**3A.4(b)** Which of  $\text{H}_2\text{O}(\text{g})$  and  $\text{CO}_2(\text{g})$  is likely to have the higher standard molar entropy at  $298 \text{ K}$ ?

**3A.5(a)** Calculate the change in entropy when  $15 \text{ g}$  of carbon dioxide gas is allowed to expand from  $1.0 \text{ dm}^3$  to  $3.0 \text{ dm}^3$  at  $300 \text{ K}$ .

**3A.5(b)** Calculate the change in entropy when  $4.00 \text{ g}$  of nitrogen is allowed to expand from  $500 \text{ cm}^3$  to  $750 \text{ cm}^3$  at  $300 \text{ K}$ .

**3A.6(a)** Predict the enthalpy of vaporization of benzene from its normal boiling point,  $80.1^\circ\text{C}$ .

**3A.6(b)** Predict the enthalpy of vaporization of cyclohexane from its normal boiling point,  $80.7^\circ\text{C}$ .

**3A.7(a)** Calculate the molar entropy of a constant-volume sample of neon at  $500 \text{ K}$  given that it is  $146.22 \text{ J K}^{-1} \text{ mol}^{-1}$  at  $298 \text{ K}$ .

**3A.7(b)** Calculate the molar entropy of a constant-volume sample of argon at  $250 \text{ K}$  given that it is  $154.84 \text{ J K}^{-1} \text{ mol}^{-1}$  at  $298 \text{ K}$ .

**3A.8(a)** Calculate  $\Delta S$  (for the system) when the state of  $3.00 \text{ mol}$  of perfect gas atoms, for which  $C_{p,m} = \frac{5}{2}R$ , is changed from  $25^\circ\text{C}$  and  $1.00 \text{ atm}$  to  $125^\circ\text{C}$  and  $5.00 \text{ atm}$ . How do you rationalize the sign of  $\Delta S$ ?

**3A.8(b)** Calculate  $\Delta S$  (for the system) when the state of  $2.00 \text{ mol}$  diatomic perfect gas molecules, for which  $C_{p,m} = \frac{5}{2}R$ , is changed from  $25^\circ\text{C}$  and  $1.50 \text{ atm}$  to  $135^\circ\text{C}$  and  $7.00 \text{ atm}$ . How do you rationalize the sign of  $\Delta S$ ?

**3A.9(a)** Calculate  $\Delta S_{\text{tot}}$  when two copper blocks, each of mass  $1.00 \text{ kg}$ , one at  $50^\circ\text{C}$  and the other at  $0^\circ\text{C}$  are placed in contact in an isolated container. The specific heat capacity of copper is  $0.385 \text{ J K}^{-1} \text{ g}^{-1}$  and may be assumed constant over the temperature range involved.

**3A.9(b)** Calculate  $\Delta S_{\text{tot}}$  when two iron blocks, each of mass  $10.0 \text{ kg}$ , one at  $100^\circ\text{C}$  and the other at  $25^\circ\text{C}$ , are placed in contact in an isolated container. The specific heat capacity of iron is  $0.449 \text{ J K}^{-1} \text{ g}^{-1}$  and may be assumed constant over the temperature range involved.

**3A.10(a)** Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when a sample of nitrogen gas of mass  $14 \text{ g}$  at  $298 \text{ K}$  and  $1.00 \text{ bar}$  doubles its volume in (i) an isothermal reversible expansion, (ii) an isothermal irreversible expansion against  $p_{\text{ex}} = 0$ , and (iii) an adiabatic reversible expansion.

**3A.10(b)** Calculate the change in the entropies of the system and the surroundings, and the total change in entropy, when the volume of a sample of argon gas of mass  $21 \text{ g}$  at  $298 \text{ K}$  and  $1.50 \text{ bar}$  increases from  $1.20 \text{ dm}^3$  to  $4.60 \text{ dm}^3$  in (i) an isothermal reversible expansion, (ii) an isothermal irreversible expansion against  $p_{\text{ex}} = 0$ , and (iii) an adiabatic reversible expansion.

**3A.11(a)** The enthalpy of vaporization of chloroform ( $\text{CHCl}_3$ ) is  $29.4 \text{ kJ mol}^{-1}$  at its normal boiling point of  $334.88 \text{ K}$ . Calculate (i) the entropy of vaporization of chloroform at this temperature and (ii) the entropy change of the surroundings.

**3A.11(b)** The enthalpy of vaporization of methanol is  $35.27 \text{ kJ mol}^{-1}$  at its normal boiling point of  $64.1^\circ\text{C}$ . Calculate (i) the entropy of vaporization of methanol at this temperature and (ii) the entropy change of the surroundings.

**3A.12(a)** Calculate the change in entropy of the system when  $10.0 \text{ g}$  of ice at  $-10.0^\circ\text{C}$  is converted into water vapour at  $115.0^\circ\text{C}$  and at a constant pressure of  $1 \text{ bar}$ . The constant-pressure molar heat capacity of  $\text{H}_2\text{O}(\text{s})$  and  $\text{H}_2\text{O}(\text{l})$  is  $75.291 \text{ J K}^{-1} \text{ mol}^{-1}$  and that of  $\text{H}_2\text{O}(\text{g})$  is  $33.58 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**3A.12(b)** Calculate the change in entropy of the system when  $15.0 \text{ g}$  of ice at  $-12.0^\circ\text{C}$  is converted to water vapour at  $105.0^\circ\text{C}$  at a constant pressure of  $1 \text{ bar}$ . For data, see the preceding exercise.

## Problems

**3A.1** Represent the Carnot cycle on a temperature–entropy diagram and show that the area enclosed by the cycle is equal to the work done.

**3A.2** The cycle involved in the operation of an internal combustion engine is called the *Otto cycle*. Air can be considered to be the working substance and can be assumed to be a perfect gas. The cycle consists of the following steps: (1) Reversible adiabatic compression from A to B, (2) reversible constant-volume pressure increase from B to C due to the combustion of a small amount of fuel, (3) reversible adiabatic expansion from C to D, and (4) reversible and constant-volume pressure decrease back to state A. Determine the change in entropy (of the system and of the surroundings) for each step of the cycle and determine an expression for the efficiency of the cycle, assuming that the heat is supplied in Step 2. Evaluate the efficiency for a compression ratio of 10:1. Assume that in state A,  $V=4.00\text{ dm}^3$ ,  $p=1.00\text{ atm}$ , and  $T=300\text{ K}$ , that  $V_A=10V_B$ ,  $p_C/p_B=5$ , and that  $C_{p,m}=\frac{7}{2}R$ .

**3A.3** Prove that two reversible adiabatic paths can never cross. Assume that the energy of the system under consideration is a function of temperature only. (*Hint*: Suppose that two such paths can intersect, and complete a cycle with the two paths plus one isothermal path. Consider the changes accompanying each stage of the cycle and show that they conflict with the Kelvin statement of the Second Law.)

**3A.4** To calculate the work required to lower the temperature of an object, we need to consider how the coefficient of performance  $c$  (see *Impact* I3.1) changes with the temperature of the object. (a) Find an expression for the work of cooling an object from  $T_i$  to  $T_f$  when the refrigerator is in a room at a temperature  $T_h$ . (*Hint*: Write  $dw=dq/c(T)$ , relate  $dq$  to  $dT$  through the heat capacity  $C_p$ , and integrate the resulting expression. Assume that the heat capacity is independent of temperature in the range of interest. (b) Use the result in part (a) to calculate the work needed to freeze 250 g of water in a refrigerator at 293 K. How long will it take when the refrigerator operates at 100 W?

**3A.5** The expressions that apply to the treatment of refrigerators (Problem 3A.4) also describe the behaviour of heat pumps, where warmth is obtained from the back of a refrigerator while its front is being used to cool the outside world. Heat pumps are popular home heating devices because they are very efficient. Compare heating of a room at 295 K by each of two methods: (a) direct conversion of 1.00 kJ of electrical energy in an electrical heater, and (b) use of 1.00 kJ of electrical energy to run a reversible heat pump with the outside at 260 K. Discuss the origin of the difference in the energy delivered to the interior of the house by the two methods.

**3A.6** Calculate the difference in molar entropy (a) between liquid water and ice at  $-5^\circ\text{C}$ , (b) between liquid water and its vapour at  $95^\circ\text{C}$  and 1.00 atm. The differences in heat capacities on melting and on vaporization are  $37.3\text{ J K}^{-1}\text{ mol}^{-1}$  and  $-41.9\text{ J K}^{-1}\text{ mol}^{-1}$ , respectively. Distinguish between the entropy changes of the sample, the surroundings, and the total system, and discuss the spontaneity of the transitions at the two temperatures.

**3A.7** The molar heat capacity of chloroform (trichloromethane,  $\text{CHCl}_3$ ) in the range 240 K to 330 K is given by  $C_{p,m}/(\text{J K}^{-1}\text{ mol}^{-1})=91.47+7.5\times 10^{-2}(T/\text{K})$ .

In a particular experiment, 1.00 mol  $\text{CHCl}_3$  is heated from 273 K to 300 K. Calculate the change in molar entropy of the sample.

**3A.8** A block of copper of mass 2.00 kg ( $C_{p,m}=24.44\text{ J K}^{-1}\text{ mol}^{-1}$ ) and temperature  $0^\circ\text{C}$  is introduced into an insulated container in which there is 1.00 mol  $\text{H}_2\text{O}(\text{g})$  at  $100^\circ\text{C}$  and 1.00 atm. (a) Assuming all the steam is condensed to water, what will be the final temperature of the system, the heat transferred from water to copper, and the entropy change of the water, copper, and the total system? (b) In fact, some water vapour is present at equilibrium. From the vapour pressure of water at the temperature calculated in (a), and assuming that the heat capacities of both gaseous and liquid water are constant and given by their values at that temperature, obtain an improved value of the final temperature, the heat transferred, and the various entropies. (*Hint*: You will need to make plausible approximations.)

**3A.9** A sample consisting of 1.00 mol of perfect gas molecules at  $27^\circ\text{C}$  is expanded isothermally from an initial pressure of 3.00 atm to a final pressure of 1.00 atm in two ways: (a) reversibly, and (b) against a constant external pressure of 1.00 atm. Determine the values of  $q$ ,  $w$ ,  $\Delta U$ ,  $\Delta H$ ,  $\Delta S$ ,  $\Delta S_{\text{sur}}$ , and  $\Delta S_{\text{tot}}$  for each path.

**3A.10** A block of copper of mass 500 g and initially at 293 K is in thermal contact with an electric heater of resistance 1.00 k $\Omega$  and negligible mass. A current of 1.00 A is passed for 15.0 s. Calculate the change in entropy of the copper, taking  $C_{p,m}=24.4\text{ J K}^{-1}\text{ mol}^{-1}$ . The experiment is then repeated with the copper immersed in a stream of water that maintains its temperature at 293 K. Calculate the change in entropy of the copper and the water in this case.

**3A.11** Find an expression for the change in entropy when two blocks of the same substance and of equal mass, one at the temperature  $T_h$  and the other at  $T_c$ , are brought into thermal contact and allowed to reach equilibrium. Evaluate the change for two blocks of copper, each of mass 500 g, with  $C_{p,m}=24.4\text{ J K}^{-1}\text{ mol}^{-1}$ , taking  $T_h=500\text{ K}$  and  $T_c=250\text{ K}$ .

**3A.12** According to Newton's law of cooling, the rate of change of temperature is proportional to the temperature difference between the system and its surroundings. Given that  $S(T)-S(T_i)=C\ln(T/T_i)$ , where  $T_i$  is the initial temperature and  $C$  the heat capacity, deduce an expression for the rate of change of entropy of the system as it cools.

**3A.13** The protein lysozyme unfolds at a transition temperature of  $75.5^\circ\text{C}$  and the standard enthalpy of transition is  $509\text{ kJ mol}^{-1}$ . Calculate the entropy of unfolding of lysozyme at  $25.0^\circ\text{C}$ , given that the difference in the constant-pressure heat capacities upon unfolding is  $6.28\text{ kJ K}^{-1}\text{ mol}^{-1}$  and can be assumed to be independent of temperature. (*Hint*: Imagine that the transition at  $25.0^\circ\text{C}$  occurs in three steps: (i) heating of the folded protein from  $25.0^\circ\text{C}$  to the transition temperature, (ii) unfolding at the transition temperature, and (iii) cooling of the unfolded protein to  $25.0^\circ\text{C}$ . Because the entropy is a state function, the entropy change at  $25.0^\circ\text{C}$  is equal to the sum of the entropy changes of the steps.

## TOPIC 3B The measurement of entropy

### Discussion question

**3B.1** Discuss why the standard entropies of ions in solution may be positive, negative, or zero.

## Exercises

**3B.1(a)** Calculate the residual molar entropy of a solid in which the molecules can adopt (i) three, (ii) five, (iii) six orientations of equal energy at  $T=0$ .

**3B.1(b)** Suppose that the hexagonal molecule  $C_6H_nF_{6-n}$  has a residual entropy on account of the similarity of the H and F atoms. Calculate the residual for each value of  $n$ .

**3B.2(a)** Calculate the standard reaction entropy at 298 K of

**3B.2(b)** Calculate the standard reaction entropy at 298 K of

## Problems

**3B.1** The standard molar entropy of  $NH_3(g)$  is  $192.45 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K, and its heat capacity is given by eqn 2B.8 with the coefficients given in Table 2B.1. Calculate the standard molar entropy at (a)  $100^\circ\text{C}$  and (b)  $500^\circ\text{C}$ .

**3B.2** The molar heat capacity of lead varies with temperature as follows:

$T/\text{K}$	10	15	20	25	30	50
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	2.8	7.0	10.8	14.1	16.5	21.4
$T/\text{K}$	70	100	150	200	250	298
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	23.3	24.5	25.3	25.8	26.2	26.6

Calculate the standard Third-Law entropy of lead at (a)  $0^\circ\text{C}$  and (b)  $25^\circ\text{C}$ .

**3B.3** From standard enthalpies of formation, standard entropies, and standard heat capacities available from tables in the *Resource section*, calculate:

(a) the standard enthalpies and entropies at 298 K and 398 K for the reaction  $CO_2(g) + H_2(g) \rightarrow CO(g) + H_2O(g)$ . Assume that the heat capacities are constant over the temperature range involved.

**3B.4** The molar heat capacity of anhydrous potassium hexacyanoferrate(II) varies with temperature as follows:

$T/\text{K}$	10	20	30	40	50	60
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	2.09	14.43	36.44	62.55	87.03	111.0
$T/\text{K}$	70	80	90	100	110	150
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	131.4	149.4	165.3	179.6	192.8	237.6
$T/\text{K}$	160	170	180	190	200	
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	247.3	256.5	265.1	273.0	280.3	

Calculate the molar enthalpy relative to its value at  $T=0$  and the Third-Law entropy at each of these temperatures.

**3B.5** The compound 1,3,5-trichloro-2,4,6-trifluorobenzene is an intermediate in the conversion of hexachlorobenzene to hexafluorobenzene, and its thermodynamic properties have been examined by measuring its heat capacity over a wide temperature range (R.L. Andon and J.F. Martin, *J. Chem. Soc. Faraday Trans. I*, 871 (1973)). Some of the data are as follows:

$T/\text{K}$	14.14	16.33	20.03	31.15	44.08	64.81
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	9.492	12.70	18.18	32.54	46.86	66.36
$T/\text{K}$	100.90	140.86	183.59	225.10	262.99	298.06
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	95.05	121.3	144.4	163.7	180.2	196.4

Calculate the molar enthalpy relative to its value at  $T=0$  and the Third-Law molar entropy of the compound at these temperatures.

**3B.6\*** Given that  $S_m^\ominus = 29.79 \text{ J K}^{-1} \text{ mol}^{-1}$  for bismuth at 100 K and the following tabulated heat capacity data (D.G. Archer, *J. Chem. Eng. Data* **40**, 1015 (1995)), compute the standard molar entropy of bismuth at 200 K.

$T/\text{K}$	100	120	140	150	160	180	200
$C_{p,m}/(\text{J K}^{-1} \text{ mol}^{-1})$	23.00	23.74	24.25	24.44	24.61	24.89	25.11

Compare the value to the value that would be obtained by taking the heat capacity to be constant at  $24.44 \text{ J K}^{-1} \text{ mol}^{-1}$  over this range.

**3B.7** Derive an expression for the molar entropy of a monatomic solid on the basis of the Einstein and Debye models and plot the molar entropy against the temperature (use  $T/\theta$  in each case, with  $\theta$  the Einstein or Debye temperature). Use the following expressions for the temperature-dependence of the heat capacities:

$$\text{Einstein: } C_{V,m}(T) = 3Rf^E(T) \quad f^E(T) = \left(\frac{\theta^E}{T}\right)^2 \left(\frac{e^{\theta^E/2T}}{e^{\theta^E/T} - 1}\right)^2$$

$$\text{Debye: } C_{V,m}(T) = 3Rf^D(T) \quad f^D(T) = 3 \left(\frac{T}{\theta^D}\right)^2 \int_0^{\theta^D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx$$

Use mathematical software to evaluate the appropriate expressions.

**3B.8** An average human DNA molecule has  $5 \times 10^8$  binucleotides (rungs on the DNA ladder) of four different kinds. If each rung were a random choice of one of these four possibilities, what would be the residual entropy associated with this typical DNA molecule?

## TOPIC 3C Concentrating on the system

## Discussion questions

**3C.1** The following expressions have been used to establish criteria for spontaneous change:  $dA_{T,V} < 0$  and  $dG_{T,p} < 0$ . Discuss the origin, significance, and applicability of each criterion.

**3C.2** Under what circumstances, and why, can the spontaneity of a process be discussed in terms of the properties of the system alone?

\* These problems were provided by Charles Trapp and Carmen Giunta.

## Exercises

**3C.1(a)** Combine the reaction entropies calculated in Exercise 3B.2(a) with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

**3C.1(b)** Combine the reaction entropies calculated in Exercise 3B.2(b) with the reaction enthalpies, and calculate the standard reaction Gibbs energies at 298 K.

**3C.2(a)** Calculate the standard Gibbs energy of the reaction  $4 \text{HI}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{I}_2(\text{s}) + 2 \text{H}_2\text{O}(\text{l})$  at 298 K, from the standard entropies and enthalpies of formation given in the *Resource section*.

**3C.2(b)** Calculate the standard Gibbs energy of the reaction  $\text{CO}(\text{g}) + \text{CH}_3\text{CH}_2\text{OH}(\text{l}) \rightarrow \text{CH}_3\text{CH}_2\text{COOH}(\text{l})$  at 298 K, from the standard entropies and enthalpies of formation given in the *Resource section*.

**3C.3(a)** Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of methane at 298 K.

**3C.3(b)** Calculate the maximum non-expansion work per mole that may be obtained from a fuel cell in which the chemical reaction is the combustion of propane at 298 K.

**3C.4(a)** Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions

**3C.4(b)** Use standard Gibbs energies of formation to calculate the standard reaction Gibbs energies at 298 K of the reactions

**3C.5(a)** The standard enthalpy of combustion of ethyl acetate ( $\text{CH}_3\text{COOC}_2\text{H}_5$ ) is  $-2231 \text{ kJ mol}^{-1}$  at 298 K and its standard molar entropy is  $259.4 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of the compound at 298 K.

**3C.5(b)** The standard enthalpy of combustion of the amino acid glycine ( $\text{NH}_2\text{CH}_2\text{COOH}$ ) is  $-969 \text{ kJ mol}^{-1}$  at 298 K and its standard molar entropy is  $103.5 \text{ J K}^{-1} \text{ mol}^{-1}$ . Calculate the standard Gibbs energy of formation of glycine at 298 K.

## Problems

**3C.1** Consider a perfect gas contained in a cylinder and separated by a frictionless adiabatic piston into two sections A and B. All changes in B are isothermal; that is, a thermostat surrounds B to keep its temperature constant. There is 2.00 mol of the gas molecules in each section. Initially  $T_A = T_B = 300 \text{ K}$ ,  $V_A = V_B = 2.00 \text{ dm}^3$ . Energy is supplied as heat to Section A and the piston moves to the right reversibly until the final volume of Section B is  $1.00 \text{ dm}^3$ . Calculate (a)  $\Delta S_A$  and  $\Delta S_B$ , (b)  $\Delta A_A$  and  $\Delta A_B$ , (c)  $\Delta G_A$  and  $\Delta G_B$ , (d)  $\Delta S$  of the total system and its surroundings. If numerical values cannot be obtained, indicate whether the values should be positive, negative, or zero or are indeterminate from the information given. (Assume  $C_{v,m} = 20 \text{ J K}^{-1} \text{ mol}^{-1}$ .)

**3C.2** Calculate the molar internal energy, molar entropy, and molar Helmholtz energy of a collection of harmonic oscillators and plot your expressions as a function of  $T/\theta^v$ , where  $\theta^v = h\nu/k$ .

**3C.3** In biological cells, the energy released by the oxidation of foods is stored in adenosine triphosphate (ATP or  $\text{ATP}^{4-}$ ). The essence of ATP's action is its ability to lose its terminal phosphate group by hydrolysis and to form adenosine diphosphate (ADP or  $\text{ADP}^{3-}$ ):

At  $\text{pH} = 7.0$  and  $37^\circ\text{C}$  (310 K, blood temperature) the enthalpy and Gibbs energy of hydrolysis are  $\Delta_r H = -20 \text{ kJ mol}^{-1}$  and  $\Delta_r G = -31 \text{ kJ mol}^{-1}$ , respectively. Under these conditions, the hydrolysis of 1 mol  $\text{ATP}^{4-}(\text{aq})$  results in the extraction of up to 31 kJ of energy that can be used to do non-expansion work, such as the synthesis of proteins from amino acids, muscular contraction, and the activation of neuronal circuits in our brains. (a) Calculate and account for the sign of the entropy of hydrolysis of ATP at  $\text{pH} = 7.0$  and 310 K. (b) Suppose that the radius of a typical biological cell is  $10 \mu\text{m}$  and that inside it  $1 \times 10^6$  ATP molecules are hydrolysed each second. What is the power density of the cell in watts per cubic metre ( $1 \text{ W} = 1 \text{ J s}^{-1}$ )? A computer battery delivers about 15 W and has a volume of  $100 \text{ cm}^3$ . Which has the greater power density, the cell or the battery? (c) The formation of glutamine from glutamate and ammonium ions requires  $14.2 \text{ kJ mol}^{-1}$  of energy input. It is driven by the hydrolysis of ATP to ADP mediated by the enzyme glutamine synthetase. How many moles of ATP must be hydrolysed to form 1 mol glutamine?

## TOPIC 3D Combining the First and Second Laws

### Discussion questions

**3D.1** Suggest a physical interpretation of the dependence of the Gibbs energy on the temperature.

**3D.2** Suggest a physical interpretation of the dependence of the Gibbs energy on the pressure.

### Exercises

**3D.1(a)** Suppose that 2.5 mmol  $\text{N}_2(\text{g})$  occupies  $42 \text{ cm}^3$  at 300 K and expands isothermally to  $600 \text{ cm}^3$ . Calculate  $\Delta G$  for the process.

**3D.1(b)** Suppose that 6.0 mmol  $\text{Ar}(\text{g})$  occupies  $52 \text{ cm}^3$  at 298 K and expands isothermally to  $122 \text{ cm}^3$ . Calculate  $\Delta G$  for the process.

**3D.2(a)** The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression  $\Delta G/J = -85.40 + 36.5(T/K)$ . Calculate the value of  $\Delta S$  for the process.

**3D.2(b)** The change in the Gibbs energy of a certain constant-pressure process was found to fit the expression  $\Delta G/J = -73.1 + 42.8(T/K)$ . Calculate the value of  $\Delta S$  for the process.

**3D.3(a)** Estimate the change in the Gibbs energy and molar Gibbs energy of  $1.0 \text{ dm}^3$  of octane when the pressure acting on it is increased from 1.0 atm to 100 atm. The mass density of octane is  $0.703 \text{ g cm}^{-3}$ .

**3D.3(b)** Estimate the change in the Gibbs energy and molar Gibbs energy of  $100 \text{ cm}^3$  of water when the pressure acting on it is increased from 100 kPa to 500 kPa. The mass density of water is  $0.997 \text{ g cm}^{-3}$ .

**3D.4(a)** Calculate the change in the molar Gibbs energy of hydrogen gas when its pressure is increased isothermally from 1.0 atm to 100.0 atm at 298 K.

**3D.4(b)** Calculate the change in the molar Gibbs energy of oxygen when its pressure is increased isothermally from 50.0 kPa to 100.0 kPa at 500 K.

## Problems

**3D.1** Calculate  $\Delta_r G^\ominus$  (375 K) for the reaction  $2 \text{ CO(g)} + \text{O}_2(\text{g}) \rightarrow 2 \text{ CO}_2(\text{g})$  from the value of  $\Delta_r G^\ominus$  (298 K),  $\Delta_r H^\ominus$  (298 K), and the Gibbs–Helmholtz equation.

**3D.2** Estimate the standard reaction Gibbs energy of  $\text{N}_2(\text{g}) + 3 \text{ H}_2(\text{g}) \rightarrow 2 \text{ NH}_3(\text{g})$  at (a) 500 K, (b) 1000 K from their values at 298 K.

**3D.3** At 298 K the standard enthalpy of combustion of sucrose is  $-5797 \text{ kJ mol}^{-1}$  and the standard Gibbs energy of the reaction is  $-6333 \text{ kJ mol}^{-1}$ . Estimate the additional non-expansion work that may be obtained by raising the temperature to blood temperature,  $37^\circ\text{C}$ .

**3D.4** Two empirical equations of state of a real gas are as follows:

$$\text{van der Waals: } p = \frac{RT}{V_m - b} - \frac{a}{V_m^2}$$

$$\text{Dieterici: } p = \frac{RTe^{-a/RTV_m}}{V_m - b}$$

Evaluate  $(\partial S/\partial V)_T$  for each gas. For an isothermal expansion, for which kind of gas (also consider a perfect gas) will  $\Delta S$  be greatest? Explain your conclusion.

**3D.5** Two of the four Maxwell relations were derived in the text, but two were not. Complete their derivation by showing that  $(\partial S/\partial V)_T = (\partial p/\partial T)_V$  and  $(\partial T/\partial p)_S = (\partial V/\partial S)_p$ .

**3D.6** (a) Use the Maxwell relations to express the derivatives  $(\partial S/\partial V)_T$ ,  $(\partial V/\partial S)_p$ ,  $(\partial p/\partial S)_V$ , and  $(\partial V/\partial S)_p$  in terms of the heat capacities, the expansion coefficient  $\alpha = (1/V)(\partial V/\partial T)_p$ , and the isothermal compressibility,  $\kappa_T = -(1/V)(\partial V/\partial p)_T$ . (b) The Joule coefficient,  $\mu_J$ , is defined as  $\mu_J = (\partial T/\partial V)_U$ . Show that  $\mu_J C_V = p - \alpha T/\kappa_T$ .

**3D.7** Suppose that  $S$  is regarded as a function of  $p$  and  $T$ . Show that  $TdS = C_p dT - \alpha TV dp$ . Hence, show that the energy transferred as heat when the pressure

on an incompressible liquid or solid is increased by  $\Delta p$  is equal to  $-\alpha TV \Delta p$ , where  $\alpha = (1/V)(\partial V/\partial T)_p$ . Evaluate  $q$  when the pressure acting on  $100 \text{ cm}^3$  of mercury at  $0^\circ\text{C}$  is increased by 1.0 kbar. ( $\alpha = 1.82 \times 10^{-4} \text{ K}^{-1}$ .)

**3D.8** Equation 3D.6 ( $\pi_T = T(\partial p/\partial T)_V - p$ ) expresses the internal pressure  $\pi_T$  in terms of the pressure and its derivative with respect to temperature. Express  $\pi_T$  in terms of the molecular partition function.

**3D.9** Explore the consequences of replacing the equation of state of a perfect gas by the van der Waals equation of state for the pressure-dependence of the molar Gibbs energy. Proceed in three steps. First, consider the case when  $a=0$  and only repulsions are significant. Then consider the case when  $b=0$  and only attractions are significant. For the latter, you should consider making the approximation that the attractions are weak. Finally, explore the full expression by using mathematical software. In each case plot your results graphically and account physically for the deviations from the perfect gas expression.

**3D.10\*** Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions which bring about the Antarctic ozone hole. Worsnop et al. (*Science* 259, 71 (1993)) investigated the thermodynamic stability of these hydrates under conditions typical of the polar winter stratosphere. They report thermodynamic data for the sublimation of mono-, di-, and trihydrates to nitric acid and water vapour,  $\text{HNO}_3 \cdot n\text{H}_2\text{O(s)} \rightarrow \text{HNO}_3(\text{g}) + n\text{H}_2\text{O(g)}$ , for  $n=1, 2$ , and 3. Given  $\Delta_r G^\ominus$  and  $\Delta_r H^\ominus$  for these reactions at 220 K, use the Gibbs–Helmholtz equation to compute  $\Delta_r G^\ominus$  at 190 K.

$n$	1	2	3
$\Delta_r G^\ominus/(\text{kJ mol}^{-1})$	46.2	69.4	93.2
$\Delta_r H^\ominus/(\text{kJ mol}^{-1})$	127	188	237

## Integrated activities

**3.1** A gaseous sample consisting of 1.00 mol molecules is described by the equation of state  $pV_m = RT(1 + Bp)$ . Initially at 373 K, it undergoes Joule–Thomson expansion from 100 atm to 1.00 atm. Given that  $C_{p,m} = \frac{5}{2}R$ ,  $\mu = 0.21 \text{ K atm}^{-1}$ ,  $B = -0.525(\text{K}/T) \text{ atm}^{-1}$  and that these are constant over the temperature range involved, calculate  $\Delta T$  and  $\Delta S$  for the gas.

**3.2** Discuss the relationship between the thermodynamic and statistical definitions of entropy.

**3.3** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to:

(a) Evaluate the change in entropy of 1.00 mol  $\text{CO}_2(\text{g})$  on expansion from  $0.001 \text{ m}^3$  to  $0.010 \text{ m}^3$  at 298 K, treated as a van der Waals gas.

(b) Allow for the temperature dependence of the heat capacity by writing  $C = a + bT + c/T^2$ , and plot the change in entropy for different values of the three coefficients (including negative values of  $c$ ).

(c) Show how the first derivative of  $G$ ,  $(\partial G/\partial p)_T$ , varies with pressure, and plot the resulting expression over a pressure range. What is the physical significance of  $(\partial G/\partial p)_T$ ?

(d) Evaluate the fugacity coefficient as a function of the reduced volume of a van der Waals gas and plot the outcome for a selection of reduced temperatures over the range  $0.8 \leq V_r \leq 3$ .

# CHAPTER 4

## Physical transformations of pure substances

Vaporization, melting (fusion), and the conversion of graphite to diamond are all examples of changes of phase without change of chemical composition. The discussion of the phase transitions of pure substances is among the simplest applications of thermodynamics to chemistry, and is guided by the principle that the tendency of systems at constant temperature and pressure is to minimize their Gibbs energy.

### 4A Phase diagrams of pure substances

First, we see that one type of phase diagram is a map of the pressures and temperatures at which each phase of a substance is the most stable. The thermodynamic criterion of phase stability enables us to deduce a very general result, the ‘phase rule’, which summarizes the constraints on the equilibria between phases. In preparation for later chapters, we express the rule in a general way that can be applied to systems of more than one component. Then, we describe the interpretation of empirically determined phase diagrams for a selection of substances.

### 4B Thermodynamic aspects of phase transitions

Here we consider the factors that determine the positions and shapes of the boundaries between the regions on a phase

diagram. The practical importance of the expressions we derive is that they show how the vapour pressure of a substance varies with temperature and how the melting point varies with pressure. Transitions between phases are classified by noting how various thermodynamic functions change when the transition occurs. This chapter also introduces the ‘chemical potential’, a property that will be at the centre of our discussions of mixtures and chemical reactions.

### What is the impact of this material?

The properties of carbon dioxide in its supercritical fluid phase can form the basis for novel and useful chemical separation methods, and have considerable promise for ‘green’ chemistry synthetic procedures. Its properties and applications are discussed in *Impact* I4.1.

To read more about the impact of this material, scan the QR code, or go to [bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-4-1.html](https://bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-4-1.html)

### ► Why do you need to know this material?

Phase diagrams summarize the behaviour of substances under different conditions. In metallurgy, the ability to control the microstructure resulting from phase equilibria makes it possible to tailor the mechanical properties of the materials to a particular application.

### ► What is the key idea?

A pure substance tends to adopt the phase with the lowest chemical potential.

### ► What do you need to know already?

This Topic builds on the fact that the Gibbs energy is a signpost of spontaneous change under conditions of constant temperature and pressure (Topic 3C).

One of the most succinct ways of presenting the physical changes of state that a substance can undergo is in terms of its 'phase diagram'. This material is also the basis of the discussion of mixtures in Chapter 5.

## 4A.1 The stabilities of phases

Thermodynamics provides a powerful language for describing and understanding the stabilities and transformations of phases, but to apply it we need to employ definitions carefully.

### (a) The number of phases

A **phase** is a form of matter that is uniform throughout in chemical composition and physical state. Thus, we speak of solid, liquid, and gas phases of a substance, and of its various solid phases, such as the white and black allotropes of phosphorus or the aragonite and calcite polymorphs of calcium carbonate.

*A note on good practice* An *allotrope* is a particular molecular form of an element (such as O<sub>2</sub> and O<sub>3</sub>) and may be solid, liquid, or gas. A *polymorph* is one of a number of solid phases of an element or compound.

The number of phases in a system is denoted  $P$ . A gas, or a gaseous mixture, is a single phase ( $P=1$ ), a crystal of a substance is a single phase, and two fully miscible liquids form a single phase.

### Brief illustration 4A.1 The number of phases

A solution of sodium chloride in water is a single phase ( $P=1$ ). Ice is a single phase even though it might be chipped into small fragments. A slurry of ice and water is a two-phase system ( $P=2$ ) even though it is difficult to map the physical boundaries between the phases. A system in which calcium carbonate undergoes the thermal decomposition  $\text{CaCO}_3(\text{s}) \rightarrow \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$  consists of two solid phases (one consisting of calcium carbonate and the other of calcium oxide) and one gaseous phase (consisting of carbon dioxide), so  $P=3$ .

**Self-test 4A.1** How many phases are present in a sealed, half-full vessel containing water?

Answer: 2

**Figure 4A.1** The difference between (a) a single-phase solution, in which the composition is uniform on a microscopic scale, and (b) a dispersion, in which regions of one component are embedded in a matrix of a second component.

Two metals form a two-phase system ( $P=2$ ) if they are immiscible, but a single-phase system ( $P=1$ ), an alloy, if they are miscible. This example shows that it is not always easy to decide whether a system consists of one phase or of two. A solution of solid B in solid A—a homogeneous mixture of the two substances—is uniform on a molecular scale. In a solution, atoms of A are surrounded by atoms of A and B, and any sample cut from the sample, even microscopically small, is representative of the composition of the whole.

A dispersion is uniform on a macroscopic scale but not on a microscopic scale, for it consists of grains or droplets of one substance in a matrix of the other. A small sample could come entirely from one of the minute grains of pure A and would not be representative of the whole (Fig. 4A.1). Dispersions are important because, in many advanced materials (including steels), heat treatment cycles are used to achieve the precipitation of a fine dispersion of particles of one phase (such as a carbide phase) within a matrix formed by a saturated solid solution phase.

### (b) Phase transitions

A **phase transition**, the spontaneous conversion of one phase into another phase, occurs at a characteristic temperature for a given pressure. The **transition temperature**,  $T_{\text{trs}}$ , is the temperature at which the two phases are in equilibrium and the Gibbs energy of the system is minimized at the prevailing pressure.

#### Brief illustration 4A.2 Phase transitions

At 1 atm, ice is the stable phase of water below  $0^\circ\text{C}$ , but above  $0^\circ\text{C}$  liquid water is more stable. This difference indicates that below  $0^\circ\text{C}$  the Gibbs energy decreases as liquid water changes into ice and that above  $0^\circ\text{C}$  the Gibbs energy decreases as ice changes into liquid water. The numerical values of the Gibbs energies are considered in the next *Brief illustration*.

**Self-test 4A.2** Which has the higher standard molar Gibbs energy at  $105^\circ\text{C}$ , liquid water or its vapour?

Answer: Liquid water

**Figure 4A.2** A cooling curve at constant pressure. The flat section corresponds to the pause in the fall of temperature while the first-order exothermic transition (freezing) occurs. This pause enables  $T_f$  to be located even if the transition cannot be observed visually.

Detecting a phase transition is not always as simple as seeing water boil in a kettle, so special techniques have been developed. One technique is **thermal analysis**, which takes advantage of the heat that is evolved or absorbed during any transition. The transition is detected by noting that the temperature does not change even though heat is being supplied or removed from the sample (Fig. 4A.2). Differential scanning calorimetry (Topic 2C) is also used. Thermal techniques are useful for solid–solid transitions, where simple visual inspection of the sample may be inadequate. X-ray diffraction (Topic 18A) also reveals the occurrence of a phase transition in a solid, for different structures are found on either side of the transition temperature.

As always, it is important to distinguish between the thermodynamic description of a process and the rate at which the process occurs. A phase transition that is predicted from thermodynamics to be spontaneous may occur too slowly to be significant in practice. For instance, at normal temperatures and pressures the molar Gibbs energy of graphite is lower than that of diamond, so there is a thermodynamic tendency for diamond to change into graphite. However, for this transition to take place, the C atoms must change their locations, which is an immeasurably slow process in a solid except at high temperatures. The discussion of the rate of attainment of equilibrium is a kinetic problem and is outside the range of thermodynamics. In gases and liquids the mobilities of the molecules allow phase transitions to occur rapidly, but in solids thermodynamic instability may be frozen in. Thermodynamically unstable phases that persist because the transition is kinetically hindered are called **metastable phases**. Diamond is a metastable but persistent phase of carbon under normal conditions.

### (c) Thermodynamic criteria of phase stability

All our considerations will be based on the Gibbs energy of a substance, and in particular on its molar Gibbs energy,  $G_m$ . In

**Figure 4A.3** When two or more phases are in equilibrium, the chemical potential of a substance (and, in a mixture, a component) is the same in each phase and is the same at all points in each phase.

fact, this quantity plays such an important role in this chapter and the rest of the text that we give it a special name and symbol, the **chemical potential**,  $\mu$  (mu). For a one-component system, ‘molar Gibbs energy’ and ‘chemical potential’ are synonyms, so  $\mu = G_m$ , but in Topic 5A we see that chemical potential has a broader significance and a more general definition. The name ‘chemical potential’ is also instructive: as we develop the concept, we shall see that  $\mu$  is a measure of the potential that a substance has for undergoing change in a system. In this chapter and Chapter 5, it reflects the potential of a substance to undergo physical change. In Chapter 6, we see that  $\mu$  is the potential of a substance to undergo chemical change.

We base the entire discussion on the following consequence of the Second Law (Fig. 4A.3):

At equilibrium, the chemical potential of a substance is the same throughout a sample, regardless of how many phases are present.

Criterion of phase equilibrium

To see the validity of this remark, consider a system in which the chemical potential of a substance is  $\mu_1$  at one location and  $\mu_2$  at another location. The locations may be in the same or in different phases. When an infinitesimal amount  $dn$  of the substance is transferred from one location to the other, the Gibbs energy of the system changes by  $-\mu_1 dn$  when material is removed from location 1, and it changes by  $+\mu_2 dn$  when that material is added to location 2. The overall change is therefore  $dG = (\mu_2 - \mu_1)dn$ . If the chemical potential at location 1 is higher than that at location 2, the transfer is accompanied by a decrease in  $G$ , and so has a spontaneous tendency to occur. Only if  $\mu_1 = \mu_2$  is there no change in  $G$ , and only then is the system at equilibrium.

#### Brief illustration 4A.3 Gibbs energy and phase transition

The standard molar Gibbs energy of formation of water vapour at 298 K (25 °C) is  $-229 \text{ kJ mol}^{-1}$  and that of liquid water at the same temperature is  $-237 \text{ kJ mol}^{-1}$ . It follows that there is a decrease in Gibbs energy when water vapour condenses

to the liquid at 298 K, so condensation is spontaneous at that temperature (and 1 bar).

**Self-test 4A.3** The standard Gibbs energies of formation of  $\text{HN}_3$  at 298 K are  $+327 \text{ kJ mol}^{-1}$  and  $+328 \text{ kJ mol}^{-1}$  for the liquid and gas phases, respectively. Which phase of hydrogen azide is the more stable at that temperature and 1 bar?

Answer: Liquid

## 4A.2 Phase boundaries

The **phase diagram** of a pure substance shows the regions of pressure and temperature at which its various phases are thermodynamically stable (Fig. 4A.4). In fact, any two intensive variables may be used (such as temperature and magnetic field; in Topic 5A mole fraction is another variable), but in this Topic we concentrate on pressure and temperature. The lines separating the regions, which are called **phase boundaries** (or *coexistence curves*), show the values of  $p$  and  $T$  at which two phases coexist in equilibrium and their chemical potentials are equal.

### (a) Characteristic properties related to phase transitions

Consider a liquid sample of a pure substance in a closed vessel. The pressure of a vapour in equilibrium with the liquid is called the **vapour pressure** of the substance (Fig. 4A.5). Therefore, the liquid–vapour phase boundary in a phase diagram shows how the vapour pressure of the liquid varies with temperature. Similarly, the solid–vapour phase boundary shows the temperature variation of the **sublimation vapour pressure**, the vapour pressure of the solid phase. The vapour pressure of a substance increases with temperature because at higher temperatures

**Figure 4A.4** The general regions of pressure and temperature where solid, liquid, or gas is stable (that is, has minimum molar Gibbs energy) are shown on this phase diagram. For example, the solid phase is the most stable phase at low temperatures and high pressures. In the following paragraphs we locate the precise boundaries between the regions.

**Figure 4A.5** The vapour pressure of a liquid or solid is the pressure exerted by the vapour in equilibrium with the condensed phase.

more molecules have sufficient energy to escape from their neighbours.

When a liquid is heated in an open vessel, the liquid vaporizes from its surface. When the vapour pressure is equal to the external pressure, vaporization can occur throughout the bulk of the liquid and the vapour can expand freely into the surroundings. The condition of free vaporization throughout the liquid is called **boiling**. The temperature at which the vapour pressure of a liquid is equal to the external pressure is called the **boiling temperature** at that pressure. For the special case of an external pressure of 1 atm, the boiling temperature is called the **normal boiling point**,  $T_b$ . With the replacement of 1 atm by 1 bar as standard pressure, there is some advantage in using the **standard boiling point** instead: this is the temperature at which the vapour pressure reaches 1 bar. Because 1 bar is slightly less than 1 atm (1.00 bar = 0.987 atm), the standard boiling point of a liquid is slightly lower than its normal boiling point. The normal boiling point of water is 100.0°C; its standard boiling point is 99.6°C. We need to distinguish normal and standard properties only for precise work in thermodynamics because any thermodynamic properties that we intend to add together must refer to the same conditions.

Boiling does not occur when a liquid is heated in a rigid, closed vessel. Instead, the vapour pressure, and hence the density of the vapour, rise as the temperature is raised (Fig. 4A.6). At the same time, the density of the liquid decreases slightly as a result of its expansion. There comes a stage when the density of the vapour is equal to that of the remaining liquid and the surface between the two phases disappears. The temperature at which the surface disappears is the **critical temperature**,  $T_c$ , of the substance. The vapour pressure at the critical temperature is called the **critical pressure**,  $p_c$ . At and above the critical temperature, a single uniform phase called a **supercritical fluid** fills the container and an interface no longer exists. That is, above the critical temperature, the liquid phase of the substance does not exist.

The temperature at which, under a specified pressure, the liquid and solid phases of a substance coexist in equilibrium is

**Figure 4A.6** (a) A liquid in equilibrium with its vapour. (b) When a liquid is heated in a sealed container, the density of the vapour phase increases and that of the liquid decreases slightly. There comes a stage (c) at which the two densities are equal and the interface between the fluids disappears. This disappearance occurs at the critical temperature. The container needs to be strong: the critical temperature of water is 374°C and the vapour pressure is then 218 atm.

called the **melting temperature**. Because a substance melts at exactly the same temperature as it freezes, the melting temperature of a substance is the same as its **freezing temperature**. The freezing temperature when the pressure is 1 atm is called the **normal freezing point**,  $T_f$ , and its freezing point when the pressure is 1 bar is called the **standard freezing point**. The normal and standard freezing points are negligibly different for most purposes. The normal freezing point is also called the **normal melting point**.

There is a set of conditions under which three different phases of a substance (typically solid, liquid, and vapour) all simultaneously coexist in equilibrium. These conditions are represented by the **triple point**, a point at which the three phase boundaries meet. The temperature at the triple point is denoted  $T_3$ . The triple point of a pure substance is outside our control: it occurs at a single definite pressure and temperature characteristic of the substance.

As we can see from Fig. 4A.4, the triple point marks the lowest pressure at which a liquid phase of a substance can exist. If (as is common) the slope of the solid–liquid phase boundary is as shown in the diagram, then the triple point also marks the lowest temperature at which the liquid can exist; the critical temperature is the upper limit.

#### Brief illustration 4A.4 The triple point

The triple point of water lies at 273.16 K and 611 Pa (6.11 mbar, 4.58 Torr), and the three phases of water (ice, liquid water, and water vapour) coexist in equilibrium at no other combination of pressure and temperature. This invariance of the triple point was the basis of its use in the about-to-be superseded definition of the Kelvin scale of temperature (Topic 3A).

**Self-test 4A.4** How many triple points are present (as far as it is known) in the full phase diagram for water shown later in this Topic in Fig. 4A.9?

Answer: 6

## (b) The phase rule

In one of the most elegant arguments of the whole of chemical thermodynamics, which is presented in the following *Justification*, J.W. Gibbs deduced the **phase rule**, which gives the number of parameters that can be varied independently (at least to a small extent) while the number of phases in equilibrium is preserved. The phase rule is a general relation between the variance,  $F$ , the number of components,  $C$ , and the number of phases at equilibrium,  $P$ , for a system of any composition:

$$F = C - P + 2 \quad \text{The phase rule} \quad (4A.1)$$

A **component** is a *chemically independent* constituent of a system. The number of components,  $C$ , in a system is the minimum number of types of independent species (ions or molecules) necessary to define the composition of all the phases present in the system. In this chapter we deal only with one-component systems ( $C=1$ ), so for this chapter

$$F = 3 - P \quad \text{A one-component system} \quad \text{The phase rule} \quad (4A.2)$$

By a **constituent** of a system we mean a chemical species that is present. The **variance** (or *number of degrees of freedom*),  $F$ , of a system is the number of intensive variables that can be changed independently without disturbing the number of phases in equilibrium.

### Brief illustration 4A.5 The number of components

A mixture of ethanol and water has two constituents. A solution of sodium chloride has three constituents: water,  $\text{Na}^+$  ions, and  $\text{Cl}^-$  ions but only two components because the numbers of  $\text{Na}^+$  and  $\text{Cl}^-$  ions are constrained to be equal by the requirement of charge neutrality.

**Self-test 4A.5** How many components are present in an aqueous solution of acetic acid, allowing for its partial deprotonation and the autoprotolysis of water?

Answer: 2

In a single-component, single-phase system ( $C=1, P=1$ ), the pressure and temperature may be changed independently without changing the number of phases, so  $F=2$ . We say that such a system is **bivariant**, or that it has two **degrees of freedom**. On

the other hand, if two phases are in equilibrium (a liquid and its vapour, for instance) in a single-component system ( $C=1, P=2$ ), the temperature (or the pressure) can be changed at will, but the change in temperature (or pressure) demands an accompanying change in pressure (or temperature) to preserve the number of phases in equilibrium. That is, the variance of the system has fallen to 1.

### Justification 4A.1 The phase rule

Consider first the special case of a one-component system for which the phase rule is  $F=3-P$ . For two phases  $\alpha$  and  $\beta$  in equilibrium ( $P=2, F=1$ ) at a given pressure and temperature, we can write

$$\mu(\alpha; p, T) = \mu(\beta; p, T)$$

(For instance, when ice and water are in equilibrium, we have  $\mu(s; p, T) = \mu(l; p, T)$  for  $\text{H}_2\text{O}$ .) This is an equation relating  $p$  and  $T$ , so only one of these variables is independent (just as the equation  $x+y=xy$  is a relation for  $y$  in terms of  $x$ :  $y=x/(x-1)$ ). That conclusion is consistent with  $F=1$ . For three phases of a one-component system in mutual equilibrium ( $P=3, F=0$ ),

$$\mu(\alpha; p, T) = \mu(\beta; p, T) = \mu(\gamma; p, T)$$

This relation is actually two equations for two unknowns,  $\mu(\alpha; p, T) = \mu(\beta; p, T)$  and  $\mu(\beta; p, T) = \mu(\gamma; p, T)$ , and therefore has a solution only for a single value of  $p$  and  $T$  (just as the pair of equations  $x+y=xy$  and  $3x-y=xy$  has the single solution  $x=2$  and  $y=2$ ). That conclusion is consistent with  $F=0$ . Four phases cannot be in mutual equilibrium in a one-component system because the three equalities

$$\mu(\alpha; p, T) = \mu(\beta; p, T)$$

$$\mu(\beta; p, T) = \mu(\gamma; p, T)$$

$$\mu(\gamma; p, T) = \mu(\delta; p, T)$$

are three equations for two unknowns ( $p$  and  $T$ ) and are not consistent (just as  $x+y=xy$ ,  $3x-y=xy$ , and  $x+y=2xy^2$  have no solution).

Now consider the general case. We begin by counting the total number of intensive variables. The pressure,  $p$ , and temperature,  $T$ , count as 2. We can specify the composition of a phase by giving the mole fractions of  $C-1$  components. We need specify only  $C-1$  and not all  $C$  mole fractions because  $x_1 + x_2 + \dots + x_C = 1$ , and all mole fractions are known if all except one are specified. Because there are  $P$  phases, the total number of composition variables is  $P(C-1)$ . At this stage, the total number of intensive variables is  $P(C-1) + 2$ .

At equilibrium, the chemical potential of a component  $J$  must be the same in every phase:

$$\mu(\alpha; p, T) = \mu(\beta; p, T) = \dots \text{ for } P \text{ phases}$$

That is, there are  $P-1$  equations of this kind to be satisfied for each component  $J$ . As there are  $C$  components, the total number of equations is  $C(P-1)$ . Each equation reduces our freedom to vary one of the  $P(C-1)+2$  intensive variables. It follows that the total number of degrees of freedom is

$$F = P(C-1) + 2 - C(P-1) = C - P + 2$$

which is eqn 4A.1.

### 4A.3 Three representative phase diagrams

For a one-component system, such as pure water,  $F=3-P$ . When only one phase is present,  $F=2$  and both  $p$  and  $T$  can be varied independently (at least over a small range) without changing the number of phases. In other words, a single phase is represented by an *area* on a phase diagram. When two phases are in equilibrium  $F=1$ , which implies that pressure is not freely variable if the temperature is set; indeed, at a given temperature, a liquid has a characteristic vapour pressure. It follows that the equilibrium of two phases is represented by a *line* in the phase diagram. Instead of selecting the temperature, we could select the pressure, but having done so the two phases would be in equilibrium at a single definite temperature. Therefore, freezing (or any other phase transition) occurs at a definite temperature at a given pressure.

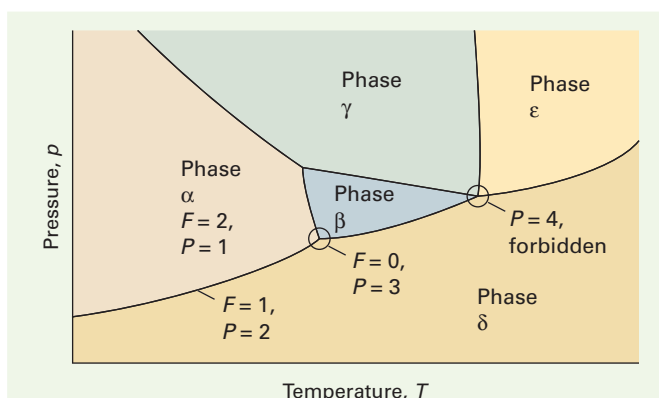

When three phases are in equilibrium,  $F=0$  and the system is invariant. This special condition can be established only at a definite temperature and pressure that is characteristic of the substance and outside our control. The equilibrium of three phases is therefore represented by a *point*, the triple point, on a phase diagram. Four phases cannot be in equilibrium in a one-component system because  $F$  cannot be negative.

#### Brief illustration 4A.6 Characteristics of phase diagrams

Figure 4A.7 shows a reasonably typical phase diagram of a single pure substance, with one forbidden feature, the ‘quadruple point’ where phases  $\beta$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$  are said to be in equilibrium. Two triple points are shown (for the equilibria  $\alpha \rightleftharpoons \beta \rightleftharpoons \gamma$  and  $\alpha \rightleftharpoons \beta \rightleftharpoons \delta$ , respectively), corresponding to  $P=3$  and  $F=0$ . The lines represent various equilibria, including  $\alpha \rightleftharpoons \beta$ ,  $\alpha \rightleftharpoons \delta$ , and  $\gamma \rightleftharpoons \epsilon$ .

**Self-test 4A.6** What is the minimum number of components necessary before five phases can be in mutual equilibrium in a system?

Answer: 3

**Figure 4A.7** The typical regions of a one-component phase diagram. The lines represent conditions under which the two adjoining phases are in equilibrium. A point represents the unique set of conditions under which three phases coexist in equilibrium. Four phases cannot mutually coexist in equilibrium.

#### (a) Carbon dioxide

The phase diagram for carbon dioxide is shown in Fig. 4A.8. The features to notice include the positive slope (up from left to right) of the solid–liquid boundary; the direction of this line is characteristic of most substances. This slope indicates that the melting temperature of solid carbon dioxide rises as the pressure is increased. Notice also that, as the triple point lies above 1 atm, the liquid cannot exist at normal atmospheric pressures whatever the temperature. As a result, the solid sublimates when left in the open (hence the name ‘dry ice’). To obtain the liquid, it is necessary to exert a pressure of at least 5.11 atm. Cylinders of carbon dioxide generally contain the liquid or compressed gas; at 25°C that implies a vapour pressure of 67 atm if both

**Figure 4A.8** The experimental phase diagram for carbon dioxide. Note that, as the triple point lies at pressures well above atmospheric, liquid carbon dioxide does not exist under normal conditions (a pressure of at least 5.11 atm must be applied). The path ABCD is discussed in *Brief illustration 4A.7*

gas and liquid are present in equilibrium. When the gas squirts through the throttle it cools by the Joule–Thomson effect, so when it emerges into a region where the pressure is only 1 atm, it condenses into a finely divided snow-like solid. That carbon dioxide gas cannot be liquefied except by applying high pressure reflects the weakness of the intermolecular forces between the nonpolar carbon dioxide molecules (Topic 16B).

#### Brief illustration 4A.7 A phase diagram 1

Consider the path ABCD in Fig. 4A.8. At A the carbon dioxide is a gas. When the temperature and pressure are adjusted to B, the vapour condenses directly to a solid. Increasing the pressure and temperature to C results in the formation of the liquid phase, which evaporates to the vapour when the conditions are changed to D.

**Self-test 4A.7** Describe what happens on circulating around the critical point, Path E.

Answer: Liquid  $\rightarrow$   $\text{scCO}_2$   $\rightarrow$  vapour  $\rightarrow$  liquid

### (b) Water

Figure 4A.9 shows the phase diagram for water. The liquid–vapour boundary in the phase diagram summarizes how the vapour pressure of liquid water varies with temperature. It also summarizes how the boiling temperature varies with pressure: we simply read off the temperature at which the vapour pressure is equal to the prevailing atmospheric pressure. The solid–liquid boundary shows how the melting temperature varies with the pressure; its very steep slope indicates that enormous pressures are needed to bring about significant changes. Notice that the line has a negative slope (down from left to right) up to 2 kbar, which means that the melting temperature falls as the

**Figure 4A.9** The experimental phase diagram for water showing the different solid phases. The path ABCD is discussed in *Brief illustration 4A.8*.

**Figure 4A.10** A fragment of the structure of ice (ice-I). Each O atom is linked by two covalent bonds to H atoms and by two hydrogen bonds to a neighbouring O atom, in a tetrahedral array.

pressure is raised. The reason for this almost unique behaviour can be traced to the decrease in volume that occurs on melting: it is more favourable for the solid to transform into the liquid as the pressure is raised. The decrease in volume is a result of the very open structure of ice: as shown in Fig. 4A.10, the water molecules are held apart, as well as together, by the hydrogen bonds between them but the hydrogen-bonded structure partially collapses on melting and the liquid is denser than the solid. Other consequences of its extensive hydrogen bonding are the anomalously high boiling point of water for a molecule of its molar mass and its high critical temperature and pressure.

Figure 4A.9 shows that water has one liquid phase but many different solid phases other than ordinary ice ('ice I'). Some of these phases melt at high temperatures. Ice VII, for instance, melts at 100 °C but exists only above 25 kbar. Two further phases, Ice XIII and XIV, were identified in 2006 at  $-160$  °C but have not yet been allocated regions in the phase diagram. Note that five more triple points occur in the diagram other than the one where vapour, liquid, and ice I coexist. Each one occurs at a definite pressure and temperature that cannot be changed. The solid phases of ice differ in the arrangement of the water molecules: under the influence of very high pressures, hydrogen bonds buckle and the  $\text{H}_2\text{O}$  molecules adopt different arrangements. These polymorphs of ice may contribute to the advance of glaciers, for ice at the bottom of glaciers experiences very high pressures where it rests on jagged rocks.

#### Brief illustration 4A.8 A phase diagram 2

Consider the path ABCD in Fig. 4A.9. At A, water is present as ice V. Increasing the pressure to B at the same temperature results in the formation of a polymorph, ice VIII. Heating to C leads to the formation of ice VII, and reduction in pressure to D results in the solid melting to liquid.

**Self-test 4A.8** Describe what happens on circulating around the critical point, Path F.

Answer: Vapour  $\rightarrow$  liquid  $\rightarrow$   $\text{scH}_2\text{O}$   $\rightarrow$  vapour

### (c) Helium

When considering helium at low temperatures it is necessary to distinguish between the isotopes  $^3\text{He}$  and  $^4\text{He}$ . Figure 4A.11 shows the phase diagram of helium-4. Helium behaves unusually at low temperatures because the mass of its atoms is so low and their small number of electrons results in them interacting only very weakly with their neighbours. For instance, the solid and gas phases of helium are never in equilibrium however low the temperature: the atoms are so light that they vibrate with a large-amplitude motion even at very low temperatures and the

**Figure 4A.11** The phase diagram for helium ( $^4\text{He}$ ). The  $\lambda$ -line marks the conditions under which the two liquid phases are in equilibrium. Helium-II is the superfluid phase. Note that a pressure of over 20 bar must be exerted before solid helium can be obtained. The labels hcp and bcc denote different solid phases in which the atoms pack together differently: hcp denotes hexagonal closed packing and bcc denotes body-centred cubic (see Topic 18B for a description of these structures). The path ABCD is discussed in *Brief illustration 4A.9*.

solid simply shakes itself apart. Solid helium can be obtained, but only by holding the atoms together by applying pressure. The isotopes of helium behave differently for quantum mechanical reasons that are explained in Part 2. (The difference stems from the different nuclear spins of the isotopes and the role of the Pauli exclusion principle: helium-4 has  $I=0$  and is a boson; helium-3 has  $I=\frac{1}{2}$  and is a fermion.)

Pure helium-4 has two liquid phases. The phase marked He-I in the diagram behaves like a normal liquid; the other phase, He-II, is a **superfluid**; it is so called because it flows without viscosity.<sup>1</sup> Provided we discount the liquid crystalline substances discussed in *Impact I5.1* on line, helium is the only known substance with a liquid–liquid boundary, shown as the  $\lambda$ -line (lambda line) in Fig. 4A.11.

The phase diagram of helium-3 differs from the phase diagram of helium-4, but it also possesses a superfluid phase. Helium-3 is unusual in that melting is exothermic ( $\Delta_{\text{fus}}H < 0$ ) and therefore (from  $\Delta_{\text{fus}}S = \Delta_{\text{fus}}H/T_f$ ) at the melting point the entropy of the liquid is lower than that of the solid.

#### Brief illustration 4A.9 A phase diagram 3

Consider the path ABCD in Fig. 4A.11. At A, helium is present as a vapour. On cooling to B it condenses to helium-I, and further cooling to C results in the formation of helium-II. Adjustment of the pressure and temperature to D results in a system in which three phases, helium-I, helium-II, and vapour, are in mutual equilibrium.

**Self-test 4A.9** Describe what happens on the path EFGH.

Answer: He-I  $\rightarrow$  solid  $\rightarrow$  solid  $\rightarrow$  He-II

<sup>1</sup> Water might also have a superfluid liquid phase.

## Checklist of concepts

1. A **phase** is a form of matter that is uniform throughout in chemical composition and physical state.
2. A **phase transition** is the spontaneous conversion of one phase into another and may be studied by techniques that include thermal analysis.
3. The thermodynamic analysis of phases is based on the fact that at equilibrium, the chemical potential of a substance is the same throughout a sample.
4. A substance is characterized by a variety of parameters that can be identified on its **phase diagram**.
5. The **phase rule** relates the number of variables that may be changed while the phases of a system remain in mutual equilibrium.
6. Carbon dioxide is a typical substance but shows features that can be traced to its weak intermolecular forces.
7. Water shows anomalies that can be traced to its extensive hydrogen bonding.
8. Helium shows anomalies that can be traced to its low mass and weak interactions.

### ► Why do you need to know this material?

This Topic illustrates how thermodynamics is used to discuss the equilibria of the phases of one-component systems and shows how to make predictions about the effect of pressure on freezing and boiling points.

### ► What is the key idea?

The effect of temperature and pressure on the chemical potentials of phases in equilibrium is determined by the molar entropy and molar volume, respectively, of the phases.

### ► What do you need to know already?

You need to be aware that phases are in equilibrium when their chemical potentials are equal (Topic 4A) and that the variation of the molar Gibbs energy of a substance depends on its molar volume and entropy (Topic 3D). We draw on expressions for the entropy of transition (Topic 3B) and the perfect gas law (Topic 1A).

As explained in Topic 4A, the thermodynamic criterion of phase equilibrium is the equality of the chemical potentials of each phase. For a one-component system, the chemical potential is the same as the molar Gibbs energy of the phase. As Topic 3D explains how the Gibbs energy varies with temperature and pressure, by combining these two aspects, we can expect to be able to deduce how phase equilibria vary as the conditions are changed.

## 4B.1 The dependence of stability on the conditions

At very low temperatures and provided the pressure is not too low, the solid phase of a substance has the lowest chemical potential and is therefore the most stable phase. However, the chemical potentials of different phases change with temperature in different ways, and above a certain temperature the chemical potential of another phase (perhaps another solid phase, a liquid, or a gas) may turn out to be the lowest. When that happens, a transition to the second phase is spontaneous and occurs if it is kinetically feasible to do so.

### (a) The temperature dependence of phase stability

The temperature dependence of the Gibbs energy is expressed in terms of the entropy of the system by eqn 3D.8  $(\partial G/\partial T)_p = -S$ . Because the chemical potential of a pure substance is just another name for its molar Gibbs energy, it follows that

$$\left(\frac{\partial \mu}{\partial T}\right)_p = -S_m \quad \text{Variation of chemical potential with } T \quad (4B.1)$$

This relation shows that, as the temperature is raised, the chemical potential of a pure substance decreases:  $S_m > 0$  for all substances, so the slope of a plot of  $\mu$  against  $T$  is negative.

Equation 4B.1 implies that because  $S_m(\text{g}) > S_m(\text{l})$  the slope of a plot of  $\mu$  against temperature is steeper for gases than for liquids. Because  $S_m(\text{l}) > S_m(\text{s})$  almost always, the slope is also steeper for a liquid than the corresponding solid. These features are illustrated in Fig. 4B.1. The steep negative slope of  $\mu(\text{l})$  results in it falling below  $\mu(\text{s})$  when the temperature is high enough, and then the liquid becomes the stable phase: the solid melts. The chemical potential of the gas phase plunges steeply downwards as the temperature is raised (because the molar entropy of the vapour is so high), and there comes a temperature at which it lies lowest. Then the gas is the stable phase and vaporization is spontaneous.

**Figure 4B.1** The schematic temperature dependence of the chemical potential of the solid, liquid, and gas phases of a substance (in practice, the lines are curved). The phase with the lowest chemical potential at a specified temperature is the most stable one at that temperature. The transition temperatures, the melting and boiling temperatures ( $T_f$  and  $T_b$ , respectively), are the temperatures at which the chemical potentials of the two phases are equal.

#### Brief illustration 4B.1 The temperature variation of $\mu$

The standard molar entropy of liquid water at 100 °C is 86.8 J K<sup>-1</sup> mol<sup>-1</sup> and that of water vapour at the same temperature is 195.98 J K<sup>-1</sup> mol<sup>-1</sup>. It follows that when the temperature is raised by 1.0 K the changes in chemical potential are

$$\delta\mu(\text{l}) \approx S_m(\text{l})\delta T = 87 \text{ J mol}^{-1} \quad \delta\mu(\text{g}) \approx S_m(\text{g})\delta T = 196 \text{ J mol}^{-1}$$

At 100 °C the two phases are in equilibrium with equal chemical potentials, so at 1.0 K higher the chemical potential of the vapour is lower (by 109 J mol<sup>-1</sup>) than that of the liquid and vaporization is spontaneous.

**Self-test 4B.1** The standard molar entropy of liquid water at 0 °C is 65 J K<sup>-1</sup> mol<sup>-1</sup> and that of ice at the same temperature is 43 J K<sup>-1</sup> mol<sup>-1</sup>. What is the effect of increasing the temperature by 1.0 K?

Answer:  $\delta\mu(\text{l}) \approx -65 \text{ J mol}^{-1}$ ,  $\delta\mu(\text{s}) \approx -43 \text{ J mol}^{-1}$ ; ice melts

### (b) The response of melting to applied pressure

Most substances melt at a higher temperature when subjected to pressure. It is as though the pressure is preventing the formation of the less dense liquid phase. Exceptions to this behaviour include water, for which the liquid is denser than the solid. Application of pressure to water encourages the formation of the liquid phase. That is, water freezes and ice melts at a lower temperature when it is under pressure.

We can rationalize the response of melting temperatures to pressure as follows. The variation of the chemical potential with pressure is expressed (from the second of eqns 3D.8,  $(\partial G/\partial p)_T = V$ ) by

$$\left(\frac{\partial \mu}{\partial p}\right)_T = V_m \quad \text{Variation of chemical potential with } p \quad (4B.2)$$

This equation shows that the slope of a plot of chemical potential against pressure is equal to the molar volume of the substance. An increase in pressure raises the chemical potential of any pure substance (because  $V_m > 0$ ). In most cases,  $V_m(\text{l}) > V_m(\text{s})$  and the equation predicts that an increase in pressure increases the chemical potential of the liquid more than that of the solid. As shown in Fig. 4B.2a, the effect of pressure in such a case is to raise the melting temperature slightly. For water, however,  $V_m(\text{l}) < V_m(\text{s})$ , and an increase in pressure increases the chemical potential of the solid more than that of the liquid. In this case, the melting temperature is lowered slightly (Fig. 4B.2b).

#### Example 4B.1 Assessing the effect of pressure on the chemical potential

Calculate the effect on the chemical potentials of ice and water of increasing the pressure from 1.00 bar to 2.00 bar at 0 °C. The density of ice is 0.917 g cm<sup>-3</sup> and that of liquid water is 0.999 g cm<sup>-3</sup> under these conditions.

**Method** From eqn 4B.2 in the form  $d\mu = V_m dp$ , we know that the change in chemical potential of an incompressible substance when the pressure is changed by  $\Delta p$  is  $\Delta\mu = V_m \Delta p$ . Therefore, to answer the question, we need to know the molar volumes of the two phases of water. These values are obtained from the mass density,  $\rho$ , and the molar mass,  $M$ , by using  $V_m = M/\rho$ . We therefore use the expression  $\Delta\mu = M\Delta p/\rho$ .

**Answer** The molar mass of water is  $18.02 \text{ g mol}^{-1}$  ( $1.802 \times 10^{-2} \text{ kg mol}^{-1}$ ); therefore,

$$\Delta\mu(\text{ice}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{917 \text{ kg m}^{-3}} = +1.97 \text{ J mol}^{-1}$$

$$\Delta\mu(\text{water}) = \frac{(1.802 \times 10^{-2} \text{ kg mol}^{-1}) \times (1.00 \times 10^5 \text{ Pa})}{999 \text{ kg m}^{-3}} = +1.80 \text{ J mol}^{-1}$$

We interpret the numerical results as follows: the chemical potential of ice rises more sharply than that of water, so if they are initially in equilibrium at 1 bar, then there will be a tendency for the ice to melt at 2 bar.

**Self-test 4B.2** Calculate the effect of an increase in pressure of 1.00 bar on the liquid and solid phases of carbon dioxide (molar mass  $44.0 \text{ g mol}^{-1}$ ) in equilibrium with densities  $2.35 \text{ g cm}^{-3}$  and  $2.50 \text{ g cm}^{-3}$ , respectively.

Answer:  $\Delta\mu(\text{l}) = +1.87 \text{ J mol}^{-1}$ ,  $\Delta\mu(\text{s}) = +1.76 \text{ J mol}^{-1}$ ; solid forms

**Figure 4B.2** The pressure dependence of the chemical potential of a substance depends on the molar volume of the phase. The lines show schematically the effect of increasing pressure on the chemical potential of the solid and liquid phases (in practice, the lines are curved), and the corresponding effects on the freezing temperatures. (a) In this case the molar volume of the solid is smaller than that of the liquid and  $\mu(\text{s})$  increases less than  $\mu(\text{l})$ . As a result, the freezing temperature rises. (b) Here the molar volume is greater for the solid than the liquid (as for water),  $\mu(\text{s})$  increases more strongly than  $\mu(\text{l})$ , and the freezing temperature is lowered.

**Figure 4B.3** Pressure may be applied to a condensed phase either (a) by compressing the condensed phase or (b) by subjecting it to an inert pressurizing gas. When pressure is applied, the vapour pressure of the condensed phase increases.

### (c) The vapour pressure of a liquid subjected to pressure

When pressure is applied to a condensed phase, its vapour pressure rises: in effect, molecules are squeezed out of the phase and escape as a gas. Pressure can be exerted on the condensed phase mechanically or by subjecting it to the applied pressure of an inert gas (Fig. 4B.3). In the latter case, the vapour pressure is the partial pressure of the vapour in equilibrium with the condensed phase. We then speak of the **partial vapour pressure** of the substance. One complication (which we ignore here) is that, if the condensed phase is a liquid, then the pressurizing gas might dissolve and change the properties of the liquid. Another complication is that the gas phase molecules might attract molecules out of the liquid by the process of **gas solvation**, the attachment of molecules to gas-phase species.

As shown in the following *Justification*, the quantitative relation between the vapour pressure,  $p$ , when a pressure  $\Delta P$  is applied and the vapour pressure,  $p^*$ , of the liquid in the absence of an additional pressure is

$$p = p^* e^{V_m(1)\Delta P/RT} \quad \text{Effect of applied pressure } \Delta P \text{ on vapour pressure } p \quad (4B.3)$$

This equation shows how the vapour pressure increases when the pressure acting on the condensed phase is increased.

#### Justification 4B.1 The vapour pressure of a pressurized liquid

We calculate the vapour pressure of a pressurized liquid by using the fact that at equilibrium the chemical potentials of the liquid and its vapour are equal:  $\mu(\text{l}) = \mu(\text{g})$ . It follows that, for any change that preserves equilibrium, the resulting change in  $\mu(\text{l})$  must be equal to the change in  $\mu(\text{g})$ ; therefore, we can write  $d\mu(\text{g}) = d\mu(\text{l})$ . When the pressure  $P$  on the liquid is increased by  $dP$ , the chemical potential of the liquid changes by  $d\mu(\text{l}) = V_m(\text{l})dP$ . The chemical potential of the vapour changes

by  $d\mu(\text{g}) = V_{\text{m}}(\text{g})dp$  where  $dp$  is the change in the vapour pressure we are trying to find. If we treat the vapour as a perfect gas, the molar volume can be replaced by  $V_{\text{m}}(\text{g}) = RT/p$ , and we obtain  $d\mu(\text{g}) = RTdp/p$ . Next, we equate the changes in chemical potentials of the vapour and the liquid:

$$\frac{RTdp}{p} = V_{\text{m}}(\text{l})dP$$

We can integrate this expression once we know the limits of integration.

When there is no additional pressure acting on the liquid,  $P$  (the pressure experienced by the liquid) is equal to the normal vapour pressure  $p^*$ , so when  $P = p^*$ ,  $p = p^*$  too. When there is an additional pressure  $\Delta P$  on the liquid, with the result that  $P = p + \Delta P$ , the vapour pressure is  $p$  (the value we want to find). Provided the effect of pressure on the vapour pressure is small (as will turn out to be the case) a good approximation is to replace the  $p$  in  $p + \Delta P$  by  $p^*$  itself, and to set the upper limit of the integral to  $p^* + \Delta P$ . The integrations required are therefore as follows:

$$RT \int_{p^*}^p \frac{dp}{p} = \int_{p^*}^{p^* + \Delta P} V_{\text{m}}(\text{l}) dP$$

We now divide both sides by  $RT$  and assume that the molar volume of the liquid is the same throughout the small range of pressures involved:

$$\ln \frac{p}{p^*} = \frac{1}{RT} \int_{p^*}^{p^* + \Delta P} V_{\text{m}}(\text{l}) dP = \frac{V_{\text{m}}(\text{l})}{RT} \int_{p^*}^{p^* + \Delta P} dP$$

Then both integrations are straightforward, and lead to

$$\ln \frac{p}{p^*} = \frac{V_{\text{m}}(\text{l})}{RT} \Delta P$$

which rearranges to eqn 4B.3 because  $e^{\ln x} = x$ .

#### Brief illustration 4B.2 The effect of pressurization

For water, which has density  $0.997 \text{ g cm}^{-3}$  at  $25^\circ\text{C}$  and therefore molar volume  $18.1 \text{ cm}^3 \text{ mol}^{-1}$ , when the pressure is increased by 10 bar (that is,  $\Delta P = 1.0 \times 10^6 \text{ Pa}$ )

$$\begin{aligned} \frac{V_{\text{m}}(\text{l})\Delta P}{RT} &= \frac{(1.81 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}) \times (1.0 \times 10^6 \text{ Pa})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} \\ &= \frac{1.81 \times 1.0 \times 10^1}{8.3145 \times 298} = 0.0073 \dots \end{aligned}$$

where we have used  $1 \text{ J} = 1 \text{ Pa m}^3$ . It follows that  $p = 1.0073p^*$ , an increase of 0.73 per cent.

**Self-test 4B.3** Calculate the effect of an increase in pressure of 100 bar on the vapour pressure of benzene at  $25^\circ\text{C}$ , which has density  $0.879 \text{ g cm}^{-3}$ .

Answer: 43 per cent increase

## 4B.2 The location of phase boundaries

The precise locations of the phase boundaries—the pressures and temperatures at which two phases can coexist—can be found by making use of the fact that, when two phases are in equilibrium, their chemical potentials must be equal. Therefore, where the phases  $\alpha$  and  $\beta$  are in equilibrium,

$$\mu(\alpha; p, T) = \mu(\beta; p, T) \quad (4B.4)$$

By solving this equation for  $p$  in terms of  $T$ , we get an equation for the phase boundary.

### (a) The slopes of the phase boundaries

It turns out to be simplest to discuss the phase boundaries in terms of their slopes,  $dp/dT$ . Let  $p$  and  $T$  be changed infinitesimally, but in such a way that the two phases  $\alpha$  and  $\beta$  remain in equilibrium. The chemical potentials of the phases are initially equal (the two phases are in equilibrium). They remain equal when the conditions are changed to another point on the phase boundary, where the two phases continue to be in equilibrium (Fig. 4B.4). Therefore, the changes in the chemical potentials of the two phases must be equal and we can write  $d\mu(\alpha) = d\mu(\beta)$ . Because, from eqn 3D.7 ( $dG = Vdp - SdT$ ), we know that  $d\mu = -S_{\text{m}}dT + V_{\text{m}}dp$  for each phase, it follows that

$$-S_{\text{m}}(\alpha)dT + V_{\text{m}}(\alpha)dp = -S_{\text{m}}(\beta)dT + V_{\text{m}}(\beta)dp$$

where  $S_{\text{m}}(\alpha)$  and  $S_{\text{m}}(\beta)$  are the molar entropies of the phases and  $V_{\text{m}}(\alpha)$  and  $V_{\text{m}}(\beta)$  are their molar volumes. Hence

$$\{S_{\text{m}}(\beta) - S_{\text{m}}(\alpha)\}dT = \{V_{\text{m}}(\beta) - V_{\text{m}}(\alpha)\}dp$$

**Figure 4B.4** When pressure is applied to a system in which two phases are in equilibrium (at  $a$ ), the equilibrium is disturbed. It can be restored by changing the temperature, so moving the state of the system to  $b$ . It follows that there is a relation between  $dp$  and  $dT$  that ensures that the system remains in equilibrium as either variable is changed.

Then, with  $\Delta_{\text{trs}}S = S_{\text{m}}(\beta) - S_{\text{m}}(\alpha)$  and  $\Delta_{\text{trs}}V = V_{\text{m}}(\beta) - V_{\text{m}}(\alpha)$ , which are the (molar) entropy and volume of transition, respectively,

$$\Delta_{\text{trs}}S dT = \Delta_{\text{trs}}V dp$$

This relation rearranges into the **Clapeyron equation**:

$$\frac{dp}{dT} = \frac{\Delta_{\text{trs}}S}{\Delta_{\text{trs}}V} \quad \text{Clapeyron equation} \quad (4B.5a)$$

The Clapeyron equation is an exact expression for the slope of the tangent to the boundary at any point and applies to any phase equilibrium of any pure substance. It implies that we can use thermodynamic data to predict the appearance of phase diagrams and to understand their form. A more practical application is to the prediction of the response of freezing and boiling points to the application of pressure, when it can be used in the form obtained by inverting both sides:

$$\frac{dT}{dp} = \frac{\Delta_{\text{trs}}V}{\Delta_{\text{trs}}S} \quad (4B.5b)$$

#### Brief illustration 4B.3 The Clapeyron equation

The standard volume and entropy of transition of water from ice to liquid are  $-1.6 \text{ cm}^3 \text{ mol}^{-1}$  and  $+22 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively, at  $0^\circ\text{C}$ . The slope of the solid–liquid phase boundary at that temperature is therefore

$$\frac{dT}{dp} = \frac{-1.6 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}}{22 \text{ J}^{-1} \text{ mol}^{-1}} = -7.3 \times 10^{-8} \frac{\text{K}}{\text{J m}^{-3}} = -7.3 \times 10^{-8} \text{ K Pa}^{-1}$$

which corresponds to  $-7.3 \text{ mK bar}^{-1}$ . An increase of 100 bar therefore results in a lowering of the freezing point of water by 0.73 K.

**Self-test 4B.4** The standard volume and entropy of transition of water from liquid to vapour are  $+30 \text{ dm}^3 \text{ mol}^{-1}$  and  $+109 \text{ J K}^{-1} \text{ mol}^{-1}$ , respectively, at  $100^\circ\text{C}$ . By how much does the boiling temperature change when the pressure is reduced from 1.0 bar to 0.80 bar?

Answer:  $-5.5 \text{ K}$

### (b) The solid–liquid boundary

Melting (fusion) is accompanied by a molar enthalpy change  $\Delta_{\text{fus}}H$  and occurs at a temperature  $T$ . The molar entropy of melting at  $T$  is therefore  $\Delta_{\text{fus}}H/T$  (Topic 3B), and the Clapeyron equation becomes

$$\frac{dp}{dT} = \frac{\Delta_{\text{fus}}H}{T\Delta_{\text{fus}}V} \quad \text{Slope of solid–liquid boundary} \quad (4B.6)$$

**Figure 4B.5** A typical solid–liquid phase boundary slopes steeply upwards. This slope implies that, as the pressure is raised, the melting temperature rises. Most substances behave in this way.

where  $\Delta_{\text{fus}}V$  is the change in molar volume that occurs on melting. The enthalpy of melting is positive (the only exception is helium-3) and the volume change is usually positive and always small. Consequently, the slope  $dp/dT$  is steep and usually positive (Fig. 4B.5).

We can obtain the formula for the phase boundary by integrating  $dp/dT$ , assuming that  $\Delta_{\text{fus}}H$  and  $\Delta_{\text{fus}}V$  change so little with temperature and pressure that they can be treated as constant. If the melting temperature is  $T^*$  when the pressure is  $p^*$ , and  $T$  when the pressure is  $p$ , the integration required is

$$\int_{p^*}^p dp = \frac{\Delta_{\text{fus}}H}{\Delta_{\text{fus}}V} \int_{T^*}^T \frac{dT}{T}$$

Therefore, the approximate equation of the solid–liquid boundary is

$$p = p^* + \frac{\Delta_{\text{fus}}H}{\Delta_{\text{fus}}V} \ln \frac{T}{T^*} \quad (4B.7)$$

This equation was originally obtained by yet another Thomson—James, the brother of William, Lord Kelvin. When  $T$  is close to  $T^*$ , the logarithm can be approximated by using

$$\ln \frac{T}{T^*} = \ln \left( 1 + \frac{T - T^*}{T^*} \right) \approx \frac{T - T^*}{T^*}$$

where we have used the expansion  $\ln(1+x) = x - \frac{1}{2}x^2 + \dots$  (*Mathematical background 1*) and neglected all but the leading term; therefore

$$p \approx p^* + \frac{\Delta_{\text{fus}}H}{T^*\Delta_{\text{fus}}V} (T - T^*) \quad (4B.8)$$

This expression is the equation of a steep straight line when  $p$  is plotted against  $T$  (as in Fig. 4B.5).

**Brief illustration 4B.4** The solid–liquid boundary

The enthalpy of fusion of ice at 0°C and 1 bar (273 K) is 6.008 kJ mol<sup>-1</sup> and the volume of fusion is -1.6 cm<sup>3</sup> mol<sup>-1</sup>. It follows that the solid–liquid phase boundary is given by the equation

$$p \approx 1 \text{ bar} + \frac{6.008 \times 10^3 \text{ J mol}^{-1}}{(273 \text{ K}) \times (-1.6 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1})} (T - T^*) \\ \approx 1 \text{ bar} - 1.4 \times 10^7 \text{ Pa K}^{-1} (T - T^*)$$

That is,

$$p/\text{bar} = 1 - 140(T - T^*)/\text{K}$$

with  $T^* = 273 \text{ K}$ . This expression is plotted in Fig. 4B.6.

**Figure 4B.6** The solid–liquid phase boundaries (the melting point curves) for water and benzene, as calculated in *Brief illustration 4B.4*.

**Self-test 4B.5** The enthalpy of fusion of benzene is 10.59 kJ mol<sup>-1</sup> at its melting point of 279 K and its volume of fusion is close to +0.50 cm<sup>3</sup> mol<sup>-1</sup> (an estimated value). What is the equation of its solid–liquid phase boundary?

Answer:  $p/\text{bar} = 1 + 760(T - T^*)$ , as in Fig. 4B.6

**(c) The liquid–vapour boundary**

The entropy of vaporization at a temperature  $T$  is equal to  $\Delta_{\text{vap}}H/T$ ; the Clapeyron equation for the liquid–vapour boundary is therefore

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}}H}{T\Delta_{\text{vap}}V} \quad \text{Slope of liquid–vapour boundary} \quad (4B.9)$$

The enthalpy of vaporization is positive;  $\Delta_{\text{vap}}V$  is large and positive. Therefore,  $dp/dT$  is positive, but it is much smaller than for the solid–liquid boundary. It follows that  $dT/dp$  is large, and hence that the boiling temperature is more responsive to pressure than the freezing temperature.

**Example 4B.2** Estimating the effect of pressure on the boiling temperature

Estimate the typical size of the effect of increasing pressure on the boiling point of a liquid.

**Method** To use eqn 4B.9 we need to estimate the right-hand side. At the boiling point, the term  $\Delta_{\text{vap}}H/T$  is Trouton's constant (Topic 3B). Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write  $\Delta_{\text{vap}}V = V_{\text{m}}(\text{g}) - V_{\text{m}}(\text{l}) \approx V_{\text{m}}(\text{g})$  and take for  $V_{\text{m}}(\text{g})$  the molar volume of a perfect gas (at low pressures, at least).

**Answer** Trouton's constant has the value 85 J K<sup>-1</sup> mol<sup>-1</sup>. The molar volume of a perfect gas is about 25 dm<sup>3</sup> mol<sup>-1</sup> at 1 atm and near but above room temperature. Therefore,

$$\frac{dp}{dT} \approx \frac{85 \text{ J K}^{-1} \text{ mol}^{-1}}{2.5 \times 10^{-2} \text{ m}^3 \text{ mol}^{-1}} = 3.4 \times 10^3 \text{ Pa K}^{-1}$$

We have used 1 J = 1 Pa m<sup>3</sup>. This value corresponds to 0.034 atm K<sup>-1</sup> and hence to  $dT/dp = 29 \text{ K atm}^{-1}$ . Therefore, a change of pressure of +0.1 atm can be expected to change a boiling temperature by about +3 K.

**Self-test 4B.6** Estimate  $dT/dp$  for water at its normal boiling point using the information in Table 3A.2 and  $V_{\text{m}}(\text{g}) = RT/p$ .

Answer: 28 K atm<sup>-1</sup>

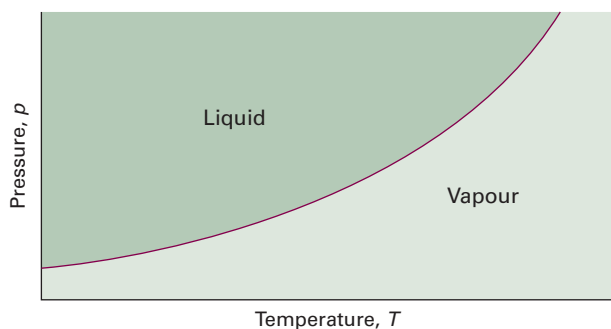

Because the molar volume of a gas is so much greater than the molar volume of a liquid, we can write  $\Delta_{\text{vap}}V \approx V_{\text{m}}(\text{g})$  (as in *Example 4B.2*). Moreover, if the gas behaves perfectly,  $V_{\text{m}}(\text{g}) = RT/p$ . These two approximations turn the exact Clapeyron equation into

$$\frac{dp}{dT} = \frac{\Delta_{\text{vap}}H}{T(RT/p)} = \frac{p\Delta_{\text{vap}}H}{RT^2}$$

which, by using  $dx/x = d \ln x$ , rearranges into the **Clausius–Clapeyron equation** for the variation of vapour pressure with temperature:

$$\frac{d \ln p}{dT} = \frac{\Delta_{\text{vap}}H}{RT^2} \quad \text{Vapour is a perfect gas} \quad \text{Clausius–Clapeyron equation} \quad (4B.10)$$

Like the Clapeyron equation (which is exact), the Clausius–Clapeyron equation (which is an approximation) is important for understanding the appearance of phase diagrams, particularly the location and shape of the liquid–vapour and solid–vapour phase boundaries. It lets us predict how the vapour pressure varies with temperature and how the boiling temperature varies with pressure. For instance, if we also assume that the enthalpy of vaporization is independent of temperature, eqn 4B.10 can be integrated as follows:

**Figure 4B.7** A typical liquid–vapour phase boundary. The boundary can be regarded as a plot of the vapour pressure against the temperature. Note that, in some depictions of phase diagrams in which a logarithmic pressure scale is used, the phase boundary has the opposite curvature (see Fig. 4B.8). This phase boundary terminates at the critical point (not shown).

$$\int_{\ln p^*}^{\ln p} d \ln p = \frac{\Delta_{\text{vap}}H}{R} \int_{T^*}^T \frac{dT}{T^2} = -\frac{\Delta_{\text{vap}}H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right)$$

where  $p^*$  is the vapour pressure when the temperature is  $T^*$  and  $p$  the vapour pressure when the temperature is  $T$ . Therefore, because the integral on the left evaluates to  $\ln(p/p^*)$ , the two vapour pressures are related by

$$p = p^* e^{-\chi} \quad \chi = \frac{\Delta_{\text{vap}}H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right) \quad (4B.11)$$

Equation 4B.11 is plotted as the liquid–vapour boundary in Fig. 4B.7. The line does not extend beyond the critical temperature  $T_c$ , because above this temperature the liquid does not exist.

#### Brief illustration 4B.5 The Clausius–Clapeyron equation

Equation 4B.11 can be used to estimate the vapour pressure of a liquid at any temperature from its normal boiling point, the temperature at which the vapour pressure is 1.00 atm (101 kPa). The normal boiling point of benzene is 80 °C (353 K) and (from Table 3A.2),  $\Delta_{\text{vap}}H^\ominus = 30.8 \text{ kJ mol}^{-1}$ . Therefore, to calculate the vapour pressure at 20 °C (293 K), we write

$$\chi = \frac{3.08 \times 10^4 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{293 \text{ K}} - \frac{1}{353 \text{ K}} \right) = 2.14 \dots$$

and substitute this value into eqn 4B.11 with  $p^* = 101 \text{ kPa}$ . The result is 12 kPa. The experimental value is 10 kPa.

*A note on good practice* Because exponential functions are so sensitive, it is good practice to carry out numerical calculations like this without evaluating the intermediate steps and using rounded values.

#### (d) The solid–vapour boundary

The only difference between this case and the last is the replacement of the enthalpy of vaporization by the enthalpy of sublimation,  $\Delta_{\text{sub}}H$ . Because the enthalpy of sublimation is greater than the enthalpy of vaporization (recall that  $\Delta_{\text{sub}}H = \Delta_{\text{fus}}H + \Delta_{\text{vap}}H$ ), the equation predicts a steeper slope for the sublimation curve than for the vaporization curve at similar temperatures, which is near where they meet at the triple point (Fig. 4B.8).

#### Brief illustration 4B.6 The solid–vapour boundary

The enthalpy of fusion of ice at the triple point of water (6.1 mbar, 273 K) is negligibly different from its standard enthalpy of fusion at its freezing point, which is 6.008 kJ mol<sup>-1</sup>. The enthalpy of vaporization at that temperature is 45.0 kJ mol<sup>-1</sup> (once again, ignoring differences due to the pressure not being 1 bar). The enthalpy of sublimation is therefore 51.0 kJ mol<sup>-1</sup>. Therefore, the equations for the slopes of (a) the liquid–vapour and (b) the solid–vapour phase boundaries at the triple point are

$$(a) \frac{d \ln p}{dT} = \frac{45.0 \times 10^3 \text{ J mol}^{-1}}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (273 \text{ K})^2} = 0.0726 \text{ K}^{-1}$$

$$(b) \frac{d \ln p}{dT} = \frac{51.0 \times 10^3 \text{ J mol}^{-1}}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (273 \text{ K})^2} = 0.0823 \text{ K}^{-1}$$

We see that the slope of  $\ln p$  plotted against  $T$  is greater for the solid–vapour boundary than for the liquid–vapour boundary at the triple point.

**Self-test 4B.7** Confirm that the same may be said for the plot of  $p$  against  $T$  at the triple point.

Answer:  $dp/dT = p d \ln p/dT$ ,  $p = p_3 = 6.1 \text{ mbar}$

**Figure 4B.8** Near the point where they coincide (at the triple point), the solid–vapour boundary has a steeper slope than the liquid–vapour boundary because the enthalpy of sublimation is greater than the enthalpy of vaporization and the temperatures that occur in the Clausius–Clapeyron equation for the slope have similar values.

### 4B.3 The Ehrenfest classification of phase transitions

There are many different types of phase transition, including the familiar examples of fusion and vaporization and the less familiar examples of solid–solid, conducting–superconducting, and fluid–superfluid transitions. We shall now see that it is possible to use thermodynamic properties of substances, and in particular the behaviour of the chemical potential, to classify phase transitions into different types. Classification is commonly a first step towards a molecular interpretation and the identification of common features. The classification scheme was originally proposed by Paul Ehrenfest, and is known as the **Ehrenfest classification**.

#### (a) The thermodynamic basis

Many familiar phase transitions, like fusion and vaporization, are accompanied by changes of enthalpy and volume. These changes have implications for the slopes of the chemical potentials of the phases at either side of the phase transition. Thus, at the transition from a phase  $\alpha$  to another phase  $\beta$ ,

$$\begin{aligned} \left(\frac{\partial\mu(\beta)}{\partial p}\right)_T - \left(\frac{\partial\mu(\alpha)}{\partial p}\right)_T &= V_m(\beta) - V_m(\alpha) = \Delta_{\text{trs}}V \\ \left(\frac{\partial\mu(\beta)}{\partial T}\right)_p - \left(\frac{\partial\mu(\alpha)}{\partial T}\right)_p &= -S_m(\beta) + S_m(\alpha) = -\Delta_{\text{trs}}S = -\frac{\Delta_{\text{trs}}H}{T_{\text{trs}}} \end{aligned} \quad (4B.12)$$

Because  $\Delta_{\text{trs}}V$  and  $\Delta_{\text{trs}}H$  are non-zero for melting and vaporization, it follows that for such transitions the slopes of the chemical potential plotted against either pressure or temperature are different on either side of the transition (Fig. 4B.9a). In other words, the first derivatives of the chemical potentials with respect to pressure and temperature are discontinuous at the transition.

**Figure 4B.9** The changes in thermodynamic properties accompanying (a) first-order and (b) second-order phase transitions.

#### Brief illustration 4B.7 Discontinuities of the transitions

The melting of water at its normal melting point of  $0^\circ\text{C}$  has  $\Delta_{\text{trs}}V = -1.6\text{ cm}^3\text{ mol}^{-1}$  and  $\Delta_{\text{trs}}H = 6.008\text{ kJ mol}^{-1}$ , so

$$\begin{aligned} \left(\frac{\partial\mu(l)}{\partial p}\right)_T - \left(\frac{\partial\mu(s)}{\partial p}\right)_T &= \Delta_{\text{fus}}V = -1.6\text{ cm}^3\text{ mol}^{-1} \\ \left(\frac{\partial\mu(l)}{\partial T}\right)_p - \left(\frac{\partial\mu(s)}{\partial T}\right)_p &= -\frac{\Delta_{\text{fus}}H}{T_{\text{fus}}} = -\frac{6.008 \times 10^3\text{ J mol}^{-1}}{273\text{ K}} \\ &= -22.0\text{ J mol}^{-1} \end{aligned}$$

and both slopes are discontinuous.

**Self-test 4B.8** Evaluate the difference in slopes at the normal boiling point.

Answer:  $+31\text{ dm}^3\text{ mol}^{-1}$ ,  $-109\text{ J mol}^{-1}$

A transition for which the first derivative of the chemical potential with respect to temperature is discontinuous is classified as a **first-order phase transition**. The constant-pressure heat capacity,  $C_p$ , of a substance is the slope of a plot of the enthalpy with respect to temperature. At a first-order phase transition,  $H$  changes by a finite amount for an infinitesimal change of temperature. Therefore, at the transition the heat capacity is infinite. The physical reason is that heating drives the transition rather than raising the temperature. For example, boiling water stays at the same temperature even though heat is being supplied.

A **second-order phase transition** in the Ehrenfest sense is one in which the first derivative of  $\mu$  with respect to temperature is continuous but its second derivative is discontinuous. A continuous slope of  $\mu$  (a graph with the same slope on either side of the transition) implies that the volume and entropy (and hence the enthalpy) do not change at the transition (Fig. 4B.9b). The heat capacity is discontinuous at the transition but does not become infinite there. An example of a second-order transition is the conducting–superconducting transition in metals at low temperatures.<sup>1</sup>

The term  **$\lambda$ -transition** is applied to a phase transition that is not first-order yet the heat capacity becomes infinite at the transition temperature. Typically, the heat capacity of a system that shows such a transition begins to increase well before the transition (Fig. 4B.10), and the shape of the heat capacity curve resembles the Greek letter lambda. Examples of  $\lambda$ -transitions include order–disorder transitions in alloys, the onset of ferromagnetism, and the fluid–superfluid transition of liquid helium.

<sup>1</sup> A metallic conductor is a substance with an electrical conductivity that decreases as the temperature increases. A superconductor is a solid that conducts electricity without resistance. See Topic 18C for more details.

**Figure 4B.10** The  $\lambda$ -curve for helium, where the heat capacity rises to infinity. The shape of this curve is the origin of the name  $\lambda$ -transition.

### (b) Molecular interpretation

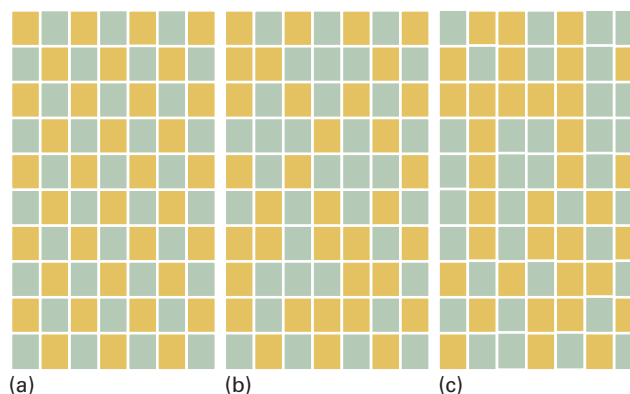

First-order transitions typically involve the relocation of atoms, molecules, or ions with a consequent change in the energies of their interactions. Thus, vaporization eliminates the attractions between molecules and a first-order phase transition from one ionic polymorph to another (as in the conversion of calcite to aragonite) involves the adjustment of the relative positions of ions.

One type of second-order transition is associated with a change in symmetry of the crystal structure of a solid. Thus, suppose the arrangement of atoms in a solid is like that represented in Fig. 4B.11a, with one dimension (technically, of the unit cell) longer than the other two, which are equal. Such a crystal structure is classified as tetragonal (see Topic 18A). Moreover, suppose the two shorter dimensions increase more than the long dimension when the temperature is raised. There may come a stage when the three dimensions become equal. At that point the crystal has cubic symmetry (Fig. 4B.11b), and at higher temperatures it will expand equally in all three directions (because there is no longer any distinction between them). The tetragonal  $\rightarrow$  cubic phase transition has occurred, but as it has not involved a discontinuity in the interaction energy between the atoms or the volume they occupy, the transition is not first-order.

The order–disorder transition in  $\beta$ -brass (CuZn) is an example of a  $\lambda$ -transition. The low-temperature phase is an orderly array of alternating Cu and Zn atoms. The high-temperature phase is a random array of the atoms (Fig. 4B.12). At  $T=0$  the order is perfect, but islands of disorder appear as the temperature is raised. The islands form because the transition is

**Figure 4B.11** One version of a second-order phase transition in which (a) a tetragonal phase expands more rapidly in two directions than a third, and hence becomes a cubic phase, which (b) expands uniformly in three directions as the temperature is raised. There is no rearrangement of atoms at the transition temperature, and hence no enthalpy of transition.

**Figure 4B.12** An order–disorder transition. (a) At  $T=0$ , there is perfect order, with different kinds of atoms occupying alternate sites. (b) As the temperature is increased, atoms exchange locations and islands of each kind of atom form in regions of the solid. Some of the original order survives. (c) At and above the transition temperature, the islands occur at random throughout the sample.

cooperative in the sense that, once two atoms have exchanged locations, it is easier for their neighbours to exchange their locations. The islands grow in extent and merge throughout the crystal at the transition temperature (742 K). The heat capacity increases as the transition temperature is approached because the cooperative nature of the transition means that it is increasingly easy for the heat supplied to drive the phase transition rather than to be stored as thermal motion.

## Checklist of concepts

- 1. The chemical potential of a substance decreases with increasing temperature at a rate determined by its molar entropy.
- 2. The chemical potential of a substance increases with increasing pressure at a rate determined by its molar volume.
- 3. When pressure is applied to a condensed phase, its vapour pressure rises.
- 4. The **Clapeyron equation** is an expression for the slope of a phase boundary.
- 5. The **Clausius–Clapeyron equation** is an approximation that relates the slope of the liquid–vapour boundary to the enthalpy of vaporization.
- 6. According to the **Ehrenfest classification**, different types of phase transition are identified by the behaviour of thermodynamic properties at the transition temperature.
- 7. The classification reveals the type of molecular process occurring at the phase transition.

## Checklist of equations

Property	Equation	Comment	Equation number
Variation of $\mu$ with temperature	$(\partial\mu/\partial T)_p = -S_m$		4B.1
Variation of $\mu$ with pressure	$(\partial\mu/\partial p)_T = V_m$		4B.2
Vapour pressure in the presence of applied pressure	$p = p^* e^{V_m(l)\Delta P/RT}$	$\Delta P = P_{\text{applied}} - p^*$	4B.3
Clapeyron equation	$dp/dT = \Delta_{\text{trs}}S/\Delta_{\text{trs}}V$		4B.5a
Clausius–Clapeyron equation	$d \ln p/dT = \Delta_{\text{vap}}H/RT^2$	Assumes $V_m(\text{g}) \gg V_m(\text{l})$ and vapour is a perfect gas	4B.10

# CHAPTER 4 Physical transformations of pure substances

## TOPIC 4A Phase diagrams of pure substances

### Discussion questions

**4A.1** Describe how the concept of chemical potential unifies the discussion of phase equilibria.

**4A.2** Why does the chemical potential change with pressure even if the system is incompressible (that is, remains at the same volume when pressure is applied)?

**4A.3** Explain why four phases cannot be in equilibrium in a one-component system.

**4A.4** Discuss what would be observed as a sample of water is taken along a path that encircles and is close to its critical point.

### Exercises

**4A.1(a)** How many phases are present at each of the points marked in Fig. 4.1a?

**4A.1(b)** How many phases are present at each of the points marked in Fig. 4.1b?

**4A.2(a)** The difference in chemical potential between two regions of a system is  $+7.1 \text{ kJ mol}^{-1}$ . By how much does the Gibbs energy change when  $0.10 \text{ mmol}$  of a substance is transferred from one region to the other?

**4A.2(b)** The difference in chemical potential between two regions of a system is  $-8.3 \text{ kJ mol}^{-1}$ . By how much does the Gibbs energy change when  $0.15 \text{ mmol}$  of a substance is transferred from one region to the other?

**4A.3(a)** What is the maximum number of phases that can be in mutual equilibrium in a two-component system?

**4A.3(b)** What is the maximum number of phases that can be in mutual equilibrium in a four-component system?

*For problems relating to one-component phase diagrams, see the Integrated activities section of this chapter.*

Figure 4.1 The phase diagrams referred to in (a) Exercise 4A.1(a) and (b) Exercise 4A.1(b).

## TOPIC 4B Thermodynamic aspects of phase transitions

### Discussion questions

**4B.1** What is the physical reason for the fact that the chemical potential of a pure substance decreases as the temperature is raised?

**4B.2** What is the physical reason for the fact that the chemical potential of a pure substance increases as the pressure is raised?

**4B.3** How may differential scanning calorimetry (DSC) be used to identify phase transitions?

**4B.4** Distinguish between a first-order phase transition, a second-order phase transition, and a  $\lambda$ -transition at both molecular and macroscopic levels.

### Exercises

**4B.1(a)** Estimate the difference between the normal and standard melting points of ice.

**4B.1(b)** Estimate the difference between the normal and standard boiling points of water.

**4B.2(a)** Water is heated from  $25^\circ\text{C}$  to  $100^\circ\text{C}$ . By how much does its chemical potential change?

**4B.2(b)** Iron is heated from  $100^\circ\text{C}$  to  $1000^\circ\text{C}$ . By how much does its chemical potential change? Take  $S_{\text{m}}^\ominus = 53 \text{ J K}^{-1} \text{ mol}^{-1}$  for the entire range.

**4B.3(a)** By how much does the chemical potential of copper change when the pressure exerted on a sample is increased from 100 kPa to 10 MPa?

**4B.3(b)** By how much does the chemical potential of benzene change when the pressure exerted on a sample is increased from 100 kPa to 10 MPa?

**4B.4(a)** Pressure was exerted with a piston on water at 20 °C. The vapour pressure of water under 1.0 bar is 2.34 kPa. What is its vapour pressure when the pressure on the liquid is 20 MPa?

**4B.4(b)** Pressure was exerted with a piston on molten naphthalene at 95 °C. The vapour pressure of naphthalene under 1.0 bar is 2.0 kPa. What is its vapour pressure when the pressure on the liquid is 15 MPa?

**4B.5(a)** The molar volume of a certain solid is 161.0 cm<sup>3</sup> mol<sup>-1</sup> at 1.00 atm and 350.75 K, its melting temperature. The molar volume of the liquid at this temperature and pressure is 163.3 cm<sup>3</sup> mol<sup>-1</sup>. At 100 atm the melting temperature changes to 351.26 K. Calculate the enthalpy and entropy of fusion of the solid.

**4B.5(b)** The molar volume of a certain solid is 142.0 cm<sup>3</sup> mol<sup>-1</sup> at 1.00 atm and 427.15 K, its melting temperature. The molar volume of the liquid at this temperature and pressure is 152.6 cm<sup>3</sup> mol<sup>-1</sup>. At 1.2 MPa the melting temperature changes to 429.26 K. Calculate the enthalpy and entropy of fusion of the solid.

**4B.6(a)** The vapour pressure of dichloromethane at 24.1 °C is 53.3 kPa and its enthalpy of vaporization is 28.7 kJ mol<sup>-1</sup>. Estimate the temperature at which its vapour pressure is 70.0 kPa.

**4B.6(b)** The vapour pressure of a substance at 20.0 °C is 58.0 kPa and its enthalpy of vaporization is 32.7 kJ mol<sup>-1</sup>. Estimate the temperature at which its vapour pressure is 66.0 kPa.

**4B.7(a)** The vapour pressure of a liquid in the temperature range 200 K to 260 K was found to fit the expression  $\ln(p/\text{Torr}) = 16.255 - 2501.8/(T/\text{K})$ . What is the enthalpy of vaporization of the liquid?

**4B.7(b)** The vapour pressure of a liquid in the temperature range 200 K to 260 K was found to fit the expression  $\ln(p/\text{Torr}) = 18.361 - 3036.8/(T/\text{K})$ . What is the enthalpy of vaporization of the liquid?

**4B.8(a)** The vapour pressure of benzene between 10 °C and 30 °C fits the expression  $\log(p/\text{Torr}) = 7.960 - 1780/(T/\text{K})$ . Calculate (i) the enthalpy of vaporization and (ii) the normal boiling point of benzene.

**4B.8(b)** The vapour pressure of a liquid between 15 °C and 35 °C fits the expression  $\log(p/\text{Torr}) = 8.750 - 1625/(T/\text{K})$ . Calculate (i) the enthalpy of vaporization and (ii) the normal boiling point of the liquid.

## Problems

**4B.1** The temperature dependence of the vapour pressure of solid sulfur dioxide can be approximately represented by the relation  $\log(p/\text{Torr}) = 10.5916 - 1871.2/(T/\text{K})$  and that of liquid sulfur dioxide by  $\log(p/\text{Torr}) = 8.3186 - 1425.7/(T/\text{K})$ . Estimate the temperature and pressure of the triple point of sulfur dioxide.

**4B.2** Prior to the discovery that freon-12 (CF<sub>2</sub>Cl<sub>2</sub>) was harmful to the Earth's ozone layer, it was frequently used as the dispersing agent in spray cans for hair spray, etc. Its enthalpy of vaporization at its normal boiling point of -29.2 °C is 20.25 kJ mol<sup>-1</sup>. Estimate the pressure that a can of hair spray using freon-12 had to withstand at 40 °C, the temperature of a can that has been standing in sunlight. Assume that  $\Delta_{\text{vap}}H$  is a constant over the temperature range involved and equal to its value at -29.2 °C.

**4B.3** The enthalpy of vaporization of a certain liquid is found to be 14.4 kJ mol<sup>-1</sup> at 180 K, its normal boiling point. The molar volumes of the liquid and the vapour at the boiling point are 115 cm<sup>3</sup> mol<sup>-1</sup> and 14.5 dm<sup>3</sup> mol<sup>-1</sup>, respectively. (a) Estimate  $dp/dT$  from the Clapeyron equation and (b) the percentage error in its value if the Clausius–Clapeyron equation is used instead.

**4B.4** Calculate the difference in slope of the chemical potential against temperature on either side of (a) the normal freezing point of water and (b) the

**4B.9(a)** When benzene freezes at 5.5 °C its density changes from 0.879 g cm<sup>-3</sup> to 0.891 g cm<sup>-3</sup>. Its enthalpy of fusion is 10.59 kJ mol<sup>-1</sup>. Estimate the freezing point of benzene at 1000 atm.

**4B.9(b)** When a certain liquid freezes at -3.65 °C its density changes from 0.789 g cm<sup>-3</sup> to 0.801 g cm<sup>-3</sup>. Its enthalpy of fusion is 8.68 kJ mol<sup>-1</sup>. Estimate the freezing point of the liquid at 100 MPa.

**4B.10(a)** In July in Los Angeles, the incident sunlight at ground level has a power density of 1.2 kW m<sup>-2</sup> at noon. A swimming pool of area 50 m<sup>2</sup> is directly exposed to the sun. What is the maximum rate of loss of water? Assume that all the radiant energy is absorbed.

**4B.10(b)** Suppose the incident sunlight at ground level has a power density of 0.87 kW m<sup>-2</sup> at noon. What is the maximum rate of loss of water from a lake of area 1.0 ha? (1 ha = 10<sup>4</sup> m<sup>2</sup>.) Assume that all the radiant energy is absorbed.

**4B.11(a)** An open vessel containing (i) water, (ii) benzene, (iii) mercury stands in a laboratory measuring 5.0 m × 5.0 m × 3.0 m at 25 °C. What mass of each substance will be found in the air if there is no ventilation? (The vapour pressures are (i) 3.2 kPa, (ii) 13.1 kPa, (iii) 0.23 Pa.)

**4B.11(b)** On a cold, dry morning after a frost, the temperature was -5 °C and the partial pressure of water in the atmosphere fell to 0.30 kPa. Will the frost sublime? What partial pressure of water would ensure that the frost remained?

**4B.12(a)** Naphthalene, C<sub>10</sub>H<sub>8</sub>, melts at 80.2 °C. If the vapour pressure of the liquid is 1.3 kPa at 85.8 °C and 5.3 kPa at 119.3 °C, use the Clausius–Clapeyron equation to calculate (i) the enthalpy of vaporization, (ii) the normal boiling point, and (iii) the enthalpy of vaporization at the boiling point.

**4B.12(b)** The normal boiling point of hexane is 69.0 °C. Estimate (i) its enthalpy of vaporization and (ii) its vapour pressure at 25 °C and 60 °C.

**4B.13(a)** Calculate the melting point of ice under a pressure of 50 bar. Assume that the density of ice under these conditions is approximately 0.92 g cm<sup>-3</sup> and that of liquid water is 1.00 g cm<sup>-3</sup>.

**4B.13(b)** Calculate the melting point of ice under a pressure of 10 MPa. Assume that the density of ice under these conditions is approximately 0.915 g cm<sup>-3</sup> and that of liquid water is 0.998 g cm<sup>-3</sup>.

**4B.14(a)** What fraction of the enthalpy of vaporization of water is spent on expanding the water vapour?

**4B.14(b)** What fraction of the enthalpy of vaporization of ethanol is spent on expanding its vapour?

normal boiling point of water. (c) By how much does the chemical potential of water supercooled to -5.0 °C exceed that of ice at that temperature?

**4B.5** Calculate the difference in slope of the chemical potential against pressure on either side of (a) the normal freezing point of water and (b) the normal boiling point of water. The densities of ice and water at 0 °C are 0.917 g cm<sup>-3</sup> and 1.000 g cm<sup>-3</sup>, and those of water and water vapour at 100 °C are 0.958 g cm<sup>-3</sup> and 0.598 g dm<sup>-3</sup>, respectively. By how much does the chemical potential of water vapour exceed that of liquid water at 1.2 atm and 100 °C?

**4B.6** The enthalpy of fusion of mercury is 2.292 kJ mol<sup>-1</sup>, and its normal freezing point is 234.3 K with a change in molar volume of +0.517 cm<sup>3</sup> mol<sup>-1</sup> on melting. At what temperature will the bottom of a column of mercury (density 13.6 g cm<sup>-3</sup>) of height 10.0 m be expected to freeze?

**4B.7** 50.0 dm<sup>3</sup> of dry air was slowly bubbled through a thermally insulated beaker containing 250 g of water initially at 25 °C. Calculate the final temperature. (The vapour pressure of water is approximately constant at 3.17 kPa throughout, and its heat capacity is 75.5 J K<sup>-1</sup> mol<sup>-1</sup>. Assume that the air is not heated or cooled and that water vapour is a perfect gas.)

**4B.8** The vapour pressure,  $p$ , of nitric acid varies with temperature as follows:

$\theta/^\circ\text{C}$	0	20	40	50	70	80	90	100
$p/\text{kPa}$	1.92	6.38	17.7	27.7	62.3	89.3	124.9	170.9

What are (a) the normal boiling point and (b) the enthalpy of vaporization of nitric acid?

**4B.9** The vapour pressure of the ketone carvone ( $M = 150.2 \text{ g mol}^{-1}$ ), a component of oil of spearmint, is as follows:

$\theta/^\circ\text{C}$	57.4	100.4	133.0	157.3	203.5	227.5
$p/\text{Torr}$	1.00	10.0	40.0	100	400	760

What are (a) the normal boiling point and (b) the enthalpy of vaporization of carvone?

**4B.10\*** In a study of the vapour pressure of chloromethane, A. Bah and N. Dupont-Pavlovsky (*J. Chem. Eng. Data* **40**, 869 (1995)) presented data for the vapour pressure over solid chloromethane at low temperatures. Some of that data is as follows:

$T/\text{K}$	145.94	147.96	149.93	151.94	153.97	154.94
$p/\text{Pa}$	13.07	18.49	25.99	36.76	50.86	59.56

Estimate the standard enthalpy of sublimation of chloromethane at 150 K. (Take the molar volume of the vapour to be that of a perfect gas, and that of the solid to be negligible.)

**4B.11** Show that, for a transition between two incompressible solid phases,  $\Delta G$  is independent of the pressure.

**4B.12** The change in enthalpy is given by  $dH = C_p dT + V dp$ . The Clapeyron equation relates  $dp$  and  $dT$  at equilibrium, and so in combination the two equations can be used to find how the enthalpy changes along a phase boundary as the temperature changes and the two phases remain in equilibrium. Show that  $d(\Delta H/T) = \Delta C_p d \ln T$ .

**4B.13** In the 'gas saturation method' for the measurement of vapour pressure, a volume  $V$  of gas (as measured at a temperature  $T$  and a pressure  $p$ ) is bubbled slowly through the liquid that is maintained at the temperature  $T$ , and a mass loss  $m$  is measured. Show that the vapour pressure,  $p$ , of the liquid is related to its molar mass,  $M$ , by  $p = AmP/(1 + Am)$ , where  $A = RT/MPV$ . The vapour pressure of geraniol ( $M = 154.2 \text{ g mol}^{-1}$ ), which is a component of oil of roses, was measured at  $110^\circ\text{C}$ . It was found that, when  $5.00 \text{ dm}^3$  of nitrogen at 760

Torr was passed slowly through the heated liquid, the loss of mass was 0.32 g. Calculate the vapour pressure of geraniol.

**4B.14** The vapour pressure of a liquid in a gravitational field varies with the depth below the surface on account of the hydrostatic pressure exerted by the overlying liquid. Adapt eqn. 4B.3 to predict how the vapour pressure of a liquid of molar mass  $M$  varies with depth. Estimate the effect on the vapour pressure of water at  $25^\circ\text{C}$  in a column 10 m high.

**4B.15** Combine the 'barometric formula',  $p = p_0 e^{-\alpha H}$ , where  $H = 8 \text{ km}$ , for the dependence of the pressure on altitude,  $a$ , with the Clausius–Clapeyron equation, and predict how the boiling temperature of a liquid depends on the altitude and the ambient temperature. Take the mean ambient temperature as  $20^\circ\text{C}$  and predict the boiling temperature of water at 3000 m.

**4B.16** Figure 4B.1 gives a schematic representation of how the chemical potentials of the solid, liquid, and gaseous phases of a substance vary with temperature. All have a negative slope, but it is unlikely that they are truly straight lines as indicated in the illustration. Derive an expression for the curvatures (specifically, the second derivatives with respect to temperature) of these lines. Is there a restriction on the curvature of these lines? Which state of matter shows the greatest curvature?

**4B.17** The Clapeyron equation does not apply to second-order phase transitions, but there are two analogous equations, the *Ehrenfest equations*, that do. They are:

$$(a) \frac{dp}{dT} = \frac{\alpha_2 - \alpha_1}{\kappa_{T,2} - \kappa_{T,1}} \quad (b) \frac{dp}{dT} = \frac{C_{p,m;2} - C_{p,m;1}}{TV_m(\alpha_2 - \alpha_1)}$$

where  $\alpha$  is the expansion coefficient,  $\kappa_T$  the isothermal compressibility, and the subscripts 1 and 2 refer to two different phases. Derive these two equations. Why does the Clapeyron equation not apply to second-order transitions?

**4B.18** For a first-order phase transition, to which the Clapeyron equation does apply, prove the relation

$$C_S = C_p - \frac{\alpha V \Delta_{\text{trs}} H}{\Delta_{\text{trs}} V}$$

where  $C_S = (\partial q / \partial T)_S$  is the heat capacity along the coexistence curve of two phases.

## Integrated activities

**4.1** Construct the phase diagram for benzene near its triple point at 36 Torr and  $5.50^\circ\text{C}$  using the following data:  $\Delta_{\text{fus}} H = 10.6 \text{ kJ mol}^{-1}$ ,  $\Delta_{\text{vap}} H = 30.8 \text{ kJ mol}^{-1}$ ,  $\rho(\text{s}) = 0.891 \text{ g cm}^{-3}$ ,  $\rho(\text{l}) = 0.879 \text{ g cm}^{-3}$ .

**4.2\*** In an investigation of thermophysical properties of toluene, R.D. Goodwin (*J. Phys. Chem. Ref. Data* **18**, 1565 (1989)) presented expressions for two phase boundaries. The solid–liquid boundary is given by

$$p/\text{bar} = p_3/\text{bar} + 1000(5.60 + 11.727x)x$$

where  $x = T/T_3 - 1$  and the triple point pressure and temperature are  $p_3 = 0.4362 \text{ }\mu\text{bar}$  and  $T_3 = 178.15 \text{ K}$ . The liquid–vapour curve is given by:

$$\ln(p/\text{bar}) = -10.418/y + 21.157 - 15.996y + 14.015y^2 - 5.0120y^3 + 4.7334(1-y)^{1.70}$$

where  $y = T/T_c = T/(593.95 \text{ K})$ . (a) Plot the solid–liquid and liquid–vapour phase boundaries. (b) Estimate the standard melting point of toluene. (c) Estimate the standard boiling point of toluene. (d) Compute the standard enthalpy of vaporization of toluene, given that the molar volumes of the liquid and vapour at the normal boiling point are  $0.12 \text{ dm}^3 \text{ mol}^{-1}$  and  $30.3 \text{ dm}^3 \text{ mol}^{-1}$ , respectively.

**4.3** Proteins are polymers of amino acids that can exist in ordered structures stabilized by a variety of molecular interactions. However, when certain conditions are changed, the compact structure of a polypeptide chain may collapse into a random coil. This structural change may be regarded as a phase transition occurring at a characteristic transition temperature, the *melting temperature*,  $T_m$ , which increases with the strength and number

\* These problems were supplied by Charles Trapp and Carmen Giunta.

of intermolecular interactions in the chain. A thermodynamic treatment allows predictions to be made of the temperature  $T_m$  for the unfolding of a helical polypeptide held together by hydrogen bonds into a random coil. If a polypeptide has  $N$  amino acids,  $N-4$  hydrogen bonds are formed to form an  $\alpha$ -helix, the most common type of helix in naturally occurring proteins (see Topic 17A). Because the first and last residues in the chain are free to move,  $N-2$  residues form the compact helix and have restricted motion. Based on these ideas, the molar Gibbs energy of unfolding of a polypeptide with  $N \geq 5$  may be written as

$$\Delta_{\text{unfold}}G = (N-4)\Delta_{\text{hb}}H - (N-2)T\Delta_{\text{hb}}S$$

where  $\Delta_{\text{hb}}H$  and  $\Delta_{\text{hb}}S$  are, respectively, the molar enthalpy and entropy of dissociation of hydrogen bonds in the polypeptide. (a) Justify the form of the equation for the Gibbs energy of unfolding. That is, why are the enthalpy and entropy terms written as  $(N-4)\Delta_{\text{hb}}H$  and  $(N-2)\Delta_{\text{hb}}S$ , respectively? (b) Show that  $T_m$  may be written as

$$T_m = \frac{(N-4)\Delta_{\text{hb}}H}{(N-2)\Delta_{\text{hb}}S}$$

(c) Plot  $T_m/(\Delta_{\text{hb}}H_m/\Delta_{\text{hb}}S_m)$  for  $5 \leq N \leq 20$ . At what value of  $N$  does  $T_m$  change by less than 1 per cent when  $N$  increases by 1?

**4.4\*** A substance as well-known as methane still receives research attention because it is an important component of natural gas, a commonly used fossil fuel. Friend et al. have published a review of thermophysical properties of

methane (D.G. Friend, J.F. Ely, and H. Ingham, *J. Phys. Chem. Ref. Data* **18**, 583 (1989)), which included the following data describing the liquid–vapour phase boundary.

$T/\text{K}$	100	108	110	112	114	120	130	140	150	160	170	190
$p/\text{MPa}$	0.034	0.074	0.088	0.104	0.122	0.192	0.368	0.642	1.041	1.593	2.329	4.521

(a) Plot the liquid–vapour phase boundary. (b) Estimate the standard boiling point of methane. (c) Compute the standard enthalpy of vaporization of methane, given that the molar volumes of the liquid and vapour at the standard boiling point are  $3.80 \times 10^{-2}$  and  $8.89 \text{ dm}^3 \text{ mol}^{-1}$ , respectively.

**4.5\*** Diamond is the hardest substance and the best conductor of heat yet characterized. For these reasons, it is used widely in industrial applications that require a strong abrasive. Unfortunately, it is difficult to synthesize diamond from the more readily available allotropes of carbon, such as graphite. To illustrate this point, calculate the pressure required to convert graphite into diamond at 25 °C. The following data apply to 25 °C and 100 kPa. Assume the specific volume,  $V_s$ , and  $\kappa_T$  are constant with respect to pressure changes.

	Graphite	Diamond
$\Delta_f G^\ominus / (\text{kJ mol}^{-1})$	0	+2.8678
$V_s / (\text{cm}^3 \text{ g}^{-1})$	0.444	0.284
$\kappa_T / \text{kPa}$	$3.04 \times 10^{-8}$	$0.187 \times 10^{-8}$

# CHAPTER 5

## Simple mixtures

Mixtures are an essential part of chemistry, either in their own right or as starting materials for chemical reactions. This group of Topics deals with the rich physical properties of mixtures and shows how to express them in terms of thermodynamic quantities.

### 5A The thermodynamic description of mixtures

The first Topic in this chapter develops the concept of chemical potential as an example of a partial molar quantity and explores how to use the chemical potential of a substance to describe the physical properties of mixtures. The underlying principle to keep in mind is that at equilibrium the chemical potential of a species is the same in every phase. We see, by making use of the experimental observations known as Raoult's and Henry's laws, how to express the chemical potential of a substance in terms of its mole fraction in a mixture.

### 5B The properties of solutions

In this Topic, the concept of chemical potential is applied to the discussion of the effect of a solute on certain thermodynamic properties of a solution. These properties include the lowering of vapour pressure of the solvent, the elevation of its boiling point, the depression of its freezing point, and the origin of osmotic pressure. We see that it is possible to construct a model of a certain class of real solutions called 'regular solutions', and see how they have properties that diverge from those of ideal solutions.

### 5C Phase diagrams of binary systems

One widely used device used to summarize the equilibrium properties of mixtures is the phase diagram. We see how to construct and interpret these diagrams. The Topic introduces systems of gradually increasing complexity. In each case we

shall see how the phase diagram for the system summarizes empirical observations on the conditions under which the various phases of the system are stable.

### 5D Phase diagrams of ternary systems

Many modern materials (and ancient ones too) have more than two components. In this Topic we show how phase diagrams are extended to the description of systems of three components and how to interpret triangular phase diagrams.

### 5E Activities

The extension of the concept of chemical potential to real solutions involves introducing an effective concentration called an 'activity'. We see how the activity may be defined and measured. We shall also see how, in certain cases, the activity may be interpreted in terms of intermolecular interactions.

### 5F The activities of ions

One of the most important types of mixtures encountered in chemistry is an electrolyte solution. Such solutions often deviate considerably from ideal behaviour on account of the strong, long-range interactions between ions. In this Topic we show how a model can be used to estimate the deviations from ideal behaviour when the solution is very dilute, and how to extend the resulting expressions to more concentrated solutions.

### What is the impact of this material?

We consider just two applications of this material, one from biology and the other from materials science, from among the

huge number that could be chosen for this centrally important field. In *Impact* I5.1, we see how the phenomenon of osmosis contributes to the ability of biological cells to maintain their shapes. In *Impact* I5.2, we see how phase diagrams are used to describe the properties of the technologically important liquid crystals.

### ► Why do you need to know this material?

Chemistry deals with a wide variety of mixtures, including mixtures of substances that can react together. Therefore, it is important to generalize the concepts introduced in Chapter 4 to deal with substances that are mingled together. This Topic also introduces the fundamental equation of chemical thermodynamics on which many of the applications of thermodynamics to chemistry are based.

### ► What is the key idea?

The chemical potential of a substance in a mixture is a logarithmic function of its concentration.

### ► What do you need to know already?

This Topic extends the concept of chemical potential to substances in mixtures by building on the concept introduced in the context of pure substances (Topic 4A). It makes use of the relation between entropy and the temperature dependence of the Gibbs energy (Topic 3D) and the concept of partial pressure (Topic 1A). It uses the notation of partial derivatives (*Mathematical background 2*) but does not draw on their advanced properties.

As a first step towards dealing with chemical reactions (which are treated in Topic 6A), here we consider mixtures of substances that do not react together. At this stage we deal mainly with **binary mixtures**, which are mixtures of two components, A and B. We shall therefore often be able to simplify equations by making use of the relation  $x_A + x_B = 1$ . In Topic 1A it is established that the partial pressure, which is the contribution of one component to the total pressure, is used to discuss the properties of mixtures of gases. For a more general description of the thermodynamics of mixtures we need to introduce other analogous 'partial' properties.

One preliminary remark is in order. Throughout this and related Topics we need to refer to various measures of concentration of a solute in a solution. The **molar concentration** (colloquially, the 'molarity', [J] or  $c_j$ ) is the amount of solute divided by the volume of the solution and is usually expressed in moles per cubic decimetre ( $\text{mol dm}^{-3}$ ; more informally,  $\text{mol L}^{-1}$ ). We write  $c^\ominus = 1 \text{ mol dm}^{-3}$ . The term **molality**,  $b$ , is the amount of solute divided by the mass of solvent and is usually expressed in moles per kilogram of solvent ( $\text{mol kg}^{-1}$ ). We write  $b^\ominus = 1 \text{ mol kg}^{-1}$ .

## 5A.1 Partial molar quantities

The easiest partial molar property to visualize is the 'partial molar volume', the contribution that a component of a mixture makes to the total volume of a sample.

### (a) Partial molar volume

Imagine a huge volume of pure water at 25 °C. When a further 1 mol H<sub>2</sub>O is added, the volume increases by 18 cm<sup>3</sup> and we can report that 18 cm<sup>3</sup> mol<sup>-1</sup> is the molar volume of pure water. However, when we add 1 mol H<sub>2</sub>O to a huge volume of pure ethanol, the volume increases by only 14 cm<sup>3</sup>. The reason for the different increase in volume is that the volume occupied by a given number of water molecules depends on the identity of the molecules that surround them. In the latter case there is so much ethanol present that each H<sub>2</sub>O molecule is surrounded by ethanol molecules. The network of hydrogen bonds that normally hold H<sub>2</sub>O molecules at certain distances from each other in pure water does not form. The packing of the molecules in the mixture results in the H<sub>2</sub>O molecules increasing the volume by only 14 cm<sup>3</sup>. The quantity 14 cm<sup>3</sup> mol<sup>-1</sup> is the partial molar volume of water in pure ethanol. In general, the **partial molar volume** of a substance A in a mixture is the change in volume per mole of A added to a large volume of the mixture.

The partial molar volumes of the components of a mixture vary with composition because the environment of each type of molecule changes as the composition changes from pure A to pure B. It is this changing molecular environment, and the consequential modification of the forces acting between molecules, that results in the variation of the thermodynamic properties of a mixture as its composition is changed. The partial molar volumes of water and ethanol across the full composition range at 25 °C are shown in Fig. 5A.1.

The partial molar volume,  $V_J$ , of a substance J at some general composition is defined formally as follows:

$$V_J = \left( \frac{\partial V}{\partial n_J} \right)_{p,T,n'} \quad \text{Definition} \quad \text{Partial molar volume} \quad (5A.1)$$

where the subscript  $n'$  signifies that the amounts of all other substances present are constant. The partial molar volume is

**Figure 5A.1** The partial molar volumes of water and ethanol at 25 °C. Note the different scales (water on the left, ethanol on the right).

**Figure 5A.2** The partial molar volume of a substance is the slope of the variation of the total volume of the sample plotted against the composition. In general, partial molar quantities vary with the composition, as shown by the different slopes at the compositions  $a$  and  $b$ . Note that the partial molar volume at  $b$  is negative: the overall volume of the sample decreases as  $A$  is added.

the slope of the plot of the total volume as the amount of  $J$  is changed, the pressure, temperature, and amount of the other components being constant (Fig. 5A.2). Its value depends on the composition, as we saw for water and ethanol.

*A note on good practice* The IUPAC recommendation is to denote a partial molar quantity by  $\bar{X}$ , but only when there is the possibility of confusion with the quantity  $X$ . For instance, to avoid confusion, the partial molar volume of NaCl in water could be written  $\bar{V}(\text{NaCl}, \text{aq})$  to distinguish it from the total volume of the solution,  $V$ .

The definition in eqn 5A.1 implies that when the composition of the mixture is changed by the addition of  $dn_A$  of  $A$  and  $dn_B$  of  $B$ , then the total volume of the mixture changes by

$$dV = \left( \frac{\partial V}{\partial n_A} \right)_{p,T,n_B} dn_A + \left( \frac{\partial V}{\partial n_B} \right)_{p,T,n_A} dn_B \quad (5A.2)$$

$$= V_A dn_A + V_B dn_B$$

Provided the relative composition is held constant as the amounts of  $A$  and  $B$  are increased, the partial molar volumes are both constant. In that case we can obtain the final volume by integration, treating  $V_A$  and  $V_B$  as constants:

$$V = \int_0^{n_A} V_A dn_A + \int_0^{n_B} V_B dn_B = V_A \int_0^{n_A} dn_A + V_B \int_0^{n_B} dn_B \quad (5A.3)$$

$$= V_A n_A + V_B n_B$$

Although we have envisaged the two integrations as being linked (in order to preserve constant relative composition), because  $V$  is a state function the final result in eqn 5A.3 is valid however the solution is in fact prepared.

Partial molar volumes can be measured in several ways. One method is to measure the dependence of the volume on the composition and to fit the observed volume to a function of the amount of the substance. Once the function has been found, its slope can be determined at any composition of interest by differentiation.

### Example 5A.1 Determining a partial molar volume

A polynomial fit to measurements of the total volume of a water/ethanol mixture at 25 °C that contains 1.000 kg of water is

$$v = 1002.93 + 54.6664x - 0.36394x^2 + 0.028256x^3$$

where  $v = V/\text{cm}^3$ ,  $x = n_{\text{E}}/\text{mol}$ , and  $n_{\text{E}}$  is the amount of  $\text{CH}_3\text{CH}_2\text{OH}$  present. Determine the partial molar volume of ethanol.

**Method** Apply the definition in eqn 5A.1 taking care to convert the derivative with respect to  $n$  to a derivative with respect to  $x$  and keeping the units intact.

**Answer** The partial molar volume of ethanol,  $V_{\text{E}}$ , is

$$\begin{aligned} V_{\text{E}} &= \left( \frac{\partial V}{\partial n_{\text{E}}} \right)_{p,T,n_{\text{W}}} = \left( \frac{\partial (V/\text{cm}^3)}{\partial (n_{\text{E}}/\text{mol})} \right)_{p,T,n_{\text{W}}} \frac{\text{cm}^3}{\text{mol}} \\ &= \left( \frac{\partial v}{\partial x} \right)_{p,T,n_{\text{W}}} \text{cm}^3 \text{mol}^{-1} \end{aligned}$$

Then, because

$$\frac{dv}{dx} = 54.6664 - 2(0.36394)x + 3(0.028256)x^2$$

we can conclude that

$$V_{\text{E}} / (\text{cm}^3 \text{mol}^{-1}) = 54.6664 - 0.72788x + 0.084768x^2$$

Figure 5A.3 shows a graph of this function.

Figure 5A.3 The partial molar volume of ethanol, as expressed by the polynomial in Example 5A.1.

**Self-test 5A.1** At 25 °C, the density of a 50 per cent by mass ethanol/water solution is  $0.914 \text{ g cm}^{-3}$ . Given that the partial molar volume of water in the solution is  $17.4 \text{ cm}^3 \text{ mol}^{-1}$ , what is the partial molar volume of the ethanol?

Answer:  $56.4 \text{ cm}^3 \text{ mol}^{-1}$ ;  $54.6 \text{ cm}^3 \text{ mol}^{-1}$  by the formula above

Molar volumes are always positive, but partial molar quantities need not be. For example, the limiting partial molar volume of  $\text{MgSO}_4$  in water (its partial molar volume in the limit of zero concentration) is  $-1.4 \text{ cm}^3 \text{ mol}^{-1}$ , which means that the addition of 1 mol  $\text{MgSO}_4$  to a large volume of water results in a decrease in volume of  $1.4 \text{ cm}^3$ . The mixture contracts because the salt breaks up the open structure of water as the  $\text{Mg}^{2+}$  and  $\text{SO}_4^{2-}$  ions become hydrated, and it collapses slightly.

### (b) Partial molar Gibbs energies

The concept of a partial molar quantity can be extended to any extensive state function. For a substance in a mixture, the chemical potential is *defined* as the partial molar Gibbs energy:

$$\mu_{\text{J}} = \left( \frac{\partial G}{\partial n_{\text{J}}} \right)_{p,T,n'} \quad \text{Definition} \quad \text{Chemical potential} \quad (5A.4)$$

That is, the chemical potential is the slope of a plot of Gibbs energy against the amount of the component J, with the pressure and temperature (and the amounts of the other substances) held constant (Fig. 5A.4). For a pure substance we can write  $G = n_{\text{J}}G_{\text{J,m}}$ , and from eqn 5A.4 obtain  $\mu_{\text{J}} = G_{\text{J,m}}$ : in this case, the chemical potential is simply the molar Gibbs energy of the substance, as is used in Topic 4B.

Figure 5A.4 The chemical potential of a substance is the slope of the total Gibbs energy of a mixture with respect to the amount of substance of interest. In general, the chemical potential varies with composition, as shown for the two values at  $a$  and  $b$ . In this case, both chemical potentials are positive.

By the same argument that led to eqn 5A.2, it follows that the total Gibbs energy of a binary mixture is

$$G = n_A \mu_A + n_B \mu_B \quad (5A.5)$$

where  $\mu_A$  and  $\mu_B$  are the chemical potentials at the composition of the mixture. That is, the chemical potential of a substance in a mixture is the contribution of that substance to the total Gibbs energy of the mixture. Because the chemical potentials depend on composition (and the pressure and temperature), the Gibbs energy of a mixture may change when these variables change, and for a system of components A, B, etc., the equation  $dG = Vdp - SdT$  becomes

$$dG = Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots \quad (5A.6)$$

Fundamental equation of chemical thermodynamics

This expression is the **fundamental equation of chemical thermodynamics**. Its implications and consequences are explored and developed in this and the next two chapters.

At constant pressure and temperature, eqn 5A.6 simplifies to

$$dG = \mu_A dn_A + \mu_B dn_B + \dots \quad (5A.7)$$

We saw in Topic 3C that under the same conditions  $dG = dw_{\text{add,max}}$ . Therefore, at constant temperature and pressure,

$$dw_{\text{add,max}} = \mu_A dn_A + \mu_B dn_B + \dots \quad (5A.8)$$

That is, additional (non-expansion) work can arise from the changing composition of a system. For instance, in an electrochemical cell, the chemical reaction is arranged to take place in two distinct sites (at the two electrodes). The electrical work the cell performs can be traced to its changing composition as products are formed from reactants.

### (c) The wider significance of the chemical potential

The chemical potential does more than show how  $G$  varies with composition. Because  $G = U + pV - TS$ , and therefore  $U = -pV + TS + G$ , we can write a general infinitesimal change in  $U$  for a system of variable composition as

$$\begin{aligned} dU &= -pdV - Vdp + SdT + TdS + dG \\ &= -pdV - Vdp + SdT + TdS + \\ &\quad (Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots) \\ &= -pdV + TdS + \mu_A dn_A + \mu_B dn_B + \dots \end{aligned}$$

This expression is the generalization of eqn 3D.1 (that  $dU = TdS - pdV$ ) to systems in which the composition may change. It follows that at constant volume and entropy,

$$dU = \mu_A dn_A + \mu_B dn_B + \dots \quad (5A.9)$$

and hence that

$$\mu_j = \left( \frac{\partial U}{\partial n_j} \right)_{S,V,n'} \quad (5A.10)$$

Therefore, not only does the chemical potential show how  $G$  changes when the composition changes, it also shows how the internal energy changes too (but under a different set of conditions). In the same way it is possible to deduce that

$$(a) \mu_j = \left( \frac{\partial H}{\partial n_j} \right)_{S,p,n'} \quad (b) \mu_j = \left( \frac{\partial A}{\partial n_j} \right)_{T,V,n'} \quad (5A.11)$$

Thus we see that the  $\mu_j$  shows how all the extensive thermodynamic properties  $U$ ,  $H$ ,  $A$ , and  $G$  depend on the composition. This is why the chemical potential is so central to chemistry.

### (d) The Gibbs–Duhem equation

Because the total Gibbs energy of a binary mixture is given by eqn 5A.5 and the chemical potentials depend on the composition, when the compositions are changed infinitesimally we might expect  $G$  of a binary system to change by

$$dG = \mu_A dn_A + \mu_B dn_B + n_A d\mu_A + n_B d\mu_B$$

However, we have seen that at constant pressure and temperature a change in Gibbs energy is given by eqn 5A.7. Because  $G$  is a state function, these two equations must be equal, which implies that at constant temperature and pressure

$$n_A d\mu_A + n_B d\mu_B = 0 \quad (5A.12a)$$

This equation is a special case of the **Gibbs–Duhem equation**:

$$\sum_j n_j d\mu_j = 0 \quad \text{Gibbs–Duhem equation} \quad (5A.12b)$$

The significance of the Gibbs–Duhem equation is that the chemical potential of one component of a mixture cannot change independently of the chemical potentials of the other components. In a binary mixture, if one partial molar quantity increases, then the other must decrease, with the two changes related by

$$d\mu_B = -\frac{n_A}{n_B} d\mu_A \quad (5A.13)$$

**Brief illustration 5A.1** The Gibbs–Duhem equation

If the composition of a mixture is such that  $n_A = 2n_B$ , and a small change in composition results in  $\mu_A$  changing by  $\delta\mu_A = +1 \text{ J mol}^{-1}$ ,  $\mu_B$  will change by

$$\delta\mu_B = -2 \times (1 \text{ J mol}^{-1}) = -2 \text{ J mol}^{-1}$$

**Self-test 5A.2** Suppose that  $n_A = 0.3n_B$  and a small change in composition results in  $\mu_A$  changing by  $\delta\mu_A = -10 \text{ J mol}^{-1}$ , by how much will  $\mu_B$  change?

Answer:  $+3 \text{ J mol}^{-1}$

The same line of reasoning applies to all partial molar quantities. We can see in Fig. 5A.1, for example, that where the partial molar volume of water increases, that of ethanol decreases. Moreover, as eqn 5A.13 shows, and as we can see from Fig 5A.1, a small change in the partial molar volume of A corresponds to a large change in the partial molar volume of B if  $n_A/n_B$  is large, but the opposite is true when this ratio is small. In practice, the Gibbs–Duhem equation is used to determine the partial molar volume of one component of a binary mixture from measurements of the partial molar volume of the second component.

**Example 5A.2** Using the Gibbs–Duhem equation

The experimental values of the partial molar volume of  $\text{K}_2\text{SO}_4(\text{aq})$  at 298 K are found to fit the expression

$$v_B = 32.280 + 18.216x^{1/2}$$

where  $v_B = V_{\text{K}_2\text{SO}_4}/(\text{cm}^3 \text{ mol}^{-1})$  and  $x$  is the numerical value of the molality of  $\text{K}_2\text{SO}_4$  ( $x = b/b^\ominus$ ; see the remark in the introduction to this chapter). Use the Gibbs–Duhem equation to derive an equation for the molar volume of water in the solution. The molar volume of pure water at 298 K is  $18.079 \text{ cm}^3 \text{ mol}^{-1}$ .

**Method** Let A denote  $\text{H}_2\text{O}$ , the solvent, and B denote  $\text{K}_2\text{SO}_4$ , the solute. The Gibbs–Duhem equation for the partial molar volumes of two components is  $n_A dV_A + n_B dV_B = 0$ . This relation implies that  $dv_A = -(n_B/n_A)dv_B$ , and therefore that  $v_A$  can be found by integration:

$$v_A = v_A^* - \int_0^{v_B} \frac{n_B}{n_A} dv_B$$

where  $v_A^* = V_A/(\text{cm}^3 \text{ mol}^{-1})$  is the numerical value of the molar volume of pure A. The first step is to change the variable  $v_B$  to  $x = b/b^\ominus$  and then to integrate the right-hand side between  $x=0$  (pure B) and the molality of interest.

**Answer** It follows from the information in the question that, with  $B = \text{K}_2\text{SO}_4$ ,  $dv_B/dx = 9.108x^{-1/2}$ . Therefore, the integration required is

$$v_A = v_A^* - 9.108 \int_0^{b/b^\ominus} \frac{n_B}{n_A} x^{-1/2} dx$$

However, the ratio of amounts of A ( $\text{H}_2\text{O}$ ) and B ( $\text{K}_2\text{SO}_4$ ) is related to the molality of B,  $b = n_B/(1 \text{ kg water})$  and  $n_A = (1 \text{ kg water})/M_A$  where  $M_A$  is the molar mass of water, by

$$\frac{n_B}{n_A} = \frac{n_B}{(1 \text{ kg})/M_A} = \frac{n_B M_A}{1 \text{ kg}} = b M_A = x b^\ominus M_A$$

and hence

$$\begin{aligned} v_A &= v_A^* - 9.108 M_A b^\ominus \int_0^{b/b^\ominus} x^{1/2} dx \\ &= v_A^* - \frac{2}{3} (9.108 M_A b^\ominus) (b/b^\ominus)^{3/2} \end{aligned}$$

It then follows, by substituting the data (including  $M_A = 1.802 \times 10^{-2} \text{ kg mol}^{-1}$ , the molar mass of water), that

$$V_A/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.1094(b/b^\ominus)^{3/2}$$

The partial molar volumes are plotted in Fig. 5A.5.

**Figure 5A.5** The partial molar volumes of the components of an aqueous solution of potassium sulfate.

**Self-test 5A.3** Repeat the calculation for a salt B for which  $V_B/(\text{cm}^3 \text{ mol}^{-1}) = 6.218 + 5.146b - 7.147b^2$ .

Answer:  $V_A/(\text{cm}^3 \text{ mol}^{-1}) = 18.079 - 0.0464b^2 + 0.0859b^3$

## 5A.2 The thermodynamics of mixing

The dependence of the Gibbs energy of a mixture on its composition is given by eqn 5A.5, and we know that at constant temperature and pressure systems tend towards lower Gibbs energy. This is the link we need in order to apply thermodynamics to the discussion of spontaneous changes of composition, as in the mixing of two substances. One simple example of a spontaneous mixing process is that of two gases introduced into the same container. The mixing is spontaneous, so it must

correspond to a decrease in  $G$ . We shall now see how to express this idea quantitatively.

### (a) The Gibbs energy of mixing of perfect gases

Let the amounts of two perfect gases in the two containers be  $n_A$  and  $n_B$ ; both are at a temperature  $T$  and a pressure  $p$  (Fig. 5A.6). At this stage, the chemical potentials of the two gases have their 'pure' values, which are obtained by applying the definition  $\mu = G_m$  to eqn 3D.15 ( $G_m(p) = G_m^\ominus + RT \ln(p/p^\ominus)$ ):

$$\mu = \mu^\ominus + RT \ln \frac{p}{p^\ominus}$$

Perfect gas Variation of chemical potential with pressure (5A.14a)

where  $\mu^\ominus$  is the **standard chemical potential**, the chemical potential of the pure gas at 1 bar. It will be much simpler notationally if we agree to let  $p$  denote the pressure relative to  $p^\ominus$ ; that is, to replace  $p/p^\ominus$  by  $p$ , for then we can write

$$\mu = \mu^\ominus + RT \ln p \quad (5A.14b)$$

To use the equations, we have to remember to replace  $p$  by  $p/p^\ominus$  again. In practice, that simply means using the numerical value of  $p$  in bars. The Gibbs energy of the total system is then given by eqn 5A.5 as

$$G_i = n_A \mu_A + n_B \mu_B = n_A (\mu_A^\ominus + RT \ln p) + n_B (\mu_B^\ominus + RT \ln p) \quad (5A.15a)$$

After mixing, the partial pressures of the gases are  $p_A$  and  $p_B$ , with  $p_A + p_B = p$ . The total Gibbs energy changes to

$$G_f = n_A (\mu_A^\ominus + RT \ln p_A) + n_B (\mu_B^\ominus + RT \ln p_B) \quad (5A.15b)$$

The difference  $G_f - G_i$ , the **Gibbs energy of mixing**,  $\Delta_{\text{mix}}G$ , is therefore

Figure 5A.6 The arrangement for calculating the thermodynamic functions of mixing of two perfect gases.

$$\Delta_{\text{mix}}G = n_A RT \ln \frac{p_A}{p} + n_B RT \ln \frac{p_B}{p} \quad (5A.15c)$$

At this point we may replace  $n_j$  by  $x_j n$ , where  $n$  is the total amount of A and B, and use the relation between partial pressure and mole fraction (Topic 1A,  $p_j = x_j p$ ) to write  $p_j/p = x_j$  for each component, which gives

$$\Delta_{\text{mix}}G = nRT(x_A \ln x_A + x_B \ln x_B)$$

Perfect gases Gibbs energy of mixing (5A.16)

Because mole fractions are never greater than 1, the logarithms in this equation are negative, and  $\Delta_{\text{mix}}G < 0$  (Fig. 5A.7). The conclusion that  $\Delta_{\text{mix}}G$  is negative for all compositions confirms that perfect gases mix spontaneously in all proportions. However, the equation extends common sense by allowing us to discuss the process quantitatively.

Figure 5A.7 The Gibbs energy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The Gibbs energy of mixing is negative for all compositions and temperatures, so perfect gases mix spontaneously in all proportions.

#### Example 5A.3 Calculating a Gibbs energy of mixing

A container is divided into two equal compartments (Fig. 5A.8). One contains 3.0 mol  $\text{H}_2(\text{g})$  at  $25^\circ\text{C}$ ; the other contains 1.0 mol  $\text{N}_2(\text{g})$  at  $25^\circ\text{C}$ . Calculate the Gibbs energy of mixing when the partition is removed. Assume perfect behaviour.

**Method** Equation 5A.16 cannot be used directly because the two gases are initially at different pressures. We proceed by calculating the initial Gibbs energy from the chemical potentials. To do so, we need the pressure of each gas. Write the pressure of nitrogen as  $p$ ; then the pressure of hydrogen as a multiple of  $p$  can be found from the gas laws. Next, calculate the Gibbs energy for the system when the partition is removed. The volume occupied by each gas doubles, so its initial partial pressure is halved.

**Figure 5A.8** The initial and final states considered in the calculation of the Gibbs energy of mixing of gases at different initial pressures.

**Answer** Given that the pressure of nitrogen is  $p$ , the pressure of hydrogen is  $3p$ ; therefore, the initial Gibbs energy is

$$G_i = (3.0 \text{ mol})\{\mu^\ominus(\text{H}_2) + RT \ln 3p\} + (1.0 \text{ mol})\{\mu^\ominus(\text{N}_2) + RT \ln p\}$$

When the partition is removed and each gas occupies twice the original volume, the partial pressure of nitrogen falls to  $\frac{1}{2}p$  and that of hydrogen falls to  $\frac{3}{2}p$ . Therefore, the Gibbs energy changes to

$$G_f = (3.0 \text{ mol})\{\mu^\ominus(\text{H}_2) + RT \ln \frac{3}{2}p\} + (1.0 \text{ mol})\{\mu^\ominus(\text{N}_2) + RT \ln \frac{1}{2}p\}$$

The Gibbs energy of mixing is the difference of these two quantities:

$$\begin{aligned} \Delta_{\text{mix}}G &= (3.0 \text{ mol})RT \ln \frac{\frac{3}{2}p}{3p} + (1.0 \text{ mol})RT \ln \frac{\frac{1}{2}p}{p} \\ &= -(3.0 \text{ mol})RT \ln 2 - (1.0 \text{ mol})RT \ln 2 \\ &= -(4.0 \text{ mol})RT \ln 2 = -6.9 \text{ kJ} \end{aligned}$$

In this example, the value of  $\Delta_{\text{mix}}G$  is the sum of two contributions: the mixing itself, and the changes in pressure of the two gases to their final total pressure,  $2p$ . When 3.0 mol  $\text{H}_2$  mixes with 1.0 mol  $\text{N}_2$  at the same pressure, with the volumes of the vessels adjusted accordingly, the change of Gibbs energy is  $-5.6 \text{ kJ}$ . However, do not be misled into interpreting this negative change in Gibbs energy as a sign of spontaneity: in this case, the pressure changes, and  $\Delta G < 0$  is a signpost of spontaneous change only at constant temperature and pressure.

**Self-test 5A.4** Suppose that 2.0 mol  $\text{H}_2$  at 2.0 atm and  $25^\circ\text{C}$  and 4.0 mol  $\text{N}_2$  at 3.0 atm and  $25^\circ\text{C}$  are mixed by removing the partition between them. Calculate  $\Delta_{\text{mix}}G$ .

Answer:  $-9.7 \text{ kJ}$

## (b) Other thermodynamic mixing functions

In Topic 3D it is shown that  $(\partial G/\partial T)_{p,n} = -S$ . It follows immediately from eqn 5A.16 that, for a mixture of perfect gases initially at the same pressure, the entropy of mixing,  $\Delta_{\text{mix}}S$ , is

$$\Delta_{\text{mix}}S = -\left(\frac{\partial \Delta_{\text{mix}}G}{\partial T}\right)_{p,n_A,n_B} = -nR(x_A \ln x_A + x_B \ln x_B)$$

Perfect gases    Entropy of mixing    (5A.17)

Because  $\ln x < 0$ , it follows that  $\Delta_{\text{mix}}S > 0$  for all compositions (Fig. 5A.9).

**Figure 5A.9** The entropy of mixing of two perfect gases and (as discussed later) of two liquids that form an ideal solution. The entropy increases for all compositions and temperatures, so perfect gases mix spontaneously in all proportions. Because there is no transfer of heat to the surroundings when perfect gases mix, the entropy of the surroundings is unchanged. Hence, the graph also shows the total entropy of the system plus the surroundings when perfect gases mix.

### Brief illustration 5A.2 The entropy of mixing

For equal amounts of perfect gas molecules that are mixed at the same pressure we set  $x_A = x_B = \frac{1}{2}$  and obtain

$$\Delta_{\text{mix}}S = -nR\left\{\frac{1}{2} \ln \frac{1}{2} + \frac{1}{2} \ln \frac{1}{2}\right\} = nR \ln 2$$

with  $n$  the total amount of gas molecules. For 1 mol of each species, so  $n = 2 \text{ mol}$ ,

$$\Delta_{\text{mix}}S = (2 \text{ mol}) \times R \ln 2 = +11.5 \text{ J mol}^{-1}$$

An increase in entropy is what we expect when one gas disperses into the other and the disorder increases.

**Self-test 5A.5** Calculate the change in entropy for the arrangement in *Example 5A.3*.

Answer:  $+23 \text{ J mol}^{-1}$

We can calculate the isothermal, isobaric (constant pressure) **enthalpy of mixing**,  $\Delta_{\text{mix}}H$ , the enthalpy change accompanying mixing, of two perfect gases from  $\Delta G = \Delta H - T\Delta S$ . It follows from eqns 5A.16 and 5A.17 that

$$\Delta_{\text{mix}}H = 0 \quad \text{Perfect gases} \quad \text{Enthalpy of mixing} \quad (5A.18)$$

The enthalpy of mixing is zero, as we should expect for a system in which there are no interactions between the molecules forming the gaseous mixture. It follows that the whole of the driving force for mixing comes from the increase in entropy of the system because the entropy of the surroundings is unchanged.

### 5A.3 The chemical potentials of liquids

To discuss the equilibrium properties of liquid mixtures we need to know how the Gibbs energy of a liquid varies with composition. To calculate its value, we use the fact that, as established in Topic 4A, at equilibrium the chemical potential of a substance present as a vapour must be equal to its chemical potential in the liquid.

#### (a) Ideal solutions

We shall denote quantities relating to pure substances by a superscript  $*$ , so the chemical potential of pure A is written  $\mu_A^*$  and as  $\mu_A^*(\text{l})$  when we need to emphasize that A is a liquid. Because the vapour pressure of the pure liquid is  $p_A^*$  it follows from eqn 5A.14 that the chemical potential of A in the vapour (treated as a perfect gas) is  $\mu_A^\ominus = +RT \ln p_A$  (with  $p_A$  to be interpreted as the relative pressure,  $p_A/p^\ominus$ ). These two chemical potentials are equal at equilibrium (Fig. 5A.10), so we can write

$$\mu_A^* = \mu_A^\ominus + RT \ln p_A^* \quad (5A.19a)$$

If another substance, a solute, is also present in the liquid, the chemical potential of A in the liquid is changed to  $\mu_A$  and its vapour pressure is changed to  $p_A$ . The vapour and solvent are still in equilibrium, so we can write

$$\mu_A = \mu_A^\ominus + RT \ln p_A \quad (5A.19b)$$

Next, we combine these two equations to eliminate the standard chemical potential of the gas. To do so, we write eqn 5A.19a as  $\mu_A^\ominus = \mu_A^* - RT \ln p_A^*$  and substitute this expression into eqn 5A.19b to obtain

**Figure 5A.10** At equilibrium, the chemical potential of the gaseous form of a substance A is equal to the chemical potential of its condensed phase. The equality is preserved if a solute is also present. Because the chemical potential of A in the vapour depends on its partial vapour pressure, it follows that the chemical potential of liquid A can be related to its partial vapour pressure.

$$\mu_A = \mu_A^* - RT \ln p_A^* + RT \ln p_A = \mu_A^* + RT \ln \frac{p_A}{p_A^*} \quad (5A.20)$$

In the final step we draw on additional experimental information about the relation between the ratio of vapour pressures and the composition of the liquid. In a series of experiments on mixtures of closely related liquids (such as benzene and methylbenzene), the French chemist François Raoult found that the ratio of the partial vapour pressure of each component to its vapour pressure as a pure liquid,  $p_A/p_A^*$ , is approximately equal to the mole fraction of A in the liquid mixture. That is, he established what we now call **Raoult's law**:

$$p_A = x_A p_A^* \quad \text{Ideal solution} \quad \text{Raoult's law} \quad (5A.21)$$

This law is illustrated in Fig. 5A.11. Some mixtures obey Raoult's law very well, especially when the components are

**Figure 5A.11** The total vapour pressure and the two partial vapour pressures of an ideal binary mixture are proportional to the mole fractions of the components.

**Figure 5A.12** Two similar liquids, in this case benzene and methylbenzene (toluene), behave almost ideally, and the variation of their vapour pressures with composition resembles that for an ideal solution.

structurally similar (Fig. 5A.12). Mixtures that obey the law throughout the composition range from pure A to pure B are called **ideal solutions**.

#### Brief illustration 5A.3 Raoult's law

The vapour pressure of benzene at 20 °C is 75 Torr and that of methylbenzene is 21 Torr at the same temperature. In an equimolar mixture,  $x_{\text{benzene}} = x_{\text{methylbenzene}} = \frac{1}{2}$  so the vapour pressure of each one in the mixture is

$$p_{\text{benzene}} = \frac{1}{2} \times 75 \text{ Torr} = 38 \text{ Torr}$$

$$p_{\text{methylbenzene}} = \frac{1}{2} \times 21 \text{ Torr} = 11 \text{ Torr}$$

The total vapour pressure of the mixture is 49 Torr. Given the two partial vapour pressures, it follows from the definition of partial pressure (Topic 1A) that the mole fractions in the vapour are  $x_{\text{vap,benzene}} = (38 \text{ Torr})/(49 \text{ Torr}) = 0.78$  and  $x_{\text{vap,methylbenzene}} = (11 \text{ Torr})/(49 \text{ Torr}) = 0.22$ . The vapour is richer in the more volatile component (benzene).

**Self-test 5A.6** At 90 °C the vapour pressure of 1,2-dimethylbenzene is 20 kPa and that of 1,3-dimethylbenzene is 18 kPa. What is the composition of the vapour when the liquid mixture has the composition  $x_{12} = 0.33$  and  $x_{13} = 0.67$ ?

Answer:  $x_{\text{vap},12} = 0.35$ ,  $x_{\text{vap},13} = 0.65$

For an ideal solution, it follows from eqns 5A.19a and 5A.21 that

$$\mu_A = \mu_A^* + RT \ln x_A \quad \text{Ideal solution} \quad \text{Chemical potential} \quad (5A.22)$$

This important equation can be used as the *definition* of an ideal solution (so that it implies Raoult's law rather than stemming

**Figure 5A.13** Strong deviations from ideality are shown by dissimilar liquids, in this case carbon disulfide and acetone (propanone).

from it). It is in fact a better definition than eqn 5A.21 because it does not assume that the vapour is a perfect gas.

The molecular origin of Raoult's law is the effect of the solute on the entropy of the solution. In the pure solvent, the molecules have a certain disorder and a corresponding entropy; the vapour pressure then represents the tendency of the system and its surroundings to reach a higher entropy. When a solute is present, the solution has a greater disorder than the pure solvent because we cannot be sure that a molecule chosen at random will be a solvent molecule. Because the entropy of the solution is higher than that of the pure solvent, the solution has a lower tendency to acquire an even higher entropy by the solvent vaporizing. In other words, the vapour pressure of the solvent in the solution is lower than that of the pure solvent.

Some solutions depart significantly from Raoult's law (Fig. 5A.13). Nevertheless, even in these cases the law is obeyed increasingly closely for the component in excess (the solvent) as it approaches purity. The law is another example of a limiting law (in this case, achieving reliability as  $x_A \rightarrow 1$ ) and is a good approximation for the properties of the solvent if the solution is dilute.

#### (b) Ideal-dilute solutions

In ideal solutions the solute, as well as the solvent, obeys Raoult's law. However, the English chemist William Henry found experimentally that, for real solutions at low concentrations, although the vapour pressure of the solute is proportional to its mole fraction, the constant of proportionality is not the vapour pressure of the pure substance (Fig. 5A.14). **Henry's law** is:

$$p_B = x_B K_B \quad \text{Ideal-dilute solution} \quad \text{Henry's law} \quad (5A.23)$$

In this expression,  $x_B$  is the mole fraction of the solute and  $K_B$  is an empirical constant (with the dimensions of pressure)

**Figure 5A.14** When a component (the solvent) is nearly pure, it has a vapour pressure that is proportional to mole fraction with a slope  $p_B^*$  (Raoult's law). When it is the minor component (the solute) its vapour pressure is still proportional to the mole fraction, but the constant of proportionality is now  $K_B$  (Henry's law).

chosen so that the plot of the vapour pressure of B against its mole fraction is tangent to the experimental curve at  $x_B=0$ . Henry's law is therefore also a limiting law, achieving reliability as  $x_B \rightarrow 0$ .

Mixtures for which the solute B obeys Henry's law and the solvent A obeys Raoult's law are called **ideal-dilute solutions**. The difference in behaviour of the solute and solvent at low concentrations (as expressed by Henry's and Raoult's laws, respectively) arises from the fact that in a dilute solution the solvent molecules are in an environment very much like the one they have in the pure liquid (Fig. 5A.15). In contrast, the solute molecules are surrounded by solvent molecules, which is entirely different from their environment when pure. Thus, the solvent behaves like a slightly modified pure liquid, but the solute behaves entirely differently from its pure state unless the solvent and solute molecules happen to be very similar. In the latter case, the solute also obeys Raoult's law.

**Figure 5A.15** In a dilute solution, the solvent molecules (the blue spheres) are in an environment that differs only slightly from that of the pure solvent. The solute particles (the purple spheres), however, are in an environment totally unlike that of the pure solute.

#### Example 5A.4 Investigating the validity of Raoult's and Henry's laws

The vapour pressures of each component in a mixture of propanone (acetone, A) and trichloromethane (chloroform, C) were measured at 35 °C with the following results:

$x_C$	0	0.20	0.40	0.60	0.80	1
$p_C/\text{kPa}$	0	4.7	11	18.9	26.7	36.4
$p_A/\text{kPa}$	46.3	33.3	23.3	12.3	4.9	0

Confirm that the mixture conforms to Raoult's law for the component in large excess and to Henry's law for the minor component. Find the Henry's law constants.

**Method** Both Raoult's and Henry's laws are statements about the form of the graph of partial vapour pressure against mole fraction. Therefore, plot the partial vapour pressures against mole fraction. Raoult's law is tested by comparing the data with the straight line  $p_i = x_i p_i^*$  for each component in the region in which it is in excess (and acting as the solvent). Henry's law is tested by finding a straight line  $p_i = x_i K_i^*$  that is tangent to each partial vapour pressure at low  $x$ , where the component can be treated as the solute.

**Answer** The data are plotted in Fig. 5A.16 together with the Raoult's law lines. Henry's law requires  $K_A = 16.9 \text{ kPa}$  for propanone and  $K_C = 20.4 \text{ kPa}$  for trichloromethane. Notice how the system deviates from both Raoult's and Henry's laws even for quite small departures from  $x=1$  and  $x=0$ , respectively. We deal with these deviations in Topic 5E.

**Figure 5A.16** The experimental partial vapour pressures of a mixture of chloroform (trichloromethane) and acetone (propanone) based on the data in Example 5A.3. The values of  $K$  are obtained by extrapolating the dilute solution vapour pressures, as explained in the Example.

**Self-test 5A.7** The vapour pressure of chloromethane at various mole fractions in a mixture at 25 °C was found to be as follows:

$x$	0.005	0.009	0.019	0.024
$p/\text{kPa}$	27.3	48.4	101	126

Estimate Henry's law constant.

Answer: 5 MPa

For practical applications, Henry's law is expressed in terms of the molality,  $b$ , of the solute,  $p_B = b_B K_B$ . Some Henry's law data for this convention are listed in Table 5A.1. As well as providing a link between the mole fraction of solute and its partial pressure, the data in the table may also be used to calculate gas solubilities. A knowledge of Henry's law constants for gases in blood and fats is important for the discussion of respiration, especially when the partial pressure of oxygen is abnormal, as in diving and mountaineering, and for the discussion of the action of gaseous anaesthetics.

**Table 5A.1\*** Henry's law constants for gases in water at 298 K,  $K/(\text{kPa kg mol}^{-1})$

	$K/(\text{kPa kg mol}^{-1})$
$\text{CO}_2$	$3.01 \times 10^3$
$\text{H}_2$	$1.28 \times 10^5$
$\text{N}_2$	$1.56 \times 10^5$
$\text{O}_2$	$7.92 \times 10^4$

\* More values are given in the *Resource section*.

#### Brief illustration 5A.4 Henry's law and gas solubility

To estimate the molar solubility of oxygen in water at 25 °C and a partial pressure of 21 kPa, its partial pressure in the atmosphere at sea level, we write

$$b_{\text{O}_2} = \frac{p_{\text{O}_2}}{K_{\text{O}_2}} = \frac{21 \text{ kPa}}{7.9 \times 10^4 \text{ kPa kg mol}^{-1}} = 2.9 \times 10^{-4} \text{ mol kg}^{-1}$$

The molality of the saturated solution is therefore  $0.29 \text{ mmol kg}^{-1}$ . To convert this quantity to a molar concentration, we assume that the mass density of this dilute solution is essentially that of pure water at 25 °C, or  $\rho = 0.997 \text{ kg dm}^{-3}$ . It follows that the molar concentration of oxygen is

$$[\text{O}_2] = b_{\text{O}_2} \rho = (2.9 \times 10^{-4} \text{ mol kg}^{-1}) \times (0.997 \text{ kg dm}^{-3}) \\ = 0.29 \text{ mmol dm}^{-3}$$

**Self-test 5A.8** Calculate the molar solubility of nitrogen in water exposed to air at 25 °C; partial pressures were calculated in *Example 1A.3* of Topic 1A.

Answer:  $0.51 \text{ mmol dm}^{-3}$

## Checklist of concepts

- 1. The **molar concentration** of a solute is the amount of solute divided by the volume of the solution.
- 2. The **molality** of a solute is the amount of solute divided by the mass of solvent.
- 3. The **partial molar volume** of a substance is the contribution to the volume that a substance makes when it is part of a mixture.
- 4. The **chemical potential** is the partial molar Gibbs energy and enables us to express the dependence of the Gibbs energy on the composition of a mixture.
- 5. The chemical potential also shows how, under a variety of different conditions, the thermodynamic functions vary with composition.
- 6. The **Gibbs–Duhem equation** shows how the changes in chemical potential of the components of a mixture are related.
- 7. The **Gibbs energy of mixing** is calculated by forming the difference of the Gibbs energies before and after mixing: the quantity is negative for perfect gases at the same pressure.
- 8. The **entropy of mixing** of perfect gases initially at the same pressure is positive and the enthalpy of mixing is zero.
- 9. **Raoult's law** provides a relation between the vapour pressure of a substance and its mole fraction in a mixture; it is the basis of the definition of an ideal solution.
- 10. **Henry's law** provides a relation between the vapour pressure of a solute and its mole fraction in a mixture; it is the basis of the definition of an ideal–dilute solution.

## Checklist of equations

Property	Equation	Comment	Equation number
Partial molar volume	$V_j = (\partial V / \partial n_j)_{p,T,n'}$	Definition	5A.1
Chemical potential	$\mu_j = (\partial G / \partial n_j)_{p,T,n'}$	Definition	5A.4
Total Gibbs energy	$G = n_A \mu_A + n_B \mu_B$		5A.5

Property	Equation	Comment	Equation number
Fundamental equation of chemical thermodynamics	$dG = Vdp - SdT + \mu_A dn_A + \mu_B dn_B + \dots$		5A.6

### ► Why do you need to know this material?

Mixtures and solutions play a central role in chemistry, and it is important to understand how their compositions affect their thermodynamic properties, such as their boiling and freezing points. One very important property of a solution is its osmotic pressure, which is used, among other things, to determine the molar masses of macromolecules.

### ► What is the key idea?

The chemical potential of a substance in a mixture is the same in each phase in which it occurs.

### ► What do you need to know already?

This Topic is based on the expression derived from Raoult's law (Topic 5A) in which chemical potential is related to mole fraction. The derivations make use of the Gibbs–Helmholtz equation (Topic 3D) and the effect of pressure on chemical potential (Topic 3D). Some of the derivations are the same as those used in the discussion of the mixing of perfect gases (Topic 5A).

First, we consider the simple case of mixtures of liquids that mix to form an ideal solution. In this way, we identify the thermodynamic consequences of molecules of one species mingling randomly with molecules of the second species. The calculation provides a background for discussing the deviations from ideal behaviour exhibited by real solutions. Then we consider the effect of a solute on the properties of ideal and real solutions.

## 5B.1 Liquid mixtures

Thermodynamics can provide insight into the properties of liquid mixtures, and a few simple ideas can bring the whole field of study together. The development here is based on the relation derived in Topic 5A between the chemical potential of a component (which here we call J for reasons that will become clear) in an ideal mixture or solution,  $\mu_J$ , its value when pure,  $\mu_J^*$ , and its mole fraction in the mixture,  $x_J$ :

$$\mu_J = \mu_J^* + RT \ln x_J \quad \text{Ideal solution} \quad \text{Chemical potential} \quad (5B.1)$$

### (a) Ideal solutions

The Gibbs energy of mixing of two liquids to form an ideal solution is calculated in exactly the same way as for two gases (Topic 5A). The total Gibbs energy before liquids are mixed is

$$G_i = n_A \mu_A^* + n_B \mu_B^* \quad (5B.2a)$$

where the \* denotes the pure liquid. When they are mixed, the individual chemical potentials are given by eqn 5B.1 and the total Gibbs energy is

$$G_f = n_A (\mu_A^* + RT \ln x_A) + n_B (\mu_B^* + RT \ln x_B) \quad (5B.2b)$$

Consequently, the Gibbs energy of mixing, the difference of these two quantities, is

$$\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B) \quad \text{Ideal solution} \quad \text{Gibbs energy of mixing} \quad (5B.3)$$

where  $n = n_A + n_B$ . As for gases, it follows that the ideal entropy of mixing of two liquids is

$$\Delta_{\text{mix}} S = -nR(x_A \ln x_A + x_B \ln x_B) \quad \text{Ideal solution} \quad \text{Entropy of mixing} \quad (5B.4)$$

Because  $\Delta_{\text{mix}}H = \Delta_{\text{mix}}G + T\Delta_{\text{mix}}S = 0$ , the ideal enthalpy of mixing is zero,  $\Delta_{\text{mix}}H = 0$ . The ideal volume of mixing, the change in volume on mixing, is also zero because it follows from eqn 3D.8 ( $(\partial G/\partial p)_T = V$ ) that  $\Delta_{\text{mix}}V = (\partial \Delta_{\text{mix}}G/\partial p)_T$ , but  $\Delta_{\text{mix}}G$  in eqn 5B.3 is independent of pressure, so the derivative with respect to pressure is zero.

Equations 5B.3 and 5B.4 are the same as those for the mixing of two perfect gases and all the conclusions drawn there are valid here: the driving force for mixing is the increasing entropy of the system as the molecules mingle and the enthalpy of mixing is zero. It should be noted, however, that solution ideality means something different from gas perfection. In a perfect gas there are no forces acting between molecules. In ideal solutions there are interactions, but the average energy of A–B interactions in the mixture is the same as the average energy of A–A and B–B interactions in the pure liquids. The variation of the Gibbs energy and entropy of mixing with composition is the same as that for gases (Figs. 5A.7 and 5A.9); both graphs are repeated here (as Figs. 5B.1 and 5B.2).

*A note on good practice* It is on the basis of this distinction that the term ‘perfect gas’ is preferable to the more

Figure 5B.1 The Gibbs energy of mixing of two liquids that form an ideal solution.

Figure 5B.2 The entropy of mixing of two liquids that form an ideal solution.

common ‘ideal gas’. In an ideal solution there are interactions, but they are effectively the same between the various species. In a perfect gas, not only are the interactions the same, but they are also zero. Few people, however, trouble to make this valuable distinction.

#### Brief illustration 5B.1 Ideal solutions

Consider a mixture of benzene and methylbenzene, which form an approximately ideal solution, and suppose 1.0 mol  $\text{C}_6\text{H}_6(\text{l})$  is mixed with 2.0 mol  $\text{C}_6\text{H}_5\text{CH}_3(\text{l})$ . For the mixture,  $x_{\text{benzene}} = 0.33$  and  $x_{\text{methylbenzene}} = 0.67$ . The Gibbs energy and entropy of mixing at  $25^\circ\text{C}$ , when  $RT = 2.48 \text{ kJ mol}^{-1}$ , are

$$\begin{aligned}\Delta_{\text{mix}}G/n &= (2.48 \text{ kJ mol}^{-1}) \times (0.33 \ln 0.33 + 0.67 \ln 0.67) \\ &= -1.6 \text{ kJ mol}^{-1}\end{aligned}$$

$$\begin{aligned}\Delta_{\text{mix}}S/n &= -(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (0.33 \ln 0.33 + 0.67 \ln 0.67) \\ &= +5.3 \text{ J K}^{-1} \text{ mol}^{-1}\end{aligned}$$

The enthalpy of mixing is zero (presuming that the solution is ideal).

**Self-test 5B.1** Calculate the Gibbs energy and entropy of mixing when the proportions are reversed.

Answer: same:  $-1.6 \text{ kJ mol}^{-1}$ ,  $+5.3 \text{ J K}^{-1} \text{ mol}^{-1}$

Real solutions are composed of particles for which A–A, A–B, and B–B interactions are all different. Not only may there be enthalpy and volume changes when liquids mix, but there may also be an additional contribution to the entropy arising from the way in which the molecules of one type might cluster together instead of mingling freely with the others. If the enthalpy change is large and positive or if the entropy change is adverse (because of a reorganization of the molecules that results in an orderly mixture), then the Gibbs energy might be positive for mixing. In that case, separation is spontaneous and the liquids may be immiscible. Alternatively, the liquids might be **partially miscible**, which means that they are miscible only over a certain range of compositions.

#### (b) Excess functions and regular solutions

The thermodynamic properties of real solutions are expressed in terms of the **excess functions**,  $X^E$ , the difference between the observed thermodynamic function of mixing and the function for an ideal solution:

$$X^E = \Delta_{\text{mix}}X - \Delta_{\text{mix}}X^{\text{ideal}} \quad \text{Definition} \quad \text{Excess function} \quad (5B.5)$$

The **excess entropy**,  $S^E$ , for example, is calculated using the value of  $\Delta_{\text{mix}}S^{\text{ideal}}$  given by eqn 5B.4. The excess enthalpy and volume are both equal to the observed enthalpy and volume of mixing, because the ideal values are zero in each case.

## Brief illustration 5B.2 Excess functions

Figure 5B.3 shows two examples of the composition dependence of molar excess functions. In Fig 5B.3a, the positive values of  $H^E$ , which implies that  $\Delta_{\text{mix}}H > 0$ , indicate that the A–B interactions in the mixture are less attractive than the A–A and B–B interactions in the pure liquids (which are benzene and pure cyclohexane). The symmetrical shape of the curve reflects the similar strengths of the A–A and B–B interactions. Figure 5B.3b shows the composition dependence of the excess volume,  $V^E$ , of a mixture of tetrachloroethene and cyclopentane. At high mole fractions of cyclopentane, the solution contracts as tetrachloroethene is added because the ring structure of cyclopentane results in inefficient packing of the molecules but as tetrachloroethene is added, the molecules in the mixture pack together more tightly. Similarly, at high mole fractions of tetrachloroethene, the solution expands as cyclopentane is added because tetrachloroethene molecules are nearly flat and pack efficiently in the pure liquid but become disrupted as bulky ring cyclopentane is added.

**Figure 5B.3** Experimental excess functions at 25 °C. (a)  $H^E$  for benzene/cyclohexane; this graph shows that the mixing is endothermic (because  $\Delta_{\text{mix}}H=0$  for an ideal solution). (b) The excess volume,  $V^E$ , for tetrachloroethene/cyclopentane; this graph shows that there is a contraction at low tetrachloroethene mole fractions, but an expansion at high mole fractions (because  $\Delta_{\text{mix}}V=0$  for an ideal mixture).

**Self-test 5B.2** Would you expect the excess volume of mixing of oranges and melons to be positive or negative?

Answer: Positive; close-packing disrupted

Deviations of the excess energies from zero indicate the extent to which the solutions are non-ideal. In this connection a useful model system is the **regular solution**, a solution for which  $H^E \neq 0$  but  $S^E=0$ . We can think of a regular solution as one in which the two kinds of molecules are distributed randomly (as in an ideal solution) but have different energies of interactions with each other. To express this concept more quantitatively we can suppose that the excess enthalpy depends on composition as

$$H^E = n\xi RTx_Ax_B \quad (5B.6)$$

where  $\xi(x_i)$  is a dimensionless parameter that is a measure of the energy of AB interactions relative to that of the AA and BB interactions. (For  $H^E$  expressed as a molar quantity, discard the  $n$ .) The function given by eqn 5B.6 is plotted in Fig. 5B.4, and we see it resembles the experimental curve in Fig. 5B.3a. If  $\xi < 0$ , mixing is exothermic and the solute–solvent interactions are more favourable than the solvent–solvent and solute–solute interactions. If  $\xi > 0$ , then the mixing is endothermic. Because the entropy of mixing has its ideal value for a regular solution, the excess Gibbs energy is equal to the excess enthalpy, and the Gibbs energy of mixing is

$$\Delta_{\text{mix}}G = nRT(x_A \ln x_A + x_B \ln x_B + \xi x_A x_B) \quad (5B.7)$$

Figure 5B.5 shows how  $\Delta_{\text{mix}}G$  varies with composition for different values of  $\xi$ . The important feature is that for  $\xi > 2$  the graph shows two minima separated by a maximum. The implication of this observation is that, provided  $\xi > 2$ , then the

**Figure 5B.4** The excess enthalpy according to a model in which it is proportional to  $\xi x_A x_B$ , for different values of the parameter  $\xi$ .

**Figure 5B.5** The Gibbs energy of mixing for different values of the parameter  $\xi$ .

system will separate spontaneously into two phases with compositions corresponding to the two minima, for that separation corresponds to a reduction in Gibbs energy. We develop this point in Topic 5C.

### Example 5B.1 Identifying the parameter for a regular solution

Identify the value of the parameter  $\xi$  that would be appropriate to model a mixture of benzene and cyclohexane at 25 °C and estimate the Gibbs energy of mixing to produce an equimolar mixture.

**Method** Refer to Fig. 5B.3a and identify the value at the curve maximum, and then relate it to eqn 5B.6 written as a molar quantity ( $H^E = \xi RTx_Ax_B$ ). For the second part, assume that the solution is regular and that the Gibbs energy of mixing is given by eqn 5B.7.

**Answer** The experimental value occurs close to  $x_A = x_B = \frac{1}{2}$  and its value is close to 710 J mol<sup>-1</sup>. It follows that

$$\xi = \frac{H^E}{RTx_Ax_B} = \frac{701 \text{ J mol}^{-1}}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \times \frac{1}{2} \times \frac{1}{2}} = 1.13$$

The total Gibbs energy of mixing to achieve the stated composition (provided the solution is regular) is therefore

$$\begin{aligned} \Delta_{\text{mix}}G/n &= -RT \ln 2 + 701 \text{ J mol}^{-1} \\ &= -1.72 \text{ kJ mol}^{-1} + 0.701 \text{ kJ mol}^{-1} = -1.02 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test 5B.3** Fit the entire data set, as best as can be inferred from the graph in Fig. 5B.3a, to an expression of the form in eqn 5B.6 by a curve-fitting procedure.

Answer: The best fit of the form  $Ax(1-x)$  to the data pairs

X	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
$H^E/(\text{J mol}^{-1})$	150	350	550	680	700	690	600	500	280

is  $A = 690 \text{ J mol}^{-1}$

## 5B.2 Colligative properties

The properties we consider are the lowering of vapour pressure, the elevation of boiling point, the depression of freezing point, and the osmotic pressure arising from the presence of a solute. In dilute solutions these properties depend only on the number of solute particles present, not their identity. For this reason, they are called **colligative properties** (denoting ‘depending on the collection’). In this development, we denote the solvent by A and the solute by B.

We assume throughout the following that the solute is not volatile, so it does not contribute to the vapour. We also assume that the solute does not dissolve in the solid solvent: that is, the

pure solid solvent separates when the solution is frozen. The latter assumption is quite drastic, although it is true of many mixtures; it can be avoided at the expense of more algebra, but that introduces no new principles.

### (a) The common features of colligative properties

All the colligative properties stem from the reduction of the chemical potential of the liquid solvent as a result of the presence of solute. For an ideal solution (one that obeys Raoult’s law, Topic 5A;  $p_A = x_A p_A^*$ ), the reduction is from  $\mu_A^*$  for the pure solvent to  $\mu_A = \mu_A^* + RT \ln x_A$  when a solute is present ( $\ln x_A$  is negative because  $x_A < 1$ ). There is no direct influence of the solute on the chemical potential of the solvent vapour and the solid solvent because the solute appears in neither the vapour nor the solid. As can be seen from Fig. 5B.6, the reduction in chemical potential of the solvent implies that the liquid–vapour equilibrium occurs at a higher temperature (the boiling point is raised) and the solid–liquid equilibrium occurs at a lower temperature (the freezing point is lowered).

The molecular origin of the lowering of the chemical potential is not the energy of interaction of the solute and solvent particles, because the lowering occurs even in an ideal solution (for which the enthalpy of mixing is zero). If it is not an enthalpy effect, it must be an entropy effect. The vapour pressure of the pure liquid reflects the tendency of the solution towards greater entropy, which can be achieved if the liquid vaporizes to form a gas. When a solute is present, there is an additional contribution to the entropy of the liquid, even in an ideal solution. Because the entropy of the liquid is already higher than that of the pure liquid, there is a weaker tendency to form the gas (Fig. 5B.7). The effect of the solute appears as a lowered vapour pressure, and hence a higher boiling point. Similarly, the enhanced molecular randomness of the solution opposes the tendency to freeze. Consequently, a lower temperature must be reached

**Figure 5B.6** The chemical potential of a solvent in the presence of a solute. The lowering of the liquid’s chemical potential has a greater effect on the freezing point than on the boiling point because of the angles at which the lines intersect.

**Figure 5B.7** The vapour pressure of a pure liquid represents a balance between the increase in disorder arising from vaporization and the decrease in disorder of the surroundings. (a) Here the structure of the liquid is represented highly schematically by the grid of squares. (b) When solute (the dark squares) is present, the disorder of the condensed phase is higher than that of the pure liquid, and there is a decreased tendency to acquire the disorder characteristic of the vapour.

before equilibrium between solid and solution is achieved. Hence, the freezing point is lowered.

The strategy for the quantitative discussion of the elevation of boiling point and the depression of freezing point is to look for the temperature at which, at 1 atm, one phase (the pure solvent vapour or the pure solid solvent) has the same chemical potential as the solvent in the solution. This is the new equilibrium temperature for the phase transition at 1 atm, and hence corresponds to the new boiling point or the new freezing point of the solvent.

### (b) The elevation of boiling point

The heterogeneous equilibrium of interest when considering boiling is between the solvent vapour and the solvent in solution at 1 atm (Fig. 5B.8). The equilibrium is established at a temperature for which

**Figure 5B.8** The heterogeneous equilibrium involved in the calculation of the elevation of boiling point is between A in the pure vapour and A in the mixture, A being the solvent and B a non-volatile solute.

$$\mu_A^*(g) = \mu_A^*(l) + RT \ln x_A \quad (5B.8)$$

(The pressure of 1 atm is the same throughout, and will not be written explicitly.) We show in the following *Justification* that this equation implies that the presence of a solute at a mole fraction  $x_B$  causes an increase in normal boiling point from  $T^*$  to  $T^* + \Delta T_b$ , where

$$\Delta T_b = Kx_B \quad K = \frac{RT^{*2}}{\Delta_{\text{vap}}H} \quad \text{Ideal solution} \quad \text{Elevation of boiling point} \quad (5B.9)$$

#### Justification 5B.1 The elevation of the boiling point of a solvent

Equation 5B.8 can be rearranged into

$$\ln x_A = \frac{\mu_A^*(g) - \mu_A^*(l)}{RT} = \frac{\Delta_{\text{vap}}G}{RT}$$

where  $\Delta_{\text{vap}}G$  is the Gibbs energy of vaporization of the pure solvent (A). First, to find the relation between a change in composition and the resulting change in boiling temperature, we differentiate both sides with respect to temperature and use the Gibbs–Helmholtz equation (Topic 3D,  $(\partial(G/T)/\partial T)_p = -H/T^2$ ) to express the term on the right:

$$\frac{d \ln x_A}{dT} = \frac{1}{R} \frac{d(\Delta_{\text{vap}}G/T)}{dT} = -\frac{\Delta_{\text{vap}}H}{RT^2}$$

Now multiply both sides by  $dT$  and integrate from  $x_A = 1$ , corresponding to  $\ln x_A = 0$  (and when  $T = T^*$ , the boiling point of pure A) to  $x_A$  (when the boiling point is  $T$ ):

$$\int_0^{\ln x_A} d \ln x_A = -\frac{1}{R} \int_{T^*}^T \frac{\Delta_{\text{vap}}H}{T^2} dT$$

The left-hand side integrates to  $\ln x_A$ , which is equal to  $\ln(1 - x_B)$ . The right-hand side can be integrated if we assume that the enthalpy of vaporization is a constant over the small range of temperatures involved and can be taken outside the integral. Thus, we obtain

$$\ln(1 - x_B) = -\frac{\Delta_{\text{vap}}H}{R} \int_{T^*}^T \frac{1}{T^2} dT$$

and therefore

$$\ln(1 - x_B) = \frac{\Delta_{\text{vap}}H}{R} \left( \frac{1}{T} - \frac{1}{T^*} \right)$$

We now suppose that the amount of solute present is so small that  $x_B \ll 1$ , and use the expansion  $\ln(1 - x) = -x - \frac{1}{2}x^2 + \dots \approx -x$  (*Mathematical background 1*) and hence obtain

$$x_B = \frac{\Delta_{\text{vap}}H}{R} \left( \frac{1}{T^*} - \frac{1}{T} \right)$$

Finally, because  $T \approx T^*$ , it also follows that

$$\frac{1}{T^*} - \frac{1}{T} = \frac{T - T^*}{TT^*} \approx \frac{T - T^*}{T^{*2}} = \frac{\Delta T_b}{T^{*2}}$$

with  $\Delta T_b = T - T^*$ . The previous equation then rearranges into eqn 5B.9.

Because eqn 5B.9 makes no reference to the identity of the solute, only to its mole fraction, we conclude that the elevation of boiling point is a colligative property. The value of  $\Delta T$  does depend on the properties of the solvent, and the biggest changes occur for solvents with high boiling points. By Trouton's rule (Topic 3B),  $\Delta_{\text{vap}}H/T^*$  is a constant; therefore eqn 5B.9 has the form  $\Delta T \propto T^*$  and is independent of  $\Delta_{\text{vap}}H$  itself. For practical applications of eqn 5B.9, we note that the mole fraction of B is proportional to its molality,  $b$ , in the solution, and write

$$\Delta T_b = K_b b \quad \text{Empirical relation} \quad \text{Boiling point elevation} \quad (5B.10)$$

where  $K_b$  is the empirical **boiling-point constant** of the solvent (Table 5B.1).

#### Brief illustration 5B.3 Elevation of boiling point

The boiling-point constant of water is  $0.51 \text{ K kg mol}^{-1}$ , so a solute present at a molality of  $0.10 \text{ mol kg}^{-1}$  would result in an elevation of boiling point of only  $0.051 \text{ K}$ . The boiling-point constant of benzene is significantly larger, at  $2.53 \text{ K kg mol}^{-1}$ , so the elevation would be  $0.25 \text{ K}$ .

**Self-test 5B.4** Identify the feature that accounts for the difference in boiling-point constants of water and benzene.

Answer: High enthalpy of vaporization of water; given molality corresponds to a smaller mole fraction

### (c) The depression of freezing point

The heterogeneous equilibrium now of interest is between pure solid solvent A and the solution with solute present at a mole fraction  $x_B$  (Fig. 5B.9). At the freezing point, the chemical potentials of A in the two phases are equal:

**Table 5B.1\*** Freezing-point ( $K_f$ ) and boiling-point ( $K_b$ ) constants

	$K_f/(\text{K kg mol}^{-1})$	$K_b/(\text{K kg mol}^{-1})$
Benzene	5.12	2.53
Camphor	40	
Phenol	7.27	3.04
Water	1.86	0.51

\* More values are given in the *Resource section*.

**Figure 5B.9** The heterogeneous equilibrium involved in the calculation of the lowering of freezing point is between A in the pure solid and A in the mixture, A being the solvent and B a solute that is insoluble in solid A.

$$\mu_A^*(s) = \mu_A^*(l) + RT \ln x_A \quad (5B.11)$$

The only difference between this calculation and the last is the appearance of the solid's chemical potential in place of the vapour's. Therefore we can write the result directly from eqn 5B.9:

$$\Delta T_f = K'_f x_B \quad K'_f = \frac{RT^{*2}}{\Delta_{\text{fus}}H} \quad \text{Freezing point depression} \quad (5B.12)$$

where  $\Delta T_f$  is the freezing point depression,  $T^* - T$ , and  $\Delta_{\text{fus}}H$  is the enthalpy of fusion of the solvent. Larger depressions are observed in solvents with low enthalpies of fusion and high melting points. When the solution is dilute, the mole fraction is proportional to the molality of the solute,  $b$ , and it is common to write the last equation as

$$\Delta T_f = K_f b \quad \text{Empirical relation} \quad \text{Freezing point depression} \quad (5B.13)$$

where  $K_f$  is the empirical **freezing-point constant** (Table 5B.1). Once the freezing-point constant of a solvent is known, the depression of freezing point may be used to measure the molar mass of a solute in the method known as **cryoscopy**; however, the technique is of little more than historical interest.

#### Brief illustration 5B.4 Depression of freezing point

The freezing-point constant of water is  $1.86 \text{ K kg mol}^{-1}$ , so a solute present at a molality of  $0.10 \text{ mol kg}^{-1}$  would result in a depression of freezing point of only  $0.19 \text{ K}$ . The freezing-point constant of camphor is significantly larger, at  $40 \text{ K kg mol}^{-1}$ , so the depression would be  $4.0 \text{ K}$ . Camphor was once widely used for estimates of molar mass by cryoscopy.

**Self-test 5B.5** Why are freezing-point constants typically larger than the corresponding boiling-point constants of a solvent?

Answer: Enthalpy of fusion is smaller than the enthalpy of vaporization of a substance

**Figure 5B.10** The heterogeneous equilibrium involved in the calculation of the solubility is between pure solid B and B in the mixture.

### (d) Solubility

Although solubility is not a colligative property (because solubility varies with the identity of the solute), it may be estimated by the same techniques as we have been using. When a solid solute is left in contact with a solvent, it dissolves until the solution is saturated. Saturation is a state of equilibrium, with the undissolved solute in equilibrium with the dissolved solute. Therefore, in a saturated solution the chemical potential of the pure solid solute,  $\mu_B^*(s)$ , and the chemical potential of B in solution,  $\mu_B$ , are equal (Fig. 5B.10). Because the latter is related to the mole fraction in the solution by  $\mu_B = \mu_B^*(l) + RT \ln x_B$ , we can write

$$\mu_B^*(s) = \mu_B^*(l) + RT \ln x_B \quad (5B.14)$$

This expression is the same as the starting equation of the last section, except that the quantities refer to the solute B, not the solvent A. We now show in the following *Justification* that

$$\ln x_B = \frac{\Delta_{\text{fus}}H}{R} \left( \frac{1}{T_f} - \frac{1}{T} \right) \quad \text{Ideal solubility} \quad (5B.15)$$

where  $\Delta_{\text{fus}}H$  is the enthalpy of fusion of the solute and  $T_f$  is its melting point.

#### Justification 5B.2 The solubility of an ideal solute

The starting point is the same as in *Justification 5B.1* but the aim is different. In the present case, we want to find the mole fraction of B in solution at equilibrium when the temperature is  $T$ . Therefore, we start by rearranging eqn 5B.14 into

$$\ln x_B = \frac{\mu_B^*(s) - \mu_B^*(l)}{RT} = -\frac{\Delta_{\text{fus}}G}{RT}$$

As in *Justification 5B.1*, we relate the change in composition  $d \ln x_B$  to the change in temperature by differentiation and use of the Gibbs–Helmholtz equation. Then we integrate from the melting temperature of B (when  $x_B = 1$  and  $\ln x_B = 0$ ) to the lower temperature of interest (when  $x_B$  has a value between 0 and 1):

$$\int_0^{\ln x_B} d \ln x_B = \frac{1}{R} \int_{T_f}^T \frac{\Delta_{\text{fus}}H}{T^2} dT$$

If we suppose that the enthalpy of fusion of B is constant over the range of temperatures of interest, it can be taken outside the integral, and we obtain eqn 5B.15.

**Figure 5B.11** The variation of solubility (the mole fraction of solute in a saturated solution) with temperature ( $T_f$  is the freezing temperature of the solute). Individual curves are labelled with the value of  $\Delta_{\text{fus}}H/RT_f$ .

Equation 5B.15 is plotted in Fig. 5B.11. It shows that the solubility of B decreases exponentially as the temperature is lowered from its melting point. The illustration also shows that solutes with high melting points and large enthalpies of melting have low solubilities at normal temperatures. However, the detailed content of eqn 5B.15 should not be treated too seriously because it is based on highly questionable approximations, such as the ideality of the solution. One aspect of its approximate character is that it fails to predict that solutes will have different solubilities in different solvents, for no solvent properties appear in the expression.

#### Brief illustration 5B.5 Ideal solubility

The ideal solubility of naphthalene in benzene is calculated from eqn 5B.15 by noting that the enthalpy of fusion of naphthalene is  $18.80 \text{ kJ mol}^{-1}$  and its melting point is 354 K. Then, at  $20^\circ\text{C}$ ,

$$\ln x_{\text{naphthalene}} = \frac{1.880 \times 10^4 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{354 \text{ K}} - \frac{1}{293 \text{ K}} \right) = -1.32 \dots$$

and therefore  $x_{\text{naphthalene}} = 0.26$ . This mole fraction corresponds to a molality of  $4.5 \text{ mol kg}^{-1}$  (580 g of naphthalene in 1 kg of benzene).

**Self-test 5B.6** Plot the solubility of naphthalene as a function of temperature against mole fraction: in Topic 5C we

see that such diagrams are ‘temperature–composition phase diagrams’.

Answer: See Fig. 5B.12.

Figure 5B.12 The theoretical solubility of naphthalene in benzene, as calculated in *Self-test* 5B.6.

### (e) Osmosis

The phenomenon of **osmosis** (from the Greek word for ‘push’) is the spontaneous passage of a pure solvent into a solution separated from it by a **semipermeable membrane**, a membrane permeable to the solvent but not to the solute (Fig. 5B.13). The **osmotic pressure**,  $\Pi$ , is the pressure that must be applied to the solution to stop the influx of solvent. Important examples of osmosis include transport of fluids through cell membranes, dialysis and **osmometry**, the determination of molar mass by the measurement of osmotic pressure. Osmometry is widely used to determine the molar masses of macromolecules.

In the simple arrangement shown in Fig. 5B.14, the opposing pressure arises from the head of solution that the osmosis itself produces. Equilibrium is reached when the hydrostatic pressure of the column of solution matches the osmotic pressure.

Figure 5B.13 The equilibrium involved in the calculation of osmotic pressure,  $\Pi$ , is between pure solvent A at a pressure  $p$  on one side of the semipermeable membrane and A as a component of the mixture on the other side of the membrane, where the pressure is  $p + \Pi$ .

Figure 5B.14 In a simple version of the osmotic pressure experiment, A is at equilibrium on each side of the membrane when enough has passed into the solution to cause a hydrostatic pressure difference.

The complicating feature of this arrangement is that the entry of solvent into the solution results in its dilution, and so it is more difficult to treat than the arrangement in Fig. 5B.13, in which there is no flow and the concentrations remain unchanged.

The thermodynamic treatment of osmosis depends on noting that, at equilibrium, the chemical potential of the solvent must be the same on each side of the membrane. The chemical potential of the solvent is lowered by the solute, but is restored to its ‘pure’ value by the application of pressure. As shown in the following *Justification*, this equality implies that for dilute solutions the osmotic pressure is given by the **van ‘t Hoff equation**:

$$\Pi = [B]RT \quad \text{van ‘t Hoff equation} \quad (5B.16)$$

where  $[B] = n_B/V$  is the molar concentration of the solute.

#### Justification 5B.3 The van ‘t Hoff equation

On the pure solvent side the chemical potential of the solvent, which is at a pressure  $p$ , is  $\mu_A^*(p)$ . On the solution side, the chemical potential is lowered by the presence of the solute, which reduces the mole fraction of the solvent from 1 to  $x_A$ . However, the chemical potential of A is raised on account of the greater pressure,  $p + \Pi$ , that the solution experiences. At equilibrium the chemical potential of A is the same in both compartments, and we can write

$$\mu_A^*(p) = \mu_A(x_A, p + \Pi)$$

The presence of solute is taken into account in the normal way by using eqn 5B.1:

$$\mu_A(x_A, p + \Pi) = \mu_A^*(p + \Pi) + RT \ln x_A$$

Equation 3D.12b,

$$G_m(p_f) = G_m(p_i) + \int_{p_i}^{p_f} V_m dp$$

written as

$$\mu_A^*(p+\Pi) = \mu_A^*(p) + \int_p^{p+\Pi} V_m dp$$

where  $V_m$  is the molar volume of the pure solvent A, shows how to take the effect of pressure into account. When these three equations are combined and the  $\mu_A^*(p)$  are cancelled we are left with

$$-RT \ln x_A = \int_p^{p+\Pi} V_m dp \quad (5B.17)$$

This expression enables us to calculate the additional pressure  $\Pi$  that must be applied to the solution to restore the chemical potential of the solvent to its 'pure' value and thus to restore equilibrium across the semipermeable membrane. For dilute solutions,  $\ln x_A$  may be replaced by  $\ln(1-x_B) \approx -x_B$ . We may also assume that the pressure range in the integration is so small that the molar volume of the solvent is a constant. That being so,  $V_m$  may be taken outside the integral, giving

$$RTx_B = \Pi V_m$$

When the solution is dilute,  $x_B \approx n_B/n_A$ . Moreover, because  $n_A V_m = V$ , the total volume of the solvent, the equation simplifies to eqn 5B.16.

Because the effect of osmotic pressure is so readily measurable and large, one of the most common applications of osmometry is to the measurement of molar masses of macromolecules, such as proteins and synthetic polymers. As these huge molecules dissolve to produce solutions that are far from ideal, it is assumed that the van 't Hoff equation is only the first term of a virial-like expansion, much like the extension of the perfect gas equation to real gases (in Topic 1C) to take into account molecular interactions:

$$\Pi = [J]RT \{1 + B[J] + \dots\} \quad \text{Osmotic virial expansion} \quad (5B.18)$$

(We have denoted the solute J to avoid too many different B's in this expression.) The additional terms take the non-ideality into account; the empirical constant  $B$  is called the **osmotic virial coefficient**.

### Example 5B.2 Using osmometry to determine the molar mass of a macromolecule

The osmotic pressures of solutions of poly(vinyl chloride), PVC, in cyclohexanone at 298 K are given below. The pressures are expressed in terms of the heights of solution (of mass density  $\rho = 0.980 \text{ g cm}^{-3}$ ) in balance with the osmotic pressure. Determine the molar mass of the polymer.

$c/(\text{g dm}^{-3})$	1.00	2.00	4.00	7.00	9.00
$h/\text{cm}$	0.28	0.71	2.01	5.10	8.00

**Method** The osmotic pressure is measured at a series of mass concentrations,  $c$ , and a plot of  $\Pi/c$  against  $c$  is used to determine the molar mass of the polymer. We use eqn 5B.18 with  $[J] = c/M$  where  $c$  is the mass concentration of the polymer and  $M$  is its molar mass. The osmotic pressure is related to the hydrostatic pressure by  $\Pi = \rho gh$  (Example 1A.1) with  $g = 9.81 \text{ m s}^{-2}$ . With these substitutions, eqn 5B.18 becomes

$$\frac{h}{c} = \frac{RT}{\rho g M} \left\{ 1 + \frac{Bc}{M} + \dots \right\} = \frac{RT}{\rho g M} + \left( \frac{RTB}{\rho g M^2} \right) c + \dots$$

Therefore, to find  $M$ , plot  $h/c$  against  $c$ , and expect a straight line with intercept  $RT/\rho g M$  at  $c=0$ .

**Answer** The data give the following values for the quantities to plot:

$c/(\text{g dm}^{-3})$	1.00	2.00	4.00	7.00	9.00
$(h/c)/(\text{cm g}^{-1} \text{ dm}^3)$	0.28	0.36	0.503	0.729	0.889

The points are plotted in Fig. 5B.15. The intercept is at 0.20. Therefore,

$$\begin{aligned} M &= \frac{RT}{\rho g} \times \frac{1}{0.20 \text{ cm g}^{-1} \text{ dm}^3} \\ &= \frac{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{(980 \text{ kg m}^{-3}) \times (9.81 \text{ m s}^{-2})} \times \frac{1}{2.0 \times 10^{-3} \text{ m}^4 \text{ kg}^{-1}} \\ &= 1.3 \times 10^2 \text{ kg mol}^{-1} \end{aligned}$$

where we have used  $1 \text{ kg m}^2 \text{ s}^{-2} = 1 \text{ J}$ . Modern osmometers give readings of osmotic pressure in pascals, so the analysis of the data is more straightforward and eqn 5B.18 can be used directly. As explained in Topic 17D, the value obtained from osmometry is the 'number average molar mass'.

**Figure 5B.15** The plot involved in the determination of molar mass by osmometry. The molar mass is calculated from the intercept at  $c=0$ .

**Self-test 5B.7** Estimate the depression of freezing point of the most concentrated of these solutions, taking  $K_f$  as about  $10 \text{ K}/(\text{mol kg}^{-1})$ .

Answer:  $0.8 \text{ mK}$

## Checklist of concepts

- 1. The **Gibbs energy of mixing** of two liquids to form an ideal solution is calculated in the same way as for two perfect gases.
- 2. The **enthalpy of mixing** is zero and the Gibbs energy is due entirely to the entropy of mixing.
- 3. A **regular solution** is one in which the entropy of mixing is the same as for an ideal solution but the enthalpy of mixing is non-zero.
- 4. A **colligative property** depends only on the number of solute particles present, not their identity.
- 5. All the colligative properties stem from the reduction of the chemical potential of the liquid solvent as a result of the presence of solute.
- 6. The **elevation of boiling point** is proportional to the molality of the solute.
- 7. The **depression of freezing point** is also proportional to the molality of the solute.
- 8. Solutes with high melting points and large enthalpies of melting have low solubilities at normal temperatures.
- 9. The **osmotic pressure** is the pressure that when applied to a solution prevents the influx of solvent through a semipermeable membrane.
- 10. The relation of the osmotic pressure to the molar concentration of the solute is given by the **van 't Hoff equation** and is a sensitive way of determining molar mass.

## Checklist of equations

### ► Why do you need to know this material?

Phase diagrams are used widely in materials science, metallurgy, geology, and the chemical industry to summarize the composition of mixtures and it is important to be able to interpret them.

### ► What is the key idea?

A phase diagram is a map showing the conditions under which each phase of a system is the most stable.

### ► What do you need to know already?

It would be helpful to review the interpretation of one-component phase diagrams and the phase rule (Topic 4A). The early part of this Topic draws on Raoult's law (Topic 4B) and the concept of partial pressure (Topic 1A).

One-component phase diagrams are described in Topic 4A. The phase equilibria of binary systems are more complex because composition is an additional variable. However, they provide very useful summaries of phase equilibria for both ideal and empirically established real systems.

## 5C.1 Vapour pressure diagrams

The partial vapour pressures of the components of an ideal solution of two volatile liquids are related to the composition of the liquid mixture by Raoult's law (Topic 5A)

$$p_A = x_A p_A^* \quad p_B = x_B p_B^* \quad (5C.1)$$

where  $p_A^*$  is the vapour pressure of pure A and  $p_B^*$  that of pure B. The total vapour pressure  $p$  of the mixture is therefore

$$p = p_A + p_B = x_A p_A^* + x_B p_B^* = p_B^* + (p_A^* - p_B^*)x_A \quad (5C.2)$$

Total vapour pressure

This expression shows that the total vapour pressure (at some fixed temperature) changes linearly with the composition from  $p_B^*$  to  $p_A^*$  as  $x_A$  changes from 0 to 1 (Fig. 5C.1).

### (a) The composition of the vapour

The compositions of the liquid and vapour that are in mutual equilibrium are not necessarily the same. Common sense suggests that the vapour should be richer in the more volatile component. This expectation can be confirmed as follows. The partial pressures of the components are given by eqn 1A.8 of Topic 1A ( $p_j = x_j p$ ). It follows from that definition that the mole fractions in the gas,  $y_A$  and  $y_B$ , are

$$y_A = \frac{p_A}{p} \quad y_B = \frac{p_B}{p} \quad (5C.3)$$

**Figure 5C.1** The variation of the total vapour pressure of a binary mixture with the mole fraction of A in the liquid when Raoult's law is obeyed.

Provided the mixture is ideal, the partial pressures and the total pressure may be expressed in terms of the mole fractions in the liquid by using eqn 5C.1 for  $p_j$  and eqn 5C.2 for the total vapour pressure  $p$ , which gives

$$y_A = \frac{x_A p_A^*}{p_B^* + (p_A^* - p_B^*)x_A} \quad y_B = 1 - y_A \quad \text{Composition of vapour} \quad (5C.4)$$

Figure 5C.2 shows the composition of the vapour plotted against the composition of the liquid for various values of  $p_A^*/p_B^* > 1$ . We see that in all cases  $y_A > x_A$ , that is, the vapour is richer than the liquid in the more volatile component. Note that if B is non-volatile, so that  $p_B^* = 0$  at the temperature of interest, then it makes no contribution to the vapour ( $y_B = 0$ ).

Equation 5C.3 shows how the total vapour pressure of the mixture varies with the composition of the liquid. Because we can relate the composition of the liquid to the composition of

**Figure 5C.2** The mole fraction of A in the vapour of a binary ideal solution expressed in terms of its mole fraction in the liquid, calculated using eqn 5C.4 for various values of  $p_A^*/p_B^*$  (the label on each curve) with A more volatile than B. In all cases the vapour is richer than the liquid in A.

**Figure 5C.3** The dependence of the vapour pressure of the same system as in Fig. 5C.2, but expressed in terms of the mole fraction of A in the vapour by using eqn 5C.5. Individual curves are labelled with the value of  $p_A^*/p_B^*$ .

the vapour through eqn 5C.3, we can now also relate the total vapour pressure to the composition of the vapour:

$$p = \frac{p_A^* p_B^*}{p_A^* + (p_B^* - p_A^*)y_A} \quad \text{Total vapour pressure} \quad (5C.5)$$

This expression is plotted in Fig. 5C.3.

#### Brief illustration 5C.1 The composition of the vapour

The vapour pressures of benzene and methylbenzene at 20 °C are 75 Torr and 21 Torr, respectively. The composition of the vapour in equilibrium with an equimolar liquid mixture ( $x_{\text{benzene}} = x_{\text{methylbenzene}} = \frac{1}{2}$ ) is

$$y_{\text{benzene}} = \frac{\frac{1}{2} \times (75 \text{ Torr})}{21 \text{ Torr} + (75 - 21 \text{ Torr}) \times \frac{1}{2}} = 0.78$$

$$y_{\text{methylbenzene}} = 1 - 0.78 = 0.22$$

The vapour pressure of each component is

$$p_{\text{benzene}} = \frac{1}{2} (75 \text{ Torr}) = 38 \text{ Torr}$$

$$p_{\text{methylbenzene}} = \frac{1}{2} (21 \text{ Torr}) = 10 \text{ Torr}$$

for a total vapour pressure of 48 Torr.

**Self-test 5C.1** What is the composition of the vapour in equilibrium with a mixture in which the mole fraction of benzene is 0.75?

Answer: 0.91, 0.09

#### (b) The interpretation of the diagrams

If we are interested in distillation, both the vapour and the liquid compositions are of equal interest. It is therefore sensible

**Figure 5C.4** The dependence of the total vapour pressure of an ideal solution on the mole fraction of A in the entire system. A point between the two lines corresponds to both liquid and vapour being present; outside that region there is only one phase present. The mole fraction of A is denoted  $z_A$ , as explained in the text.

to combine Figs. 5C.2 and 5C.3 into one (Fig. 5C.4). The point  $a$  indicates the vapour pressure of a mixture of composition  $x_A$ , and the point  $b$  indicates the composition of the vapour that is in equilibrium with the liquid at that pressure. A richer interpretation of the phase diagram is obtained, however, if we interpret the horizontal axis as showing the *overall* composition,  $z_A$ , of the system (essentially, the mole fraction showing how the mixture was prepared). If the horizontal axis of the vapour pressure diagram is labelled with  $z_A$ , then all the points down to the solid diagonal line in the graph correspond to a system that is under such high pressure that it contains only a liquid phase (the applied pressure is higher than the vapour pressure), so  $z_A = x_A$ , the composition of the liquid. On the other hand, all points below the lower curve correspond to a system that is under such low pressure that it contains only a vapour phase (the applied pressure is lower than the vapour pressure), so  $z_A = y_A$ .

Points that lie between the two lines correspond to a system in which there are two phases present, one a liquid and the other a vapour. To see this interpretation, consider the effect of lowering the pressure on a liquid mixture of overall composition  $a$  in Fig. 5C.5. The lowering of pressure can be achieved by drawing out a piston (Fig. 5C.6). The changes to the system do not affect the overall composition, so the state of the system moves down the vertical line that passes through  $a$ . This vertical line is called an **isopleth**, from the Greek words for ‘equal abundance’. Until the point  $a_1$  is reached (when the pressure has been reduced to  $p_1$ ), the sample consists of a single liquid phase. At  $a_1$  the liquid can exist in equilibrium with its vapour. As we have seen, the composition of the vapour phase is given by point  $a'_1$ . A line joining two points representing phases in equilibrium is called a **tie line**. The composition of the liquid is the same as initially ( $a_1$  lies on the isopleth through  $a$ ), so

**Figure 5C.5** The points of the pressure–composition diagram discussed in the text. The vertical line through  $a$  is an isopleth, a line of constant composition of the entire system.

we have to conclude that at this pressure there is virtually no vapour present; however, the tiny amount of vapour that is present has the composition  $a'_1$ .

Now consider the effect of lowering the pressure to  $p_2$ , so taking the system to a pressure and overall composition represented by the point  $a'_2$ . This new pressure is below the vapour pressure of the original liquid, so it vaporizes until the vapour pressure of the remaining liquid falls to  $p_2$ . Now we know that the composition of such a liquid must be  $a_2$ . Moreover, the composition of the vapour in equilibrium with that liquid must be given by the point  $a'_2$  at the other end of the tie line. If the pressure is reduced to  $p_3$ , a similar readjustment in composition takes place, and now the compositions of the liquid and vapour are represented by the points  $a_3$  and  $a'_3$ , respectively. The latter point corresponds to a system in which the composition of the vapour is the same as the overall composition, so we have

**Figure 5C.6**(a) A liquid in a container exists in equilibrium with its vapour. The superimposed fragment of the phase diagram shows the compositions of the two phases and their abundances (by the lever rule; see section 5C.1(c)). (b) When the pressure is changed by drawing out a piston, the compositions of the phases adjust as shown by the tie line in the phase diagram. (c) When the piston is pulled so far out that all the liquid has vaporized and only the vapour is present, the pressure falls as the piston is withdrawn and the point on the phase diagram moves into the one-phase region.

to conclude that the amount of liquid present is now virtually zero, but the tiny amount of liquid present has the composition  $a_3$ . A further decrease in pressure takes the system to the point  $a_4$ ; at this stage, only vapour is present and its composition is the same as the initial overall composition of the system (the composition of the original liquid).

### Example 5C.1 Constructing a vapour pressure diagram

The following temperature/composition data were obtained for a mixture of octane (O) and methylbenzene (M) at 1.00 atm, where  $x$  is the mole fraction in the liquid and  $y$  the mole fraction in the vapour at equilibrium.

$\theta/^\circ\text{C}$	110.9	112.0	114.0	115.8	117.3	119.0	121.1	123.0
$x_M$	0.908	0.795	0.615	0.527	0.408	0.300	0.203	0.097
$y_M$	0.923	0.836	0.698	0.624	0.527	0.410	0.297	0.164

The boiling points are  $110.6^\circ\text{C}$  and  $125.6^\circ\text{C}$  for M and O, respectively. Plot the temperature–composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (a)  $x_M=0.250$  and (b)  $x_O=0.250$ ?

**Method** Plot the composition of each phase (on the horizontal axis) against the temperature (on the vertical axis). The two boiling points give two further points corresponding to  $x_M=1$  and  $x_M=0$ , respectively. Use a curve-fitting program to draw the phase boundaries. For the interpretation, draw the appropriate tie-lines.

**Answer** The points are plotted in Fig. 5C.7. The two sets of points are fitted to the polynomials  $a+bx+cx^2+dx^3$  with

$$\text{For the liquid line: } \theta/^\circ\text{C} = 125.422 - 22.9494x + 6.64602x^2 + 1.32623x^3 + \dots$$

$$\text{For the vapour line: } \theta/^\circ\text{C} = 125.485 - 11.9387x - 12.5626x^2 + 9.36542x^3 + \dots$$

Figure 5C.7 The plot of data and the fitted curves for a mixture of octane and methylbenzene (M) in Example 5C.1.

The tie lines at  $x_M=0.250$  and  $x_O=0.250$  (corresponding to  $x_M=0.750$ ) have been drawn on the graph starting at the lower (liquid curve). They intersect the upper (vapour curve) at  $y_M=0.36$  and  $0.80$ , respectively.

**Self-test 5C.2** Repeat the analysis for the following data on hexane and heptane at  $70^\circ\text{C}$ :

$\theta/^\circ\text{C}$	65	66	70	77	85	100
$x_{\text{hexane}}$	0	0.20	0.40	0.60	0.80	1
$y_{\text{hexane}}$	0	0.02	0.08	0.20	0.48	1

Answer: See Fig. 5C.8.

Figure 5C.8 The plot of data and the fitted curves for a mixture of hexane (Hx) and heptane in Self-test 5C.2.

### (c) The lever rule

A point in the two-phase region of a phase diagram indicates not only qualitatively that both liquid and vapour are present, but represents quantitatively the relative amounts of each. To find the relative amounts of two phases  $\alpha$  and  $\beta$  that are in equilibrium, we measure the distances  $l_\alpha$  and  $l_\beta$  along the horizontal tie line, and then use the lever rule (Fig. 5C.9):

$$n_\alpha l_\alpha = n_\beta l_\beta \quad \text{Lever rule} \quad (5C.6)$$

Here  $n_\alpha$  is the amount of phase  $\alpha$  and  $n_\beta$  the amount of phase  $\beta$ . In the case illustrated in Fig. 5C.9, because  $l_\beta \approx 2l_\alpha$ , the amount of phase  $\alpha$  is about twice the amount of phase  $\beta$ .

### Justification 5C.1 The lever rule

To prove the lever rule we write the total amount of A and B molecules as  $n = n_\alpha + n_\beta$ , where  $n_\alpha$  is the amount of molecules in phase  $\alpha$  and  $n_\beta$  the amount in phase  $\beta$ . The mole fraction of A in phase  $\alpha$  is  $x_{A,\alpha}$ , so the amount of A in that phase is

$n_\alpha x_{A,\alpha}$ . Similarly, the amount of A in phase  $\beta$  is  $n_\beta x_{A,\beta}$ . The total amount of A is therefore

$$n_A = n_\alpha x_{A,\alpha} + n_\beta x_{A,\beta}$$

Let the composition of the entire mixture be expressed by the mole fraction  $z_A$  (this is the label on the horizontal axis, and reflects how the sample is prepared). The total amount of A molecules is therefore

$$n_A = n z_A = n_\alpha z_A + n_\beta z_A$$

By equating these two expressions it follows that

$$n_\alpha (x_{A,\alpha} - z_A) = n_\beta (z_A - x_{A,\beta})$$

which corresponds to eqn 5C.6.

**Figure 5C.9** The lever rule. The distances  $l_\alpha$  and  $l_\beta$  are used to find the proportions of the amounts of phases  $\alpha$  (such as vapour) and  $\beta$  (for example, liquid) present at equilibrium. The lever rule is so called because a similar rule relates the masses at two ends of a lever to their distances from a pivot ( $m_\alpha l_\alpha = m_\beta l_\beta$  for balance).

### Brief illustration 5C.2 The lever rule

At  $p_1$  in Fig. 5C.5, the ratio  $l_{\text{vap}}/l_{\text{liq}}$  is almost infinite for this tie line, so  $n_{\text{liq}}/n_{\text{vap}}$  is also almost infinite, and there is only a trace of vapour present. When the pressure is reduced to  $p_2$ , the value of  $l_{\text{vap}}/l_{\text{liq}}$  is about 0.3, so  $n_{\text{liq}}/n_{\text{vap}} \approx 0.3$  and the amount of liquid is about 0.3 times the amount of vapour. When the pressure has been reduced to  $p_3$ , the sample is almost completely gaseous and because  $l_{\text{vap}}/l_{\text{liq}} \approx 0$  we conclude that there is only a trace of liquid present.

**Self-test 5C.3** Suppose that in a phase diagram, when the sample was prepared with the mole fraction of component A equal to 0.40 it was found that the compositions of the two phases in equilibrium corresponded to the mole fractions  $x_{A,\alpha} = 0.60$  and  $x_{A,\beta} = 0.20$ . What is the ratio of amounts of the two phases?

Answer:  $n_\alpha/n_\beta = 1.0$

## 5C.2 Temperature–composition diagrams

To discuss distillation we need a **temperature–composition diagram**, a phase diagram in which the boundaries show the composition of the phases that are in equilibrium at various temperatures (and a given pressure, typically 1 atm). An example is shown in Fig. 5C.10. Note that the liquid phase now lies in the lower part of the diagram.

### (a) The distillation of mixtures

Consider what happens when a liquid of composition  $a_1$  in Fig. 5C.10 is heated. It boils when the temperature reaches  $T_2$ . Then the liquid has composition  $a_2$  (the same as  $a_1$ ) and the vapour (which is present only as a trace) has composition  $a'_2$ . The vapour is richer in the more volatile component A (the component with the lower boiling point). From the location of  $a_2$ , we can state the vapour's composition at the boiling point, and from the location of the tie line joining  $a_2$  and  $a'_2$  we can read off the boiling temperature ( $T_2$ ) of the original liquid mixture.

In a **simple distillation**, the vapour is withdrawn and condensed. This technique is used to separate a volatile liquid from a non-volatile solute or solid. In **fractional distillation**, the boiling and condensation cycle is repeated successively. This technique is used to separate volatile liquids. We can follow the changes that occur by seeing what happens when the first condensate of composition  $a_3$  is reheated. The phase diagram shows that this mixture boils at  $T_3$  and yields a vapour of composition  $a'_3$ , which is even richer in the more volatile component. That vapour is drawn off, and the first drop condenses to a liquid of composition  $a_4$ . The cycle can then be repeated until

**Figure 5C.10** The temperature–composition diagram corresponding to an ideal mixture with the component A more volatile than component B. Successive boilings and condensations of a liquid originally of composition  $a_1$  lead to a condensate that is pure A. The separation technique is called fractional distillation.

in due course almost pure A is obtained in the vapour and pure B remains in the liquid.

The efficiency of a fractionating column is expressed in terms of the number of **theoretical plates**, the number of effective vaporization and condensation steps that are required to achieve a condensate of given composition from a given distillate.

### Brief illustration 5C.3 Theoretical plates

To achieve the degree of separation shown in Fig. 5C.11a, the fractionating column must correspond to three theoretical plates. To achieve the same separation for the system shown in Fig. 5C.11b, in which the components have more similar partial pressures, the fractionating column must be designed to correspond to five theoretical plates.

**Figure 5C.11** The number of theoretical plates is the number of steps needed to bring about a specified degree of separation of two components in a mixture. The two systems shown correspond to (a) 3, (b) 5 theoretical plates.

**Self-test 5C.4** Refer to Fig. 5C.11b: suppose the composition of the mixture corresponds to  $z_A = 0.1$ ; how many theoretical plates would be required to achieve a composition  $z_A = 0.9$ ?

Answer: 5

## (b) Azeotropes

Although many liquids have temperature–composition phase diagrams resembling the ideal version in Fig. 5C.10, in a number of important cases there are marked deviations. A maximum in the phase diagram (Fig. 5C.12) may occur when the favourable interactions between A and B molecules reduce the vapour pressure of the mixture below the ideal value and so raise its boiling temperature: in effect, the A–B interactions stabilize the liquid. In such cases the excess Gibbs energy,  $G^E$  (Topic 5B), is negative (more favourable to mixing than ideal).

**Figure 5C.12** A high-boiling azeotrope. When the liquid of composition  $a$  is distilled, the composition of the remaining liquid changes towards  $b$  but no further.

Phase diagrams showing a minimum (Fig. 5C.13) indicate that the mixture is destabilized relative to the ideal solution, the A–B interactions then being unfavourable; in this case, the boiling temperature is lowered. For such mixtures  $G^E$  is positive (less favourable to mixing than ideal), and there may be contributions from both enthalpy and entropy effects.

Deviations from ideality are not always so strong as to lead to a maximum or minimum in the phase diagram, but when they do there are important consequences for distillation. Consider a liquid of composition  $a$  on the right of the maximum in Fig. 5C.12. The vapour (at  $a'_2$ ) of the boiling mixture (at  $a_2$ ) is richer in A. If that vapour is removed (and condensed elsewhere), then the remaining liquid will move to a composition that is richer in B, such as that represented by  $a_3$ , and the vapour in equilibrium with this mixture will have composition  $a'_2$ . As that vapour is removed, the composition of the boiling liquid shifts to a point such as  $a_4$ , and the composition of the vapour shifts to  $a'_4$ . Hence, as evaporation proceeds, the composition of the remaining liquid shifts towards B as A is drawn off. The boiling point of the liquid rises, and the vapour becomes richer in

**Figure 5C.13** A low-boiling azeotrope. When the mixture at  $a$  is fractionally distilled, the vapour in equilibrium in the fractionating column moves towards  $b$  and then remains unchanged.

B. When so much A has been evaporated that the liquid has reached the composition  $b$ , the vapour has the same composition as the liquid. Evaporation then occurs without change of composition. The mixture is said to form an **azeotrope**.<sup>1</sup> When the azeotropic composition has been reached, distillation cannot separate the two liquids because the condensate has the same composition as the azeotropic liquid.

The system shown in Fig. 5C.13 is also azeotropic, but shows its azeotropy in a different way. Suppose we start with a mixture of composition  $a_1$ , and follow the changes in the composition of the vapour that rises through a fractionating column (essentially a vertical glass tube packed with glass rings to give a large surface area). The mixture boils at  $a_2$  to give a vapour of composition  $a'_2$ . This vapour condenses in the column to a liquid of the same composition (now marked  $a_3$ ). That liquid reaches equilibrium with its vapour at  $a'_3$ , which condenses higher up the tube to give a liquid of the same composition, which we now call  $a_4$ . The fractionation therefore shifts the vapour towards the azeotropic composition at  $b$ , but not beyond, and the azeotropic vapour emerges from the top of the column.

#### Brief illustration 5C.4 Azeotropes

Examples of the behaviour of the type shown in Fig. 5C.12 include (a) trichloromethane/propanone and (b) nitric acid/water mixtures. Hydrochloric acid/water is azeotropic at 80 per cent by mass of water and boils unchanged at 108.6 °C. Examples of the behaviour of the type shown in Fig. 5C.13 include (c) dioxane/water and (d) ethanol/water mixtures. Ethanol/water boils unchanged when the water content is 4 per cent by mass and the temperature is 78 °C.

**Self-test 5C.5** Suggest a molecular interpretation of the two types of behaviour.

Answer: (a,b) favourable A–B interactions; (c,d) unfavourable A–B interactions

### (c) Immiscible liquids

Finally we consider the distillation of two immiscible liquids, such as octane and water. At equilibrium, there is a tiny amount of A dissolved in B, and similarly a tiny amount of B dissolved in A: both liquids are saturated with the other component (Fig. 5C.14a). As a result, the total vapour pressure of the mixture is close to  $p = p_A^* + p_B^*$ . If the temperature is raised to the value at which this total vapour pressure is equal to the atmospheric pressure, boiling commences and the dissolved substances are purged from their solution. However, this boiling results in a vigorous agitation of the mixture, so each component is kept saturated in the other component, and the purging continues as

<sup>1</sup> The name comes from the Greek words for ‘boiling without changing’.

**Figure 5C.14** The distillation of (a) two immiscible liquids can be regarded as (b) the joint distillation of the separated components, and boiling occurs when the sum of the partial pressures equals the external pressure.

the very dilute solutions are replenished. This intimate contact is essential: two immiscible liquids heated in a container like that shown in Fig. 5C.14b would not boil at the same temperature. The presence of the saturated solutions means that the ‘mixture’ boils at a lower temperature than either component would alone because boiling begins when the total vapour pressure reaches 1 atm, not when either vapour pressure reaches 1 atm. This distinction is the basis of **steam distillation**, which enables some heat-sensitive, water-insoluble organic compounds to be distilled at a lower temperature than their normal boiling point. The only snag is that the composition of the condensate is in proportion to the vapour pressures of the components, so oils of low volatility distil in low abundance.

## 5C.3 Liquid–liquid phase diagrams

Now we consider temperature–composition diagrams for systems that consist of pairs of **partially miscible** liquids, which are liquids that do not mix in all proportions at all temperatures. An example is hexane and nitrobenzene. The same principles of interpretation apply as to liquid–vapour diagrams.

### (a) Phase separation

Suppose a small amount of a liquid B is added to a sample of another liquid A at a temperature  $T'$ . Liquid B dissolves completely, and the binary system remains a single phase. As more B is added, a stage comes at which no more dissolves. The sample now consists of two phases in equilibrium with each other, the most abundant one consisting of A saturated with B, the minor one a trace of B saturated with A. In the temperature–composition diagram drawn in Fig. 5C.15, the composition of the former is represented by the point  $a'$  and that of the latter by the point  $a''$ . The relative abundances of the two phases are given by the lever rule. When more B is added, A dissolves in it slightly. The compositions of the two phases in equilibrium remain  $a'$  and  $a''$ . A stage is reached when so much B is present

**Figure 5C.15** The temperature–composition diagram for a mixture of A and B. The region below the curve corresponds to the compositions and temperatures at which the liquids are partially miscible. The upper critical temperature,  $T_{uc}$ , is the temperature above which the two liquids are miscible in all proportions.

that it can dissolve all the A, and the system reverts to a single phase. The addition of more B now simply dilutes the solution, and from then on a single phase remains.

The composition of the two phases at equilibrium varies with the temperature. For the system shown in Fig. 5C.15, raising the temperature increases the miscibility of A and B. The two-phase region therefore becomes narrower because each phase in equilibrium is richer in its minor component: the A-rich phase is richer in B and the B-rich phase is richer in A. We can construct the entire phase diagram by repeating the observations at different temperatures and drawing the envelope of the two-phase region.

### Example 5C.2 Interpreting a liquid–liquid phase diagram

The phase diagram for the system nitrobenzene/hexane at 1 atm is shown in Fig. 5C.16. A mixture of 50 g of hexane

**Figure 5C.16** The temperature–composition diagram for hexane and nitrobenzene at 1 atm, with the points and lengths discussed in the text.

(0.59 mol  $C_6H_{14}$ ) and 50 g of nitrobenzene (0.41 mol  $C_6H_5NO_2$ ) was prepared at 290 K. What are the compositions of the phases, and in what proportions do they occur? To what temperature must the sample be heated in order to obtain a single phase?

**Method** The compositions of phases in equilibrium are given by the points where the tie-line representing the temperature intersects the phase boundary. Their proportions are given by the lever rule (eqn 5C.6). The temperature at which the components are completely miscible is found by following the isopleth upwards and noting the temperature at which it enters the one-phase region of the phase diagram.

**Answer** We denote hexane by H and nitrobenzene by N; refer to Fig. 5C.16. The point  $x_N=0.41$ ,  $T=290$  K occurs in the two-phase region of the phase diagram. The horizontal tie line cuts the phase boundary at  $x_N=0.35$  and  $x_N=0.83$ , so those are the compositions of the two phases. According to the lever rule, the ratio of amounts of each phase is equal to the ratio of the distances  $l_\alpha$  and  $l_\beta$ :

$$\frac{n_\alpha}{n_\beta} = \frac{l_\beta}{l_\alpha} = \frac{0.83 - 0.41}{0.41 - 0.35} = \frac{0.42}{0.06} = 7$$

That is, there is about 7 times more hexane-rich phase than nitrobenzene-rich phase. Heating the sample to 292 K takes it into the single-phase region. Because the phase diagram has been constructed experimentally, these conclusions are not based on any assumptions about ideality. They would be modified if the system were subjected to a different pressure.

**Self-test 5C.6** Repeat the problem for 50 g of hexane and 100 g of nitrobenzene at 273 K.

Answer:  $x_N=0.09$  and 0.95 in ratio 1:1.3; 294 K

### (b) Critical solution temperatures

The **upper critical solution temperature**,  $T_{uc}$  (or *upper consolute temperature*), is the highest temperature at which phase separation occurs. Above the upper critical temperature the two components are fully miscible. This temperature exists because the greater thermal motion overcomes any potential energy advantage in molecules of one type being close together. One example is the nitrobenzene/hexane system shown in Fig. 5C.16. An example of a solid solution is the palladium/hydrogen system, which shows two phases, one a solid solution of hydrogen in palladium and the other a palladium hydride, up to 300 °C but forms a single phase at higher temperatures (Fig. 5C.17).

The thermodynamic interpretation of the upper critical solution temperature focuses on the Gibbs energy of mixing and its variation with temperature. The simple model of a real solution (specifically, of a regular solution) discussed in Topic 5B results in a Gibbs energy of mixing that behaves as shown in

**Figure 5C.17** The phase diagram for palladium and palladium hydride, which has an upper critical temperature at 300°C.

Fig. 5C.18. Provided the parameter  $\xi$  introduced in eqn 5B.6 ( $H^E = \xi RT x_A x_B$ ) is greater than 2, the Gibbs energy of mixing has a double minimum. As a result, for  $\xi > 2$  we can expect phase separation to occur. The same model shows that the compositions corresponding to the minima are obtained by looking for the conditions at which  $\partial \Delta_{\text{mix}} G / \partial x = 0$ , and a simple manipulation of eqn 5B.7 ( $\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B + \xi x_A x_B)$ , with  $x_B = 1 - x_A$ ) shows that we have to solve

$$\begin{aligned} & \left( \frac{\partial \Delta_{\text{mix}} G}{\partial x_A} \right)_{T,p} \\ &= nRT \left( \frac{\partial \{ x_A \ln x_A + (1-x_A) \ln(1-x_A) + \xi x_A (1-x_A) \}}{\partial x_A} \right)_{T,p} \\ &= nRT \{ \ln x_A + 1 - \ln(1-x_A) - 1 + \xi(1-2x_A) \} \\ &= nRT \left\{ \ln \frac{x_A}{1-x_A} + \xi(1-2x_A) \right\} \end{aligned}$$

**Figure 5C.18** The temperature variation of the Gibbs energy of mixing of a system that is partially miscible at low temperatures. A system of composition in the region  $P=2$  forms two phases with compositions corresponding to the two local minima of the curve. This illustration is a duplicate of Fig. 5B.5.

The Gibbs-energy minima therefore occurs where

$$\ln \frac{x_A}{1-x_A} = -\xi(1-2x_A) \quad (5C.7)$$

This equation is an example of a ‘transcendental equation’, an equation that does not have a solution that can be expressed in a closed form. The solutions (the values of  $x_A$  that satisfy the equation) can be found numerically by using mathematical software or by plotting the terms on the left and right against  $x_A$  for a choice of values of  $\xi$  and identifying the values of  $x_A$  where the plots intersect (which is where the two expressions are equal) (Fig. 5C.19). The solutions found in this way are plotted in Fig. 5C.20. We see that, as  $\xi$  decreases, which can be interpreted as an increase in temperature provided the intermolecular forces remain constant (so that  $H^E$  remains constant), then the two minima move together and merge when  $\xi=2$ .

**Figure 5C.19** The graphical procedure for solving eqn 5C.7. When  $\xi < 2$ , the only intersection occurs at  $x=0$ . When  $\xi \geq 2$ , there are two solutions (those for  $\xi=3$  are marked).

**Figure 5C.20** The location of the phase boundary as computed on the basis of the  $\xi$ -parameter model introduced in Topic 5B.

### Brief illustration 5C.5 Phase separation

In the system composed of benzene and cyclohexane treated in *Example 5B.1* it is established that  $\xi = 1.13$ , so we do not expect a two-phase system; that is, the two components are completely miscible at the temperature of the experiment. The single solution of the equation

$$\ln \frac{x_A}{1-x_A} + 1.13(1-2x_A) = 0$$

is  $x_A = \frac{1}{2}$ , corresponding to a single minimum of the Gibbs energy of mixing, and there is no phase separation.

**Self-test 5C.7** Would phase separation be expected if the excess enthalpy were modelled by the expression  $H^E = \xi RT x_A^2 x_B^2$  (Fig. 5C.21a)?

**Figure 5C.21(a)** The excess enthalpy and (b) the graphical solution of the resulting equation for the minima of the Gibbs energy of mixing in *Self-test 5C.7*.

Answer: No, see Fig. 5C.21b

Some systems show a **lower critical solution temperature**,  $T_{lc}$  (or *lower consolute temperature*), below which they mix in all proportions and above which they form two phases. An example is water and triethylamine (Fig. 5C.22). In this case, at low temperatures the two components are more miscible because they form a weak complex; at higher temperatures the complexes break up and the two components are less miscible.

Some systems have both upper and lower critical solution temperatures. They occur because, after the weak complexes have been disrupted, leading to partial miscibility, the thermal motion at higher temperatures homogenizes the mixture again, just as in the case of ordinary partially miscible liquids. The most famous example is nicotine and water, which are partially miscible between 61 °C and 210 °C (Fig. 5C.23).

### (c) The distillation of partially miscible liquids

Consider a pair of liquids that are partially miscible and form a low-boiling azeotrope. This combination is quite common because both properties reflect the tendency of the two kinds

**Figure 5C.22** The temperature–composition diagram for water and triethylamine. This system shows a lower critical temperature at 292 K. The labels indicate the interpretation of the boundaries.

**Figure 5C.23** The temperature–composition diagram for water and nicotine, which has both upper and lower critical temperatures. Note the high temperatures for the liquid (especially the water): the diagram corresponds to a sample under pressure.

of molecule to avoid each other. There are two possibilities: one in which the liquids become fully miscible before they boil; the other in which boiling occurs before mixing is complete.

Figure 5C.24 shows the phase diagram for two components that become fully miscible before they boil. Distillation of a mixture of composition  $a_1$  leads to a vapour of composition  $b_1$ , which condenses to the completely miscible single-phase solution at  $b_2$ . Phase separation occurs only when this distillate is cooled to a point in the two-phase liquid region, such as  $b_3$ . This description applies only to the first drop of distillate. If distillation continues, the composition of the remaining liquid changes. In the end, when the whole sample has evaporated and condensed, the composition is back to  $a_1$ .

Figure 5C.25 shows the second possibility, in which there is no upper critical solution temperature. The distillate obtained from a liquid initially of composition  $a_1$  has composition  $b_3$  and is a two-phase mixture. One phase has composition  $b'_3$  and the other has composition  $b''_3$ .

**Figure 5C.24** The temperature–composition diagram for a binary system in which the upper critical temperature is less than the boiling point at all compositions. The mixture forms a low-boiling azeotrope.

**Figure 5C.25** The temperature–composition diagram for a binary system in which boiling occurs before the two liquids are fully miscible.

The behaviour of a system of composition represented by the isopleth  $e$  in Fig. 5C.25 is interesting. A system at  $e_1$  forms two phases, which persist (but with changing proportions) up to the boiling point at  $e_2$ . The vapour of this mixture has the same composition as the liquid (the liquid is an azeotrope). Similarly,

**Figure 5C.26** The points of the phase diagram in Fig. 5C.25 that are discussed in Example 5C.3.

condensing a vapour of composition  $e_3$  gives a two-phase liquid of the same overall composition. At a fixed temperature, the mixture vaporizes and condenses like a single substance.

### Example 5C.3 Interpreting a phase diagram

State the changes that occur when a mixture of composition  $x_B=0.95$  ( $a_1$ ) in Fig. 5C.26 is boiled and the vapour condensed.

**Method** The area in which the point lies gives the number of phases; the compositions of the phases are given by the points at the intersections of the horizontal tie line with the phase boundaries; the relative abundances are given by the lever rule.

**Answer** The initial point is in the one-phase region. When heated it boils at 350 K ( $a_2$ ) giving a vapour of composition  $x_B=0.66$  ( $b_1$ ). The liquid gets richer in B, and the last drop (of pure B) evaporates at 390 K. The boiling range of the liquid is therefore 350 to 390 K. If the initial vapour is drawn off, it has a composition  $x_B=0.66$ . This composition would be maintained if the sample were very large, but for a finite sample it shifts to higher values and ultimately to  $x_B=0.95$ . Cooling the distillate corresponds to moving down the  $x_B=0.66$  isopleth. At 330 K, for instance, the liquid phase has composition  $x_B=0.87$ , the vapour  $x_B=0.49$ ; their relative proportions are 1:3. At 320 K the sample consists of three phases: the vapour and two liquids. One liquid phase has composition  $x_B=0.30$ ; the other has composition  $x_B=0.80$  in the ratio 0.62:1. Further cooling moves the system into the two-phase region, and at 298 K the compositions are 0.20 and 0.90 in the ratio 0.82:1. As further distillate boils over, the overall composition of the distillate becomes richer in B. When the last drop has been condensed the phase composition is the same as at the beginning.

**Self-test 5C.8** Repeat the discussion, beginning at the point  $x_B=0.4$ ,  $T=298$  K.

## 5C.4 Liquid–solid phase diagrams

Knowledge of the temperature–composition diagrams for solid mixtures guides the design of important industrial processes, such as the manufacture of liquid crystal displays and semiconductors. In this section, we shall consider systems where solid and liquid phases may both be present at temperatures below the boiling point.

### (a) Eutectics

Consider the two-component liquid of composition  $a_1$  in Fig. 5C.27. The changes that occur as the system is cooled may be expressed as follows:

- $a_1 \rightarrow a_2$ . The system enters the two-phase region labelled ‘Liquid+B’. Pure solid B begins to come out of solution and the remaining liquid becomes richer in A

**Figure 5C.27** The temperature–composition phase diagram for two almost immiscible solids and their completely miscible liquids. Note the similarity to Fig. 5C.25. The isopleth through  $e_2$  corresponds to the eutectic composition, the mixture with lowest melting point.

- $a_2 \rightarrow a_3$ . More of the solid B forms, and the relative amounts of the solid and liquid (which are in equilibrium) are given by the lever rule. At this stage there are roughly equal amounts of each. The liquid phase is richer in A than before (its composition is given by  $b_3$ ) because some B has been deposited.
- $a_3 \rightarrow a_4$ . At the end of this step, there is less liquid than at  $a_3$ , and its composition is given by  $e_2$ . This liquid now freezes to give a two-phase system of pure B and pure A.

Physical interpretation

The isopleth at  $e_2$  in Fig. 5C.27 corresponds to the **eutectic composition**, the mixture with the lowest melting point.<sup>2</sup> A liquid with the eutectic composition freezes at a single temperature, without previously depositing solid A or B. A solid with the eutectic composition melts, without change of composition, at the lowest temperature of any mixture. Solutions of composition to the right of  $e_2$  deposit B as they cool, and solutions to the left deposit A: only the eutectic mixture (apart from pure A or pure B) solidifies at a single definite temperature without gradually unloading one or other of the components from the liquid.

One technologically important eutectic is solder, which in one form has mass composition of about 67 per cent tin and 33 per cent lead and melts at 183 °C. The eutectic formed by 23 per cent NaCl and 77 per cent H<sub>2</sub>O by mass melts at –21.1 °C. When salt is added to ice under isothermal conditions (for example, when spread on an icy road) the mixture melts if the temperature is above –21.1 °C (and the eutectic composition has been achieved). When salt is added to ice under adiabatic conditions (for example, when added to ice in a vacuum flask) the ice melts, but in doing so it absorbs heat from the rest of the mixture. The temperature of the system falls and, if enough salt

<sup>2</sup> The name comes from the Greek words for ‘easily melted’.

**Figure 5C.28** The cooling curves for the system shown in Fig. 5C.27. For isopleth  $a$ , the rate of cooling slows at  $a_2$  because solid B deposits from solution. There is a complete halt at  $a_4$  while the eutectic solidifies. This halt is longest for the eutectic isopleth,  $e$ . The eutectic halt shortens again for compositions beyond  $e$  (richer in A). Cooling curves are used to construct the phase diagram.

is added, cooling continues down to the eutectic temperature. Eutectic formation occurs in the great majority of binary alloy systems, and is of great importance for the microstructure of solid materials. Although a eutectic solid is a two-phase system, it crystallizes out in a nearly homogeneous mixture of microcrystals. The two microcrystalline phases can be distinguished by microscopy and structural techniques such as X-ray diffraction (Topic 18A).

Thermal analysis is a very useful practical way of detecting eutectics. We can see how it is used by considering the rate of cooling down the isopleth through  $a_1$  in Fig. 5C.27. The liquid cools steadily until it reaches  $a_2$ , when B begins to be deposited (Fig. 5C.28). Cooling is now slower because the solidification of B is exothermic and retards the cooling. When the remaining liquid reaches the eutectic composition, the temperature remains constant until the whole sample has solidified: this region of constant temperature is the eutectic halt. If the liquid has the eutectic composition  $e$  initially, the liquid cools steadily down to the freezing temperature of the eutectic, when there is a long **eutectic halt** as the entire sample solidifies (like the freezing of a pure liquid).

#### Brief illustration 5C.6 Interpreting a binary phase diagram

Figure 5C.29 is the phase diagram for the binary system silver/tin. The regions have been labelled to show which each one represents. When a liquid of composition  $a$  is cooled, solid silver with dissolved tin begins to precipitate at  $a_1$  and the sample solidifies completely at  $a_2$ .

**Self-test 5C.9** Describe what happens when the sample of composition  $b$  is cooled.

**Figure 5C.29** The phase diagram for silver/tin discussed in *Brief illustration 5C.6*.

Answer: Solid Ag with dissolved Sn begins to precipitate at  $b_1$ , and the liquid becomes richer in Sn as the temperature falls further. At  $b_2$  solid  $\text{Ag}_3\text{Sn}$  begins to precipitate, and the liquid becomes richer in Sn. At  $b_3$  the system has its eutectic composition (a solid solution of Sn and  $\text{Ag}_3\text{Sn}$ ) and it freezes without further change in composition.

Monitoring the cooling curves at different overall compositions gives a clear indication of the structure of the phase diagram. The solid–liquid boundary is given by the points at which the rate of cooling changes. The longest eutectic halt gives the location of the eutectic composition and its melting temperature.

### (b) Reacting systems

Many binary mixtures react to produce compounds, and technologically important examples of this behaviour include the Group 13/15 (III/V) semiconductors, such as the gallium arsenide system, which forms the compound GaAs. Although three constituents are present, there are only two components because GaAs is formed from the reaction  $\text{Ga} + \text{As} \rightarrow \text{GaAs}$ . We shall illustrate some of the principles involved with a system that forms a compound C that also forms eutectic mixtures with the species A and B (Fig. 5C.30).

A system prepared by mixing an excess of B with A consists of C and unreacted B. This is a binary B, C system, which we suppose forms a eutectic. The principal change from the eutectic phase diagram in Fig. 5C.27 is that the whole of the phase diagram is squeezed into the range of compositions lying between equal amounts of A and B ( $x_B=0.5$ , marked C in Fig. 5C.30) and pure B. The interpretation of the information in the diagram is obtained in the same way as for Fig. 5C.27. The solid deposited on cooling along the isopleth  $a$  is the compound C. At temperatures below  $a_4$  there are two solid phases, one consisting of C and the other of B. The pure compound C melts **congruently**, that is, the composition of the liquid it forms is the same as that of the solid compound.

**Figure 5C.30** The phase diagram for a system in which A and B react to form a compound  $C = AB$ . This resembles two versions of Fig. 5C.27 in each half of the diagram. The constituent C is a true compound, not just an equimolar mixture.

### (c) Incongruent melting

In some cases the compound C is not stable as a liquid. An example is the alloy  $\text{Na}_2\text{K}$ , which survives only as a solid (Fig. 5C.31). Consider what happens as a liquid at  $a_1$  is cooled:

- $a_1 \rightarrow a_2$ . A solid solution rich in Na is deposited, and the remaining liquid is richer in K.
- $a_2 \rightarrow$  just below  $a_3$ . The sample is now entirely solid and consists of a solid solution rich in Na and solid  $\text{Na}_2\text{K}$ .

Now consider the isopleth through  $b_1$ :

- $b_1 \rightarrow b_2$ . No obvious change occurs until the phase boundary is reached at  $b_2$  when a solid solution rich in Na begins to deposit.

Physical interpretation

**Figure 5C.31** The phase diagram for an actual system (sodium and potassium) like that shown in Fig. 5C.30, but with two differences. One is that the compound is  $\text{Na}_2\text{K}$ , corresponding to  $\text{A}_2\text{B}$  and not  $\text{AB}$  as in that illustration. The second is that the compound exists only as the solid, not as the liquid. The transformation of the compound at its melting point is an example of incongruent melting.

- $b_2 \rightarrow b_3$ . A solid solution rich in Na deposits, but at  $b_3$  a reaction occurs to form  $\text{Na}_2\text{K}$ : this compound is formed by the K atoms diffusing into the solid Na.
- $b_3$ . At  $b_3$ , three phases are in mutual equilibrium: the liquid, the compound  $\text{Na}_2\text{K}$ , and a solid solution rich in Na. The horizontal line representing this three-phase equilibrium is called a **peritectic line**. At this stage the liquid Na/K mixture is in equilibrium with a little solid  $\text{Na}_2\text{K}$ , but there is still no liquid compound
- $b_3 \rightarrow b_4$ . As cooling continues, the amount of solid compound increases until at  $b_4$  the liquid reaches its eutectic composition. It then solidifies to give a two-phase solid consisting of a solid solution rich in K and solid  $\text{Na}_2\text{K}$ .

Physical interpretation

If the solid is reheated, the sequence of events is reversed. No liquid  $\text{Na}_2\text{K}$  forms at any stage because it is too unstable to exist as a liquid. This behaviour is an example of **incongruent melting**, in which a compound melts into its components and does not itself form a liquid phase.

## Checklist of concepts

- 1. Raoult's law is used to calculate the total vapour pressure of a binary system of two volatile liquids.
- 2. The composition of the vapour in equilibrium with a binary mixture is calculated by using Dalton's law.
- 3. The composition of the vapour and the liquid phase in equilibrium are located at each end of a tie line.
- 4. The **lever rule** is used to deduce the relative abundances of each phase in equilibrium.
- 5. A phase diagram can be used to discuss the process of **fractional distillation**.
- 6. Depending on the relative strengths of the intermolecular forces, high- or low-boiling **azeotropes** may be formed.
- 7. The vapour pressure of a system composed of immiscible liquids is the sum of the vapour pressures of the pure liquids.
- 8. A phase diagram may be used to discuss the distillation of partially miscible liquids.
- 9. Phase separation of partially miscible liquids may occur when the temperature is below the upper critical solution temperature or above the lower critical solution temperature; the process may be discussed in terms of the model of a regular solution.
- 10. A phase diagram summarizes the temperature–composition properties of a binary system with solid and liquid phases; at the **eutectic composition** the liquid phase solidifies without change of composition.
- 11. The phase equilibria of binary systems in which the components react may also be summarized by a phase diagram.
- 12. In some cases, a solid compound does not survive melting.

### ► Why do you need to know this material?

Ternary phase diagrams have become important in materials science as more complex materials are investigated, such as the ceramics found to have superconducting properties.

### ► What is the key idea?

A phase diagram is a map showing the conditions under which each phase of a system is the most stable.

### ► What do you need to know already?

It would be helpful to review the interpretation of two-component phase diagrams (Topic 5C) and the phase rule (Topic 5A). The interpretation of the phase diagrams presented here uses the lever rule (Topic 5C).

This short Topic is a brief introduction to the depiction of phases of systems of three components. In terms of the phase rule (Topic 5A),  $C=3$ , so  $F=5-P$ . If we restrict systems to constant temperature and pressure, two degrees of freedom are discarded and we are left with  $F''=3-P$ . An area on a ternary phase diagram therefore represents a region where a single phase is present, a line represents the equilibrium between two phases of varying composition, and a point corresponds to a composition at which three phases are present in equilibrium.

## 5D.1 Triangular phase diagrams

The mole fractions of the three components of a ternary system satisfy  $x_A + x_B + x_C = 1$ . A phase diagram drawn as an equilateral triangle ensures that this property is satisfied automatically because the sum of the distances to a point inside an equilateral triangle of side 1 and measured parallel to the edges is equal to 1 (Fig. 5D.1).

Figure 5D.1 shows how this approach works in practice. The edge AB corresponds to  $x_C=0$ , and likewise for the other two edges. Hence, each of the three edges corresponds to one of the three binary systems (A,B), (B,C), and (C,A). An interior point corresponds to a system in which all three components are present. The point P, for instance, represents  $x_A=0.50$ ,  $x_B=0.10$ ,  $x_C=0.40$ .

Any point on a straight line joining an apex to a point on the opposite edge (the broken line in Fig. 5D.1) represents a composition that is progressively richer in A the closer the point is to the A apex but for which the concentration ratio B:C remains constant. Therefore, if we wish to represent the changing composition of a system as A is added, we draw a line from the A apex to the point on BC representing the initial binary system. Any ternary system formed by adding A then lies at some point on this line.

**Figure 5D.1** The triangular coordinates used for the discussion of three-component systems. Each edge corresponds to a binary system. All points along the dotted line *a* correspond to mole fractions of C and B in the same ratio.

**Brief illustration 5D.1** The representation of composition

The following points are represented on Fig. 5D.2:

Point	$x_A$	$x_B$	$x_C$
<i>a</i>	0.20	0.80	0
<i>b</i>	0.42	0.26	0.32
<i>c</i>	0.80	0.10	0.10
<i>d</i>	0.10	0.20	0.70
<i>e</i>	0.20	0.40	0.40
<i>f</i>	0.30	0.60	0.10

Note that the points *d*, *e*, *f* have  $x_A/x_B=0.50$  and lie on a straight line.

**Figure 5D.2** The points referred to in *Brief illustration 5D.1* (black) and *Self-test 5D.1* (blue).

**Self-test 5D.1** Mark the following points on the triangle.

Point	$x_A$	$x_B$	$x_C$
<i>g</i>	0.25	0.25	0.50
<i>h</i>	0.50	0.25	0.25
<i>i</i>	0.80	0	0.20
<i>j</i>	0.60	0.25	0.15
<i>k</i>	0.20	0.75	0.05

Answer: See Fig. 5D.2.

A single triangle represents the equilibria when one of the discarded degrees of freedom (the temperature, for instance) has a certain value. Different temperatures give rise to different equilibrium behaviour and therefore different triangular phase diagrams. Each one may therefore be regarded as a horizontal slice through a three-dimensional triangular prism, such as that shown in Fig. 5D.3.

**Figure 5D.3** When temperature is included as a variable, the phase diagram becomes a triangular prism. Horizontal sections through the prism correspond to the triangular phase diagrams being discussed.

## 5D.2 Ternary systems

Ternary phase diagrams are widely used in metallurgy and materials science in general. Although they can become quite complex, they can be interpreted in much the same way as binary diagrams. Here we give two examples.

### (a) Partially miscible liquids

The phase diagram for a ternary system in which *W* (in due course: water) and *A* (in due course: acetic acid) are fully miscible, *A* and *C* (in due course: chloroform) are fully miscible, but *W* and *C* are only partially miscible is shown in Fig. 5D.4. This illustration is for the system water/acetic acid/chloroform at room temperature, which behaves in this way. It shows that the two fully miscible pairs, (*A*,*W*) and (*A*,*C*), form single-phase

**Figure 5D.4** The phase diagram, at fixed temperature and pressure, of the three-component system acetic acid, chloroform, and water. Only some of the tie lines have been drawn in the two-phase region. All points along the line *a* correspond to chloroform and water present in the same ratio.

regions and that (W,C) system (along the base of the triangle) has a two-phase region. The base of the triangle corresponds to one of the horizontal lines in a two-component phase diagram. The tie lines in the two-phase regions are constructed experimentally by determining the compositions of the two phases that are in equilibrium, marking them on the diagram, and then joining them with a straight line.

A single-phase system is formed when enough A is added to the binary (W,C) mixture. This effect is shown by following the line *a* in Fig. 5D.4:

- $a_1$ . The system consists of two phases and the relative amounts of the two phases can be read off by using the lever rule.
- $a_1 \rightarrow a_2$ . The addition of A takes the system along the line joining  $a_1$  to the A apex. At  $a_2$  the solution still has two phases, but there is slightly more W in the largely C phase (represented by the point  $a_2'$ ) and more C in the largely W phase  $a_2''$  because the presence of A helps both to dissolve. The phase diagram shows that there is more A in the W-rich phase than in the C-rich phase ( $a_2'$  is closer than ( $a_2''$ ) to the A apex).
- $a_2 \rightarrow a_3$ . At  $a_3$  two phases are present, but the C-rich layer is present only as a trace (lever rule).
- $a_3 \rightarrow a_4$ . Further addition of A takes the system towards and beyond  $a_4$ , and only a single phase is present.

Physical interpretation

### Brief illustration 5D.2 Partially miscible liquids

Suppose we have a mixture of water (W in Fig. 5D.4) and chloroform (C) with  $x_W=0.40$  and  $x_C=0.60$ , and acetic acid (A) is added to it. The relative proportions of A and C remain constant, so the point representing the overall composition moves along the straight line *b* from  $x_C=0.60$  on the base to the acetic acid apex. The initial composition is in a two-phase region: one phase has the composition  $(x_W, x_C, x_A)=(0.95, 0.05, 0)$  and the other has composition  $(x_W, x_C, x_A)=(0.12, 0.88, 0)$ . When sufficient acetic acid has been added to raise its mole fraction to 0.18 the system consists of two phases of composition  $(0.07, 0.82, 0.11)$  and  $(0.57, 0.20, 0.23)$  in almost equal abundance.

**Self-test 5D.2** Specify the system when enough acid has been added to raise its mole fraction to 0.34.

Answer: A trace of a phase of composition  $(0.12, 0.61, 0.27)$  and a dominating phase of composition  $(0.28, 0.37, 0.35)$

The point marked P in Fig. 5D.4 is called the **plait point**. It is yet another example of a critical point. At the plait point, the compositions of the two phases in equilibrium become identical. For convenience, the general interpretation of a triangular phase diagram is summarized in Fig. 5D.5.

**Figure 5D.5** The interpretation of a triangular phase diagram. The region inside the curved line consists of two phases, and the compositions of the two phases in equilibrium are given by the points at the ends of the tie lines (the tie lines are determined experimentally).

### (b) Ternary solids

The triangular phase diagram in Fig. 5D.6 is typical of that for a solid alloy with varying compositions of three metals, A, B, and C.

**Figure 5D.6** A simplified triangular phase diagram of the ternary system represented by a stainless steel composed of iron, chromium, and nickel.

### Brief illustration 5D.3 Stainless steel

Figure 5D.6 is a simplified version of the phase diagram for a stainless steel consisting of iron, chromium, and nickel. The axes are labelled with the mass percentage compositions instead of the mole fractions, but as the three percentages add up to 100 per cent, the interpretation of points in the triangle is essentially the same as for mole fractions. The point *a* corresponds to the composition 74 per cent Fe, 18 per cent Cr, and 8 per cent Ni. It corresponds to the most common form of stainless steel, '18-8 stainless steel'. The composition corresponding to point *b* lies in the two-phase region, one phase consisting of Cr and the other of the alloy  $\gamma$ -FeNi.

**Self-test 5D.3** Identify the composition represented by point *c*.

Answer: Three phases, Fe, Ni, and  $\gamma$ -FeNi

---

## Checklist of concepts

- 1. A phase diagram drawn as an equilateral triangle ensures that the property  $x_A + x_B + x_C = 1$  is satisfied automatically.
- 2. At the **plait point**, the compositions of the two phases in equilibrium are identical.

### ► Why do you need to know this material?

Ideal solutions are a good starting point for the discussion of mixtures, but to understand real solutions it is important to be able to describe deviations from ideal behaviour and to express them in terms of molecular interactions.

### ► What is the key idea?

The activity of a species, i.e. its effective concentration, helps to preserve the form of the expressions derived on the basis of ideal behaviour but extends their reach to real mixtures.

### ► What do you need to know already?

This Topic is based on the expression for chemical potential of a species derived from Raoult's and Henry's laws (Topic 5A). It also uses the formulation of a model of a regular solution introduced in Topic 5B. You need to be aware of the expression for the Gibbs energy of mixing of an ideal solution (Topic 5B).

In this Topic we see how to adjust the expressions developed in Topics 5A and 5B to take into account deviations from ideal behaviour. In Topic 3D it is remarked that a quantity called 'fugacity' takes into account the effects of gas imperfections in a

manner that resulted in the least upset of the form of equations. Here we see how the expressions encountered in the treatment of ideal solutions can also be preserved almost intact by introducing the concept of 'activity'. As in other Topics collected in this chapter, we denote the solvent by A, the solute by B, and a general component by J.

## 5E.1 The solvent activity

The general form of the chemical potential of a real or ideal solvent is given by a straightforward modification of eqn 5A.14 ( $\mu_A = \mu_A^* + RT \ln(p_A/p_A^*)$ , where  $p_A^*$  is the vapour pressure of pure A and  $p_A$  is the vapour pressure of A when it is a component of a solution). The solvent in an ideal solution obeys Raoult's law (Topic 5A,  $p_A = x_A p_A^*$ ) at all concentrations and we can express the chemical potential as eqn 5A.22 (that is, as  $\mu_A = \mu_A^* + RT \ln x_A$ ). The form of this relation can be preserved when the solution does not obey Raoult's law by writing

$$\mu_A = \mu_A^* + RT \ln a_A \quad \text{Definition} \quad \text{Activity of solvent} \quad (5E.1)$$

The quantity  $a_A$  is the **activity** of A, a kind of 'effective' mole fraction, just as the fugacity is an effective pressure.

Because eqn 5E.1 is true for both real and ideal solutions (the only approximation being the use of pressures rather than fugacities), we can conclude by comparing it with  $\mu_A = \mu_A^* + RT \ln(p_A/p_A^*)$  that

$$a_A = \frac{p_A}{p_A^*} \quad \text{Measurement} \quad \text{Activity of solvent} \quad (5E.2)$$

We see that there is nothing mysterious about the activity of a solvent: it can be determined experimentally simply by measuring the vapour pressure and then using eqn 5E.2.

### Brief illustration 5E.1 Solvent activity

The vapour pressure of 0.500 M  $\text{KNO}_3(\text{aq})$  at 100 °C is 99.95 kPa, so the activity of water in the solution at this temperature is

$$a_A = \frac{99.95 \text{ kPa}}{101.325 \text{ kPa}} = 0.9864$$

**Self-test 5E.1** The vapour pressure of water in a saturated solution of calcium nitrate at 20 °C is 1.381 kPa; the vapour pressure of pure water at that temperature is 2.3393 kPa. What is the activity of water in this solution?

Answer: 0.5903

Because all solvents obey Raoult's law more closely as the concentration of solute approaches zero, the activity of the solvent approaches the mole fraction as  $x_A \rightarrow 1$ :

$$a_A \rightarrow x_A \text{ as } x_A \rightarrow 1 \quad (5E.3)$$

A convenient way of expressing this convergence is to introduce the **activity coefficient**,  $\gamma$  (gamma), by the definition

$$a_A = \gamma_A x_A \quad \gamma_A \rightarrow 1 \text{ as } x_A \rightarrow 1$$

*Definition* Activity coefficient of solvent (5E.4)

at all temperatures and pressures. The chemical potential of the solvent is then

$$\mu_A = \mu_A^* + RT \ln x_A + RT \ln \gamma_A$$

*Chemical potential of solvent* (5E.5)

The standard state of the solvent is established when  $x_A = 1$  and the pressure is 1 bar.

## 5E.2 The solute activity

The problem with defining activity coefficients and standard states for solutes is that they approach ideal-dilute (Henry's law) behaviour as  $x_B \rightarrow 0$ , not as  $x_B \rightarrow 1$  (corresponding to pure solute). We shall show how to set up the definitions for a solute that obeys Henry's law exactly, and then show how to allow for deviations.

### (a) Ideal-dilute solutions

A solute B that satisfies Henry's law (Topic 5A) has a vapour pressure given by  $p_B = K_B x_B$ , where  $K_B$  is an empirical constant. In this case, the chemical potential of B is

$$\mu_B = \mu_B^* + RT \ln \frac{p_B}{p_B^*} = \mu_B^* + RT \ln \frac{K_B}{p_B^*} + RT \ln x_B \quad (5E.6)$$

Both  $K_B$  and  $p_B^*$  are characteristics of the solute, so the second term may be combined with the first to give a new standard chemical potential,  $\mu_B^\ominus$ .

$$\mu_B^\ominus = \mu_B^* + RT \ln \frac{K_B}{p_B^*} \quad (5E.7)$$

It then follows that the chemical potential of a solute in an ideal-dilute solution is related to its mole fraction by

$$\mu_B = \mu_B^\ominus + RT \ln x_B \quad (5E.8)$$

If the solution is ideal,  $K_B = p_B^*$  and eqn 5E.7 reduces to  $\mu_B^\ominus = \mu_B^*$ , as we should expect.

### Brief illustration 5E.2 The solute activity

In *Example 5A.4* it is established that in a mixture of propanone (acetone, A) and trichloromethane (chloroform, C) at 298 K  $K_{\text{propanone}} = 23.3$  kPa whereas  $p_{\text{propanone}}^* = 4.63$  kPa. It follows from eqn 5E.7 that

$$\begin{aligned} \mu_{\text{propanone}}^\ominus &= \mu_{\text{propanone}}^* + RT \ln \frac{23.3 \text{ kPa}}{4.63 \text{ kPa}} \\ &= \mu_{\text{propanone}}^* + (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \times \ln \frac{23.3}{4.63} \\ &= \mu_{\text{propanone}}^* + 4.00 \text{ kJ mol}^{-1} \end{aligned}$$

and the standard value differs from the value for the pure liquid by 4.00 kJ mol<sup>-1</sup>.

**Self-test 5E.2** In the same mixture, with trichloromethane treated as the solute,  $K_{\text{trichloromethane}} = 22.0$  kPa, whereas  $p_{\text{trichloromethane}}^* = 36.4$  kPa. What is the relation between the standard chemical potential and that of the pure liquid?

Answer:  $\mu_{\text{trichloromethane}}^\ominus = \mu_{\text{trichloromethane}}^* - 1.25 \text{ kJ mol}^{-1}$

### (b) Real solutes

We now permit deviations from ideal-dilute, Henry's law behaviour. For the solute, we introduce  $a_B$  in place of  $x_B$  in eqn 5E.8, and obtain

$$\mu_B = \mu_B^\ominus + RT \ln a_B \quad \text{Definition Activity of solute (5E.9)}$$

The standard state remains unchanged in this last stage, and all the deviations from ideality are captured in the activity  $a_B$ . The value of the activity at any concentration can be obtained in the same way as for the solvent, but in place of eqn 5E.2 we use

$$a_B = \frac{p_B}{K_B} \quad \text{Measurement Activity of solute (5E.10)}$$

As we did for the solvent, it is sensible to introduce an activity coefficient through

$$a_B = \gamma_B x_B \quad \text{Definition Activity coefficient of solute (5E.11)}$$

Now all the deviations from ideality are captured in the activity coefficient  $\gamma_B$ . Because the solute obeys Henry's law as its concentration goes to zero, it follows that

$$a_B \rightarrow x_B \text{ and } \gamma_B \rightarrow 1 \text{ as } x_B \rightarrow 0 \quad (5E.12)$$

at all temperatures and pressures. Deviations of the solute from ideality disappear as zero concentration is approached.

### Example 5E.1 Measuring activity

Use the following information to calculate the activity and activity coefficient of trichloromethane (chloroform, C) in propanone (acetone, A) at 25 °C, treating it first as a solvent and then as a solute.

$x_C$	0	0.20	0.40	0.60	0.80	1
$p_C/\text{kPa}$	0	4.7	11	18.9	26.7	36.4
$p_A/\text{kPa}$	46.3	33.3	23.3	12.3	4.9	0

**Method** For the activity of chloroform as a solvent (the Raoult's law activity), form  $a_C = p_C/p_C^*$  and  $\gamma_C = a_C/x_C$ . For its activity as a solute (the Henry's law activity), form  $a_C = p_C/K_C$  and  $\gamma_C = a_C/x_C$  with the new activity.

**Answer** Because  $p_C^* = 36.4 \text{ kPa}$  and  $K_C = 22.0 \text{ kPa}$ , we can construct the following tables. For instance, at  $x_C = 0.20$ , in the Raoult's law case we find  $a_C = (4.7 \text{ kPa})/(36.4 \text{ kPa}) = 0.13$  and  $\gamma_C = 0.13/0.20 = 0.65$ ; likewise, in the Henry's law case,  $a_C = (4.7 \text{ kPa})/(22.0 \text{ kPa}) = 0.21$  and  $\gamma_C = 0.21/0.20 = 1.05$ .

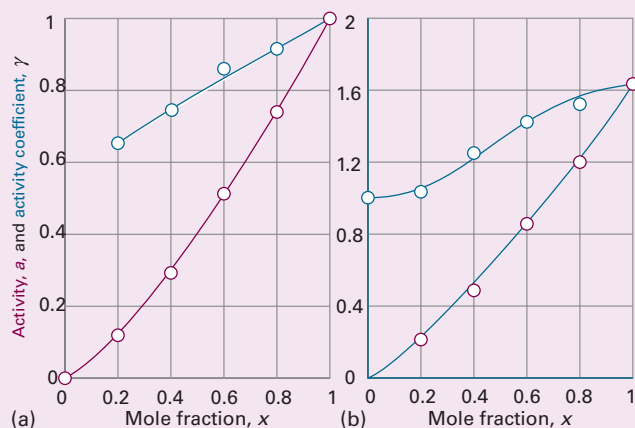

From Raoult's law (chloroform regarded as the solvent):

$a_C$	0	0.13	0.30	0.52	0.73	1.00
$\gamma_C$		0.65	0.75	0.87	0.91	1.00

From Henry's law (chloroform regarded as the solute):

$a_C$	0	0.21	0.50	0.86	1.21	1.65
$\gamma_C$	1	1.05	1.25	1.43	1.51	1.65

These values are plotted in Fig. 5E.1. Notice that  $\gamma_C \rightarrow 1$  as  $x_C \rightarrow 1$  in the Raoult's law case, but that  $\gamma_C \rightarrow 1$  as  $x_C \rightarrow 0$  in the Henry's law case.

**Figure 5E.1** The variation of activity and activity coefficient for a chloroform/acetone (trichloromethane/propanone) solution with composition according to (a) Raoult's law, (b) Henry's law.

**Self-test 5E.3** Calculate the activities and activity coefficients for acetone according to the two conventions.

Answer: At  $x_A = 0.60$ , for instance  $a_R = 0.50$ ;  $\gamma_R = 0.83$ ;  $a_H = 1.00$ ,  $\gamma_H = 1.67$

### (c) Activities in terms of molalities

The selection of a standard state is entirely arbitrary, so we are free to choose one that best suits our purpose and the description of the composition of the system. Because compositions are often expressed as molalities,  $b$ , in place of mole fractions it is convenient to write

$$\mu_B = \mu_B^\ominus + RT \ln b_B \quad (5E.13)$$

where  $\mu_B^\ominus$  has a different value from the standard values introduced earlier. According to this definition, the chemical potential of the solute has its standard value  $\mu_B^\ominus$  when the molality of B is equal to  $b^\ominus$  (that is, at  $1 \text{ mol kg}^{-1}$ ). Note that as  $b_B \rightarrow 0$ ,  $\mu_B \rightarrow \infty$ ; that is, as the solution becomes diluted, so the solute becomes increasingly stabilized. The practical consequence of this result is that it is very difficult to remove the last traces of a solute from a solution.

Now, as before, we incorporate deviations from ideality by introducing a dimensionless activity  $a_B$ , a dimensionless activity coefficient  $\gamma_B$ , and writing

$$a_B = \gamma_B \frac{b_B}{b^\ominus}, \text{ where } \gamma_B \rightarrow 1 \text{ as } b_B \rightarrow 0 \quad (5E.14)$$

at all temperatures and pressures. The standard state remains unchanged in this last stage and, as before, all the deviations from ideality are captured in the activity coefficient  $\gamma_B$ . We then arrive at the following succinct expression for the chemical potential of a real solute at any molality:

$$\mu_B = \mu_B^\ominus + RT \ln a_B \quad (5E.15)$$

### (d) The biological standard state

One important illustration of the ability to choose a standard state to suit the circumstances arises in biological applications. The conventional standard state of hydrogen ions (unit activity, corresponding to  $\text{pH} = 0$ )<sup>1</sup> is not appropriate to normal biological conditions. Therefore, in biochemistry it is common to adopt the **biological standard state**, in which  $\text{pH} = 7$  (an activity of  $10^{-7}$ , neutral solution) and to label the corresponding standard thermodynamic functions as  $G^\oplus$ ,  $H^\oplus$ ,  $\mu^\oplus$ , and  $S^\oplus$  (some texts use  $X^\ominus$ ).

<sup>1</sup> Recall from introductory chemistry courses that  $\text{pH} = -\log a(\text{H}_3\text{O}^+)$ .

To find the relation between the thermodynamic and biological standard values of the chemical potential of hydrogen ions we need to note from eqn 5E.15 that

$$\mu_{\text{H}^+} = \mu_{\text{H}^+}^{\ominus} + RT \ln a_{\text{H}^+} = \mu_{\text{H}^+}^{\ominus} - (RT \ln 10) \text{pH}$$

It follows that

$$\mu_{\text{H}^+}^{\oplus} = \mu_{\text{H}^+}^{\ominus} - 7RT \ln 10 \quad (5E.16)$$

Relation between standard state and biological standard state

### Brief illustration 5E.3 The biological standard state

At 298 K,  $7RT \ln 10 = 39.96 \text{ kJ mol}^{-1}$ , so the two standard values differ by about  $40 \text{ kJ mol}^{-1}$  and specifically  $\mu_{\text{H}^+}^{\oplus} = \mu_{\text{H}^+}^{\ominus} - 39.96 \text{ kJ mol}^{-1}$ . Thus, in a reaction of the form  $\text{A} + 2 \text{H}^+(\text{aq}) \rightarrow \text{B}$ , the standard and biological standard Gibbs energies are related as follows:

$$\begin{aligned} \Delta_r G^{\oplus} &= \mu_{\text{B}}^{\ominus} - \{\mu_{\text{A}}^{\ominus} + 2\mu_{\text{H}^+}^{\ominus}\} = \mu_{\text{B}}^{\ominus} - \{\mu_{\text{A}}^{\oplus} + 2\mu_{\text{H}^+}^{\oplus} - 14RT \ln 10\} \\ &= \mu_{\text{B}}^{\ominus} - \{\mu_{\text{A}}^{\oplus} + 2\mu_{\text{H}^+}^{\oplus}\} + 14RT \ln 10 = \Delta_r G^{\ominus} + 14RT \ln 10 \\ &= \Delta_r G^{\ominus} + 79.92 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test 5E.4** Find the relation between the standard and biological standard Gibbs energies of a reaction of the form  $\text{A} \rightarrow \text{B} + 3 \text{H}^+(\text{aq})$ .

Answer:  $\Delta_r G^{\oplus} = \Delta_r G^{\ominus} - 119.88 \text{ kJ mol}^{-1}$

## 5E.3 The activities of regular solutions

The material on regular solutions in Topic 5B gives further insight into the origin of deviations from Raoult's law and its relation to activity coefficients. The starting point is the model expression for the excess (molar) enthalpy (eqn 5B.6,  $H^{\text{E}} = \xi RT x_{\text{A}} x_{\text{B}}$ ) and its implication for the Gibbs energy of mixing for a regular solution. We show in the following *Justification* that for this model the activity coefficients are given by

$$\ln \gamma_{\text{A}} = \xi x_{\text{B}}^2 \quad \ln \gamma_{\text{B}} = \xi x_{\text{A}}^2 \quad \text{Margules equations} \quad (5E.17)$$

These relations are called the **Margules equations**.

### Justification 5E.1 The Margules equations

The Gibbs energy of mixing to form an ideal solution is

$$\Delta_{\text{mix}} G = nRT \{x_{\text{A}} \ln x_{\text{A}} + x_{\text{B}} \ln x_{\text{B}}\}$$

(This is eqn 5B.16 of Topic 5B.) The corresponding expression for a non-ideal solution is

$$\Delta_{\text{mix}} G = nRT \{x_{\text{A}} \ln a_{\text{A}} + x_{\text{B}} \ln a_{\text{B}}\}$$

This relation follows in the same way as for an ideal mixture but with activities in place of mole fractions. If each activity is replaced by  $\gamma x$ , this expression becomes

$$\begin{aligned} \Delta_{\text{mix}} G &= nRT \{x_{\text{A}} \ln x_{\text{A}} \gamma_{\text{A}} + x_{\text{B}} \ln x_{\text{B}} \gamma_{\text{B}}\} \\ &= nRT \{x_{\text{A}} \ln x_{\text{A}} + x_{\text{B}} \ln x_{\text{B}} + x_{\text{A}} \ln \gamma_{\text{A}} + x_{\text{B}} \ln \gamma_{\text{B}}\} \end{aligned}$$

Now we introduce the two expressions in eqn 5E.17, and use  $x_{\text{A}} + x_{\text{B}} = 1$ , which gives

$$\begin{aligned} \Delta_{\text{mix}} G &= nRT \{x_{\text{A}} \ln x_{\text{A}} + x_{\text{B}} \ln x_{\text{B}} + \xi x_{\text{A}} x_{\text{B}}^2 + \xi x_{\text{B}} x_{\text{A}}^2\} \\ &= nRT \{x_{\text{A}} \ln x_{\text{A}} + x_{\text{B}} \ln x_{\text{B}} + \xi x_{\text{A}} x_{\text{B}} (x_{\text{A}} + x_{\text{B}})\} \\ &= nRT \{x_{\text{A}} \ln x_{\text{A}} + x_{\text{B}} \ln x_{\text{B}} + \xi x_{\text{A}} x_{\text{B}}\} \end{aligned}$$

Note that the activity coefficients behave correctly for dilute solutions:  $\gamma_{\text{A}} \rightarrow 1$  as  $x_{\text{B}} \rightarrow 0$  and  $\gamma_{\text{B}} \rightarrow 1$  as  $x_{\text{A}} \rightarrow 0$ .

At this point we can use the Margules equations to write the activity of A as

$$a_{\text{A}} = \gamma_{\text{A}} x_{\text{A}} = x_{\text{A}} e^{\xi x_{\text{B}}^2} = x_{\text{A}} e^{\xi(1-x_{\text{A}})^2} \quad (5E.18)$$

with a similar expression for  $a_{\text{B}}$ . The activity of A, though, is just the ratio of the vapour pressure of A in the solution to the vapour pressure of pure A (eqn 5E.2,  $a_{\text{A}} = p_{\text{A}}/p_{\text{A}}^*$ ), so we can write

$$p_{\text{A}} = p_{\text{A}}^* x_{\text{A}} e^{\xi(1-x_{\text{A}})^2} \quad (5E.19)$$

This function is plotted in Fig. 5E.2. We see that

- When  $\xi = 0$ , corresponding to an ideal solution,  $p_{\text{A}} = p_{\text{A}}^* x_{\text{A}}$ , in accord with Raoult's law.
- Positive values of  $\xi$  (endothermic mixing, unfavourable solute–solvent interactions) give vapour pressures higher than ideal.
- Negative values of  $\xi$  (exothermic mixing, favourable solute–solvent interactions) give a lower vapour pressure.

Physical interpretation

All the plots of eqn 5E.19 approach linearity and coincide with the Raoult's law line as  $x_{\text{A}} \rightarrow 1$  and the exponential function in eqn 5E.19 approaches 1. When  $x_{\text{A}} \ll 1$ , eqn 5E.19 approaches

$$p_{\text{A}} = p_{\text{A}}^* x_{\text{A}} e^{\xi} \quad (5E.20)$$

This expression has the form of Henry's law once we identify  $K$  with  $e^{\xi} p_{\text{A}}^*$ , which is different for each solute–solvent system.

**Figure 5E.2** The vapour pressure of a mixture based on a model in which the excess enthalpy is proportional to  $\xi RTx_Ax_B$ . An ideal solution corresponds to  $\xi=0$  and gives a straight line, in accord with Raoult's law. Positive values of  $\xi$  give vapour pressures higher than ideal. Negative values of  $\xi$  give a lower vapour pressure.

#### Brief illustration 5E.4 The Margules equations

In *Example 5B.1* of Topic 5B it is established that  $\xi=1.13$  for a mixture of benzene and cyclohexane at 25 °C. Because  $\xi>0$  we can expect the vapour pressure of the mixture to be greater than its ideal value. The total vapour pressure of the mixture is therefore

$$p = p_{\text{benzene}}^* x_{\text{benzene}} e^{1.13(1-x_{\text{benzene}})^2} + p_{\text{cyclohexane}}^* x_{\text{cyclohexane}} e^{1.13(1-x_{\text{cyclohexane}})^2}$$

This expression is plotted in Fig. 5E.3a using  $p_{\text{benzene}}^* = 10.0 \text{ kPa}$  and  $p_{\text{cyclohexane}}^* = 10.4 \text{ kPa}$ .

**Figure 5E.3** The computed vapour pressure curves for a mixture of benzene and cyclohexane at 25 °C (a) as derived in *Brief illustration 5E.4* and (b) *Self-test 5E.5*.

**Self-test 5E.5** Suppose it is found that for a hypothetical mixture  $\xi=-1.13$ , but with other properties the same. Draw the vapour pressure diagram.

Answer: See Fig. 5E.3b

## Checklist of concepts

- 1. The **activity** is an effective concentration that preserves the form of the expression for the chemical potential. See Table 5E.1.
- 2. The chemical potential of a solute in an ideal–dilute solution is defined on the basis of Henry's law.
- 3. The activity of a solute takes into account departures from Henry's law behaviour.
- 4. An alternative approach to the definition of the solute activity is based on the molality of the solute.
- 5. The **biological standard state** of a species in solution is defined as pH=7 (and 1 bar).
- 6. The **Margules equations** relate the activities of the components of a model regular solution to its composition. They lead to expressions for the vapour pressures of the components of a regular solution.

**Table 5E.1** Activities and standard states: a summary\*

Component	Basis	Standard state	Activity	Limits
Solid or liquid		Pure, 1 bar	$a=1$	
Solvent	Raoult	Pure solvent, 1 bar	$a=p/p^*$ , $a=\gamma x$	$\gamma \rightarrow 1$ as $x \rightarrow 1$ (pure solvent)
Solute	Henry	(1) A hypothetical state of the pure solute	$a=p/K$ , $a=\gamma x$	$\gamma \rightarrow 1$ as $x \rightarrow 0$
		(2) A hypothetical state of the solute at molality $b^\ominus$	$a=\gamma b/b^\ominus$	$\gamma \rightarrow 1$ as $b \rightarrow 0$
Gas	Fugacity <sup>†</sup>	Pure, a hypothetical state of 1 bar and behaving as a perfect gas	$f=\gamma p$	$\gamma \rightarrow 1$ as $p \rightarrow 0$

\* In each case,  $\mu=\mu^\ominus+RT \ln a$ .

<sup>†</sup> Fugacity is discussed in Topic 3D.

## Checklist of equations

Property	Equation	Comment	Equation number
Chemical potential of solvent	$\mu_A = \mu_A^* + RT \ln a_A$	Definition	5E.1
Activity of solvent	$a_A = p_A/p_A^*$	$a_A \rightarrow x_A$ as $x_A \rightarrow 1$	5E.2
Activity coefficient of solvent	$a_A = \gamma_A x_A$	$\gamma_A \rightarrow 1$ as $x_A \rightarrow 1$	5E.4
Chemical potential of solute	$\mu_B = \mu_B^\ominus + RT \ln a_B$	Definition	5E.9
Activity of solute	$a_B = p_B/K_B$	$a_B \rightarrow x_B$ as $x_B \rightarrow 0$	5E.10
Activity coefficient of solute	$a_B = \gamma_B x_B$	$\gamma_B \rightarrow 1$ as $x_B \rightarrow 0$	5E.11
Conversion to biological standard state	$\mu_{\text{H}^+}^\ominus = \mu_{\text{H}^+}^\ominus - 7RT \ln 10$		5E.16

### ► Why do you need to know this material?

Interactions between ions are so strong that the approximation of replacing activities by molalities is valid only in very dilute solutions (less than 1 mmol kg<sup>-1</sup> in total ion concentration) and in precise work activities themselves must be used. We need, therefore, to pay special attention to the activities of ions in solution, especially in preparation for the discussion of electrochemical phenomena.

### ► What is the key idea?

The chemical potential of an ion is lowered as a result of its electrostatic interaction with its ionic atmosphere.

### ► What do you need to know already?

This Topic builds on the relation between chemical potential and mole fraction (Topic 5A) and on the relation between Gibbs free energy and non-expansion work (Topic 3D). If you intend to work through the derivation of the Debye–Hückel theory, you need to be familiar with some concepts from electrostatics, including the Coulomb potential and its relation to charge density through Poisson's equation (which is explained in the Topic); this Topic also draws on the Boltzmann distribution (Foundations B and, in much more detail, Topic 15A).

If the chemical potential of the cation M<sup>+</sup> is denoted  $\mu_+$  and that of the anion X<sup>-</sup> is denoted  $\mu_-$ , the total molar Gibbs energy of the ions in the electrically neutral solution is the sum of these partial molar quantities. The molar Gibbs energy of an *ideal* solution of such ions is

$$G_m^{\text{ideal}} = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} \quad (5F.1)$$

with  $\mu_j^{\text{ideal}} = \mu_j^\ominus + RT \ln x_j$ . However, for a *real* solution of M<sup>+</sup> and X<sup>-</sup> of the same molality we write  $\mu_j = \mu_j^\ominus + RT \ln a_j$  with  $a_j = \gamma_j x_j$ , which implies that  $\mu_j = \mu_j^{\text{ideal}} + RT \ln \gamma_j$ . It then follows that

$$\begin{aligned} G_m &= \mu_+ + \mu_- = \mu_+^{\text{ideal}} + \mu_-^{\text{ideal}} + RT \ln \gamma_+ + RT \ln \gamma_- \\ &= G_m^{\text{ideal}} + RT \ln \gamma_+ \gamma_- \end{aligned} \quad (5F.2)$$

All the deviations from ideality are contained in the last term.

## 5F.1 Mean activity coefficients

There is no experimental way of separating the product  $\gamma_+ \gamma_-$  into contributions from the cations and the anions. The best we can do experimentally is to assign responsibility for the non-ideality equally to both kinds of ion. Therefore, for a 1,1-electrolyte, we introduce the 'mean activity coefficient' as the geometric mean of the individual coefficients, where the geometric mean of  $x^p$  and  $y^q$  is  $(x^p y^q)^{1/(p+q)}$ . Thus:

$$\gamma_\pm = (\gamma_+ \gamma_-)^{1/2} \quad (5F.3)$$

and express the individual chemical potentials of the ions as

$$\mu_+ = \mu_+^{\text{ideal}} + RT \ln \gamma_\pm \quad \mu_- = \mu_-^{\text{ideal}} + RT \ln \gamma_\pm \quad (5F.4)$$

The sum of these two chemical potentials is the same as before, eqn 5F.2, but now the non-ideality is shared equally.

We can generalize this approach to the case of a compound M<sub>p</sub>X<sub>q</sub> that dissolves to give a solution of  $p$  cations and  $q$  anions from each formula unit. The molar Gibbs energy of the ions is the sum of their partial molar Gibbs energies:

$$G_m = p\mu_+ + q\mu_- = G_m^{\text{ideal}} + pRT \ln \gamma_+ + qRT \ln \gamma_- \quad (5F.5)$$

If we introduce the **mean activity coefficient** now defined in a more general way as

$$\gamma_{\pm} = (\gamma_+^p \gamma_-^q)^{1/s} \quad s = p + q \quad \text{Definition} \quad \text{Mean activity coefficient} \quad (5F.6)$$

and write the chemical potential of each ion as

$$\mu_i = \mu_i^{\text{ideal}} + RT \ln \gamma_{\pm} \quad (5F.7)$$

we get the same expression as in eqn 5F.2 for  $G_m$  when we write  $G_m = p\mu_+ + q\mu_-$ . However, both types of ion now share equal responsibility for the non-ideality.

### (a) The Debye–Hückel limiting law

The long range and strength of the Coulombic interaction between ions means that it is likely to be primarily responsible for the departures from ideality in ionic solutions and to dominate all the other contributions to non-ideality. This domination is the basis of the **Debye–Hückel theory** of ionic solutions, which was devised by Peter Debye and Erich Hückel in 1923. We give here a qualitative account of the theory and its principal conclusions. The calculation itself, which is a profound example of how a seemingly intractable problem can be formulated and then resolved by drawing on physical insight, is described in the following section.

Oppositely charged ions attract one another. As a result, anions are more likely to be found near cations in solution, and vice versa (Fig. 5F.1). Overall, the solution is electrically neutral, but near any given ion there is an excess of counter ions (ions of opposite charge). Averaged over time, counter ions are more likely to be found near any given ion. This time-averaged, spherical haze around the central ion, in which counter ions outnumber ions of the same charge as the central ion, has a net charge equal in magnitude but opposite in sign to that on

**Figure 5F.1** The picture underlying the Debye–Hückel theory is of a tendency for anions to be found around cations, and of cations to be found around anions (one such local clustering region is shown by the grey sphere). The ions are in ceaseless motion, and the diagram represents a snapshot of their motion. The solutions to which the theory applies are far less concentrated than shown here.

the central ion, and is called its **ionic atmosphere**. The energy, and therefore the chemical potential, of any given central ion is lowered as a result of its electrostatic interaction with its ionic atmosphere. This lowering of energy appears as the difference between the molar Gibbs energy  $G_m$  and the ideal value  $G_m^{\text{ideal}}$  of the solute, and hence can be identified with  $RT \ln \gamma_{\pm}$ . The stabilization of ions by their interaction with their ionic atmospheres is part of the explanation why chemists commonly use dilute solutions, in which the stabilization is less important, to achieve precipitation of ions from electrolyte solutions.

The model leads to the result that at very low concentrations the activity coefficient can be calculated from the **Debye–Hückel limiting law**

$$\log \gamma_{\pm} = -A |z_+ z_-| I^{1/2} \quad \text{Debye–Hückel limiting law} \quad (5F.8)$$

where  $A = 0.509$  for an aqueous solution at 25 °C and  $I$  is the dimensionless **ionic strength** of the solution:

$$I = \frac{1}{2} \sum_i z_i^2 (b_i / b^{\ominus}) \quad \text{Definition} \quad \text{Ionic strength} \quad (5F.9)$$

In this expression,  $z_i$  is the charge number of an ion  $i$  (positive for cations and negative for anions) and  $b_i$  is its molality. The ionic strength occurs widely wherever ionic solutions are discussed, as we shall see. The sum extends over all the ions present in the solution. For solutions consisting of two types of ion at molalities  $b_+$  and  $b_-$ ,

$$I = \frac{1}{2} (b_+ z_+^2 + b_- z_-^2) / b^{\ominus} \quad (5F.10)$$

The ionic strength emphasizes the charges of the ions because the charge numbers occur as their squares. Table 5F.1 summarizes the relation of ionic strength and molality in an easily usable form.

#### Brief illustration 5F.1 The limiting law

The mean activity coefficient of 5.0 mmol kg<sup>-1</sup> KCl(aq) at 25 °C is calculated by writing  $I = \frac{1}{2}(b_+ + b_-) / b^{\ominus} = b / b^{\ominus}$ , where  $b$  is the molality of the solution (and  $b_+ = b_- = b$ ). Then, from eqn 5F.8,

$$\log \gamma_{\pm} = -0.509 \times (5.0 \times 10^{-3})^{1/2} = -0.03 \dots$$

Hence,  $\gamma_{\pm} = 0.92$ . The experimental value is 0.927.

**Self-test 5F.1** Calculate the ionic strength and the mean activity coefficient of 1.00 mmol kg<sup>-1</sup> CaCl<sub>2</sub>(aq) at 25 °C.

Answer: 3.00 mmol kg<sup>-1</sup>, 0.880

The name ‘limiting law’ is applied to eqn 5F.8 because ionic solutions of moderate molalities may have activity

Table 5F.1 Ionic strength and molality,  $I = kb/b^\ominus$ 

$k$	$X^-$	$X^{2-}$	$X^{3-}$	$X^{4-}$
$M^+$	1	3	6	10
$M^{2+}$	3	4	15	12
$M^{3+}$	6	15	9	42
$M^{4+}$	10	12	42	16

For example, the ionic strength of an  $M_2X_3$  solution of molality  $b$ , which is understood to give  $M^{3+}$  and  $X^{2-}$  ions in solution is  $15b/b^\ominus$ .

Table 5F.2\* Mean activity coefficients in water at 298 K

$b/b^\ominus$	KCl	CaCl <sub>2</sub>
0.001	0.966	0.888
0.01	0.902	0.732
0.1	0.770	0.524
1.0	0.607	0.725

\* More values are given in the Resource section.

coefficients that differ from the values given by this expression, yet all solutions are expected to conform as  $b \rightarrow 0$ . Table 5F.2 lists some experimental values of activity coefficients for salts of various valence types. Figure 5F.2 shows some of these values plotted against  $I^{1/2}$ , and compares them with the theoretical straight lines calculated from eqn 5F.8. The agreement at very low molalities (less than about  $1 \text{ mmol kg}^{-1}$ , depending on charge type) is impressive and convincing evidence in support of the model. Nevertheless, the departures from the theoretical curves above these molalities are large, and show that the approximations are valid only at very low concentrations.

Figure 5F.2 An experimental test of the Debye–Hückel limiting law. Although there are marked deviations for moderate ionic strengths, the limiting slopes as  $I \rightarrow 0$  are in good agreement with the theory, so the law can be used for extrapolating data to very low molalities.

## (b) Extensions of the limiting law

When the ionic strength of the solution is too high for the limiting law to be valid, the activity coefficient may be estimated from the **extended Debye–Hückel law** (sometimes called the *Truesdell–Jones equation*):

$$\log \gamma_{\pm} = -\frac{A|z_+z_-|I^{1/2}}{1+BI^{1/2}} \quad \text{Extended Debye–Hückel law} \quad (5F.11a)$$

where  $B$  is a dimensionless constant. A more flexible extension is the **Davies equation** proposed by C.W. Davies in 1938:

$$\log \gamma_{\pm} = -\frac{A|z_+z_-|I^{1/2}}{1+BI^{1/2}} + CI \quad \text{Davies equation} \quad (5F.11b)$$

where  $C$  is another dimensionless constant. Although  $B$  can be interpreted as a measure of the closest approach of the ions, it (like  $C$ ) is best regarded as an adjustable empirical parameter. A curve drawn on the basis of the Davies equation is shown in Fig. 5F.3. It is clear that eqn 5F.11 accounts for some activity coefficients over a moderate range of dilute solutions (up to about  $0.1 \text{ mol kg}^{-1}$ ); nevertheless it remains very poor near  $1 \text{ mol kg}^{-1}$ .

Current theories of activity coefficients for ionic solutes take an indirect route. They set up a theory for the dependence of the activity coefficient of the solvent on the concentration of the solute, and then use the Gibbs–Duhem equation (eqn 5A.12a,  $n_A d\mu_A + n_B d\mu_B = 0$ ) to estimate the activity coefficient of the solute. The results are reasonably reliable for solutions with molalities greater than about  $0.1 \text{ mol kg}^{-1}$  and are valuable for the discussion of mixed salt solutions, such as sea water.

Figure 5F.3 The Davies equation gives agreement with experiment over a wider range of molalities than the limiting law (as shown here for a 1,1-electrolyte), but it fails at higher molalities.

## 5F.2 The Debye–Hückel theory

The strategy for the calculation is to establish the relation between the work needed to charge an ion and its chemical potential, and then to relate that work to the ion's interaction with the atmosphere of counter ions that has assembled around it as a result of the competition of the attraction between oppositely charged ions, the repulsion of like-charged ions, and the distributing effect of thermal motion.

### (a) The work of charging

Imagine a solution in which all the ions have their actual positions, but in which their Coulombic interactions have been turned off and so are behaving 'ideally'. The difference in molar Gibbs energy between the ideal and real solutions is equal to  $w_e$ , the electrical work of charging the system in this arrangement. For a salt  $M_pX_q$ , we write

$$w_e = \overbrace{(p\mu_+ + q\mu_-)}^{G_{m,r} \text{ charged}} - \overbrace{(p\mu_+^{\text{ideal}} + q\mu_-^{\text{ideal}})}^{G_{m,r}^{\text{ideal, uncharged}}} \quad (5F.12)$$

$$= p(\mu_+ - \mu_+^{\text{ideal}}) + q(\mu_- - \mu_-^{\text{ideal}})$$

From eqn 5F.7 we write

$$\mu_+ - \mu_+^{\text{ideal}} = \mu_- - \mu_-^{\text{ideal}} = RT \ln \gamma_{\pm}$$

So it follows that

$$\ln \gamma_{\pm} = \frac{w_e}{sRT} \quad s = p + q \quad (5F.13)$$

This equation tells us that we must first find the final distribution of the ions and then the work of charging them in that distribution.

#### Brief illustration 5F.2 The work of charging

The measured mean activity coefficient of 5.0 mmol kg<sup>-1</sup> KCl(aq) at 25 °C is 0.927. It follows that the average work involved in charging the ions in their environment in the solution is given by eqn 5F.13 in the form

$$w_e = sRT \ln \gamma_{\pm} = 2 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) \times \ln 0.927$$

$$= -0.38 \text{ kJ mol}^{-1}$$

**Self-test 5F.2** The measured mean activity coefficient of 0.1 mol kg<sup>-1</sup> Na<sub>2</sub>SO<sub>4</sub>(aq) at 25 °C is 0.445. What is the work of charging the ions in the solution?

Answer: -6.02 kJ mol<sup>-1</sup>

### (b) The potential due to the charge distribution

As explained in *Foundations B*, the Coulomb potential at a distance  $r$  from an isolated ion of charge  $z_i e$  in a medium of permittivity  $\epsilon$  is

$$\phi_i = \frac{Z_i}{r} \quad Z_i = \frac{z_i e}{4\pi\epsilon} \quad (5F.14)$$

The ionic atmosphere causes the potential to decay with distance more sharply than this expression implies. Such shielding is a familiar problem in electrostatics, and its effect is taken into account by replacing the Coulomb potential by the **shielded Coulomb potential**, an expression of the form

$$\phi_i = \frac{Z_i}{r} e^{-r/r_D} \quad \text{Shielded Coulomb potential} \quad (5F.15)$$

where  $r_D$  is called the **Debye length**. When  $r_D$  is large, the shielded potential is virtually the same as the unshielded potential. When it is small, the shielded potential is much smaller than the unshielded potential, even for short distances (Fig. 5F.4). We establish in the following *Justification* that

$$r_D = \left( \frac{\epsilon RT}{2\rho F^2 I b^{\ominus}} \right)^{1/2} \quad \text{Debye length} \quad (5F.16)$$

**Figure 5F.4** The variation of the shielded Coulomb potential with distance for different values of the Debye length,  $r_D/a$ . The smaller the Debye length, the more sharply the potential decays to zero. In each case,  $a$  is an arbitrary unit of length.

**Brief illustration 5F.3** The Debye length

To estimate the Debye length in an aqueous solution of ionic strength 0.100 and density 1.000 g cm<sup>-3</sup> at 25 °C we write

$$r_D = \left( \frac{\frac{\epsilon}{2 \times (1000 \text{ kg m}^{-3}) \times (9.649 \times 10^4 \text{ C mol}^{-1})^2 \times (0.100) \times (1 \text{ mol kg}^{-1})}{80.10 \times (8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}} \right)^{1/2}$$

= 9.72 × 10<sup>-10</sup> m, or 0.972 nm

**Self-test 5F.3** Estimate the Debye length in an ethanol solution of ionic strength 0.100 and density 0.789 g cm<sup>-3</sup> at 25 °C. Use  $\epsilon_r = 25.3$ .

Answer: 0.615 nm

**Justification 5F.1** The Debye length

To calculate  $r_D$ , we need to know how the **charge density**,  $\rho_i$ , of the ionic atmosphere, the charge in a small region divided by the volume of the region, varies with distance from the ion. This step draws on another standard result of electrostatics, in which charge density and potential are related by **Poisson's equation**:

$$\nabla^2 \phi = -\frac{\rho}{\epsilon} \quad \text{Poisson's equation}$$

where  $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ . Because we are considering only a spherical ionic atmosphere, we can use a simplified form of this equation in which the charge density varies only with distance from the central ion:

$$\frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi_i}{dr} \right) = -\frac{\rho_i}{\epsilon}$$

Substitution of the expression for the shielded potential, eqn 5F.15, results in

$$r_D^2 = -\frac{\epsilon \phi_i}{\rho_i}$$

To solve this equation we need to relate  $\rho_i$  and  $\phi_i$ .

For this next step we draw on the fact that the energy of an ion depends on its closeness to the central ion, and then use the Boltzmann distribution (*Foundations B*) to work out the probability that an ion will be found at each distance. The energy of an ion  $j$  of charge  $z_j e$  at a distance where it experiences the potential  $\phi_i$  of the central ion  $i$  relative to its energy when it is far away in the bulk solution is its charge times the potential  $z_j e \phi_i$ . Therefore, according to the Boltzmann distribution, the ratio of the molar concentration,  $c_j$ , of ions at a distance  $r$  and the molar concentration in the bulk,  $c_j^\ominus$ , where the energy is zero, is

$$\frac{c_j}{c_j^\ominus} = e^{-z_j e \phi_i / kT}$$

The charge density,  $\rho_i$ , at a distance  $r$  from the ion  $i$  is the molar concentration of each type of ion multiplied by the charge per mole of ions,  $z_i e N_A$ . The quantity  $e N_A = F$ , the magnitude of the charge per mole of electrons, is Faraday's constant. It follows that

$$\rho_i = c_+ z_+ F + c_- z_- F = c_+^\ominus z_+ F e^{-z_+ e \phi_i / kT} + c_-^\ominus z_- F e^{-z_- e \phi_i / kT}$$

At this stage we need to simplify the expression to avoid the awkward exponential terms. Because the average electrostatic interaction energy is small compared with  $kT$  we may use the expansion  $e^x = 1 + x + \dots$  and write the charge density as

$$\begin{aligned} \rho_i &= c_+^\ominus z_+ F \left( 1 - \frac{z_+ e \phi_i}{kT} + \dots \right) + c_-^\ominus z_- F \left( 1 - \frac{z_- e \phi_i}{kT} + \dots \right) \\ &= \overbrace{(c_+^\ominus z_+ + c_-^\ominus z_-)}^0 F - (c_+^\ominus z_+^2 + c_-^\ominus z_-^2) \frac{F e \phi_i}{kT} + \dots \end{aligned}$$

The first term in the expansion is zero because it is the charge density in the bulk, uniform solution, and the solution is electrically neutral. Replacing  $e$  by  $F/N_A$  and  $N_A k$  by  $R$  results in the following expression:

$$\rho_i = -(c_+^\ominus z_+^2 + c_-^\ominus z_-^2) \frac{F^2 \phi_i}{RT}$$

The unwritten terms are assumed to be too small to be significant. This one remaining term, in blue, can be expressed in terms of the ionic strength, eqn 5F.9, by noting that in the dilute aqueous solutions we are considering there is little difference between molality and molar concentration, and  $c \approx b\rho$ , where  $\rho$  is the mass density of the solvent

$$c_+^\ominus z_+^2 + c_-^\ominus z_-^2 \approx \overbrace{(b_+^\ominus z_+^2 + b_-^\ominus z_-^2)}^{2Ib^\ominus} \rho = 2Ib^\ominus \rho$$

With these approximations, the last equation becomes

$$\rho_i = -\frac{2Ib^\ominus \rho F^2 \phi_i}{RT}$$

We can now substitute this expression into  $r_D^2 = -\epsilon \phi_i / \rho_i$ , when the  $\phi_i$  cancel and we obtain eqn 5F.16.

**(c) The activity coefficient**

To calculate the activity coefficient we need to find the electrical work of charging the central ion when it is surrounded by its atmosphere. This calculation is carried through in the following *Justification*, which leads to the conclusion that the work of charging an ion  $i$  when it is surrounded by the atmosphere it has assembled is

$$w_{e,i} = -\frac{z_i^2 F^2}{8\pi N_A \epsilon r_D} \quad \text{Work of charging} \quad (5F.17)$$

**Justification 5F.2** The work of charging

To calculate the work of charging the central ion we need to know the potential at the ion due to its atmosphere,  $\phi_{\text{atmos}}$ . This potential is the difference between the total potential, given by eqn 5F.15, and the potential due to the central ion itself:

$$\phi_{\text{atmosphere}} = \phi - \phi_{\text{central ion}} = Z_i \left( \frac{e^{-r/r_D}}{r} - \frac{1}{r} \right), \quad Z_i = \frac{z_i e}{4\pi\epsilon}$$

The potential at the central ion (at  $r=0$ ) is obtained by taking the limit of this expression as  $r \rightarrow 0$  and is

$$\phi_{\text{atmosphere}}(0) = Z_i \lim_{r \rightarrow 0} \left( \frac{1-r/r_D + \dots - 1}{r} \right) = -\frac{Z_i}{r_D}$$

This expression shows us that the potential due to the ionic atmosphere is equivalent to the potential arising from a single charge of equal magnitude but opposite sign to that of the central ion and located at a distance  $r_D$  from the ion. If the charge of the central ion were  $Q$  and not  $z_i e$ , then the potential due to its atmosphere would be

$$\phi_{\text{atmosphere}}(0) = -\frac{Q}{4\pi\epsilon r_D}$$

The work of adding a charge  $dQ$  to a region where the electrical potential is  $\phi_{\text{atmosphere}}(0)$ , Table 2A.1 (from  $dw = \phi dQ$ ), is

$$dw_e = \phi_{\text{atmosphere}}(0) dQ$$

Therefore, the total molar work of fully charging the ion  $i$  in the presence of its atmosphere is

$$\begin{aligned} w_{e,i} &= N_A \int_0^{z_i e} \phi_{\text{atmosphere}}(0) dQ = -\frac{N_A}{4\pi\epsilon r_D} \int_0^{z_i e} Q dQ \\ &= -\frac{N_A z_i^2 e^2}{8\pi\epsilon r_D} = -\frac{z_i^2 F^2}{8\pi N_A \epsilon r_D} \end{aligned}$$

where in the last step we have used  $F = N_A e$ . This expression is eqn. 5F.17.

We can now collect the various pieces of this calculation and arrive at an expression for the mean activity coefficient. It follows from eqn 5F.13 with  $w_e = p w_{e,+} + q w_{e,-}$ , the total work of charging  $p$  cations and  $q$  anions in the presence of their atmospheres, that the mean activity coefficient of the ions is

$$\ln \gamma_{\pm} = \frac{p w_{e,+} + q w_{e,-}}{sRT} = -\frac{(p z_+^2 + q z_-^2) F^2}{8\pi N_A sRT \epsilon r_D}$$

However, for neutrality  $p z_+ + q z_- = 0$ ; therefore

$$p z_+^2 + q z_-^2 = \overbrace{p z_+ z_+}^{-q z_-} + \overbrace{q z_- z_-}^{-p z_+} = -\overbrace{(p+q) z_+ z_-}^s = s |z_+ z_-|$$

It then follows that

$$\ln \gamma_{\pm} = -\frac{|z_+ z_-| F^2}{8\pi N_A RT \epsilon r_D} \quad (5F.18)$$

The replacement of  $r_D$  with the expression in eqn 5F.16 gives

$$\begin{aligned} \ln \gamma_{\pm} &= -\frac{|z_+ z_-| F^2}{8\pi N_A RT \epsilon} \left( \frac{2\rho F^2 I b^{\ominus}}{\epsilon RT} \right)^{1/2} \\ &= -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A} \left( \frac{\rho b^{\ominus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2} \end{aligned} \quad (5F.19a)$$

where we have grouped terms in such a way as to show that this expression is beginning to take the form of eqn 5F.8 ( $\log \gamma_{\pm} = -|z_+ z_-| A I^{1/2}$ ). Indeed, conversion to common logarithms (by using  $\ln x = \ln 10 \times \log x$ ) gives

$$\log \gamma_{\pm} = -|z_+ z_-| \left\{ \frac{F^3}{4\pi N_A \ln 10} \left( \frac{\rho b^{\ominus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \right\} I^{1/2} \quad (5F.19b)$$

which is eqn 5F.8 with

$$A = \frac{F^3}{4\pi N_A \ln 10} \left( \frac{\rho b^{\ominus}}{2\epsilon^3 R^3 T^3} \right)^{1/2} \quad (5F.20)$$

**Brief illustration 5F.4** The Debye–Hückel constant

To evaluate the constant  $A$  for water at 25.00 °C, we use  $\rho = 0.9971 \text{ g cm}^{-3}$  and  $\epsilon = 78.54\epsilon_0$  to find

$$\begin{aligned} A &= \frac{(9.649 \times 10^4 \text{ C mol}^{-1})^3}{4\pi \times (6.022 \times 10^{23} \text{ mol}^{-1}) \ln 10} \\ &\times \left( \frac{(997.1 \text{ kg m}^{-3}) \times (1 \text{ mol kg}^{-1})}{2 \times (78.54 \times 8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1})^3 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1})^3 \times (298.15 \text{ K})^3} \right)^{1/2} \\ &= 0.5086 \end{aligned}$$

**Self-test 5F.4** Evaluate the constant  $A$  for ethanol at 25 °C, when  $\epsilon_r = 25.3$  and  $\rho = 0.789 \text{ g cm}^{-3}$ .

Answer: 2.47

## Checklist of concepts

- 1. Mean activity coefficients apportion deviations from ideality equally to the cations and anions in an ionic solution.
- 2. The Debye–Hückel theory ascribes deviations from ideality to the Coulombic interaction of an ion with the ionic atmosphere that assembles around it.
- 3. The Debye–Hückel limiting law is extended by including two further empirical constants.

## Checklist of equations

Property	Equation	Comment	Equation number
Mean activity coefficient	$\gamma_{\pm} = (\gamma_+^p \gamma_-^q)^{1/(p+q)}$	Definition	5F.6
Debye–Hückel limiting law	$\log \gamma_{\pm} = -A  z_+ z_-  I^{1/2}$	Valid as $I \rightarrow 0$	5F.8
Ionic strength	$I = \frac{1}{2} \sum_i z_i^2 (b_i / b^{\ominus})$	Definition	5F.9
Davies equation	$\log \gamma_{\pm} = -A  z_+ z_-  I^{1/2} / (1 + BI^{1/2}) + CI$	$A, B, C$ empirical constants	5F.11

# CHAPTER 5 Simple mixtures

## TOPIC 5A The thermodynamic description of mixtures

### Discussion questions

**5A.1** Explain the concept of partial molar quantity, and justify the remark that the partial molar property of a solute depends on the properties of the solvent too.

**5A.2** Explain how thermodynamics relates non-expansion work to a change in composition of a system.

**5A.3** Are there any circumstances under which two (real) gases will not mix spontaneously?

**5A.4** Explain how Raoult's law and Henry's law are used to specify the chemical potential of a component of a mixture.

**5A.5** Explain the molecular origin of Raoult's law and Henry's law.

### Exercises

**5A.1(a)** A polynomial fit to measurements of the total volume of a binary mixture of A and B is

$$v = 987.93 + 35.6774x - 0.45923x^2 + 0.017325x^3$$

where  $v = V/\text{cm}^3$ ,  $x = n_B/\text{mol}$ , and  $n_B$  is the amount of B present. Determine the partial molar volumes of A and B.

**5A.1(b)** A polynomial fit to measurements of the total volume of a binary mixture of A and B is

$$v = 778.55 - 22.5749x + 0.56892x^2 + 0.01023x^3 + 0.00234x^4$$

where  $v = V/\text{cm}^3$ ,  $x = n_B/\text{mol}$ , and  $n_B$  is the amount of B present. Determine the partial molar volumes of A and B.

**5A.2(a)** The volume of an aqueous solution of NaCl at 25 °C was measured at a series of molalities  $b$ , and it was found that the volume fitted the expression  $v = 1003 + 16.62x + 1.77x^{3/2} + 0.12x^2$  where  $v = V/\text{cm}^3$ ,  $V$  is the volume of a solution formed from 1.000 kg of water and  $x = b/b^\ominus$ . Calculate the partial molar volume of the components in a solution of molality 0.100 mol kg<sup>-1</sup>.

**5A.2(b)** At 18 °C the total volume  $V$  of a solution formed from MgSO<sub>4</sub> and 1.000 kg of water fits the expression  $v = 1001.21 + 34.69(x - 0.070)^2$ , where  $v = V/\text{cm}^3$  and  $x = b/b^\ominus$ . Calculate the partial molar volumes of the salt and the solvent when in a solution of molality 0.050 mol kg<sup>-1</sup>.

**5A.3(a)** Suppose that  $n_A = 0.10n_B$  and a small change in composition results in  $\mu_A$  changing by  $\delta\mu_A = +12\text{ J mol}^{-1}$ , by how much will  $\mu_B$  change?

**5A.3(b)** Suppose that  $n_A = 0.22n_B$  and a small change in composition results in  $\mu_A$  changing by  $\delta\mu_A = -15\text{ J mol}^{-1}$ , by how much will  $\mu_B$  change?

**5A.4(a)** Consider a container of volume 5.0 dm<sup>3</sup> that is divided into two compartments of equal size. In the left compartment there is nitrogen at 1.0 atm and 25 °C; in the right compartment there is hydrogen at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

**5A.4(b)** Consider a container of volume 250 cm<sup>3</sup> that is divided into two compartments of equal size. In the left compartment there is argon at 100 kPa and 0 °C; in the right compartment there is neon at the same temperature and pressure. Calculate the entropy and Gibbs energy of mixing when the partition is removed. Assume that the gases are perfect.

**5A.5(a)** Air is a mixture with mass percentage composition 75.5 (N<sub>2</sub>), 23.2 (O<sub>2</sub>), 1.3 (Ar). Calculate the entropy of mixing when it is prepared from the pure (and perfect) gases.

**5A.5(b)** When carbon dioxide is taken into account, the mass percentage composition of air is 75.52 (N<sub>2</sub>), 23.15 (O<sub>2</sub>), 1.28 (Ar), and 0.046 (CO<sub>2</sub>). What is the change in entropy from the value in the preceding exercise?

**5A.6(a)** The vapour pressure of benzene at 20 °C is 10 kPa and that of methylbenzene is 2.8 kPa at the same temperature. What is the vapour pressure of a mixture of equal masses of each component?

**5A.6(b)** At 90 °C the vapour pressure of 1,2-dimethylbenzene is 20 kPa and that of 1,3-dimethylbenzene is 18 kPa. What is the composition of the vapour of an equimolar mixture of the two components?

**5A.7(a)** The partial molar volumes of acetone (propanone) and chloroform (trichloromethane) in a mixture in which the mole fraction of CHCl<sub>3</sub> is 0.4693 are 74.166 cm<sup>3</sup> mol<sup>-1</sup> and 80.235 cm<sup>3</sup> mol<sup>-1</sup>, respectively. What is the volume of a solution of mass 1.000 kg?

**5A.7(b)** The partial molar volumes of two liquids A and B in a mixture in which the mole fraction of A is 0.3713 are 188.2 cm<sup>3</sup> mol<sup>-1</sup> and 176.14 cm<sup>3</sup> mol<sup>-1</sup>, respectively. The molar masses of the A and B are 241.1 g mol<sup>-1</sup> and 198.2 g mol<sup>-1</sup>. What is the volume of a solution of mass 1.000 kg?

**5A.8(a)** At 25 °C, the density of a 50 per cent by mass ethanol–water solution is 0.914 g cm<sup>-3</sup>. Given that the partial molar volume of water in the solution is 17.4 cm<sup>3</sup> mol<sup>-1</sup>, calculate the partial molar volume of the ethanol.

**5A.8(b)** At 20 °C, the density of a 20 per cent by mass ethanol/water solution is 968.7 kg m<sup>-3</sup>. Given that the partial molar volume of ethanol in the solution is 52.2 cm<sup>3</sup> mol<sup>-1</sup>, calculate the partial molar volume of the water.

**5A.9(a)** At 300 K, the partial vapour pressure of HCl (that is, the partial pressure of the HCl vapour) in liquid GeCl<sub>4</sub> is as follows:

$x_{\text{HCl}}$	0.005	0.012	0.019
$p_{\text{HCl}}/\text{kPa}$	32.0	76.9	121.8

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 300 K.

**5A.9(b)** At 310 K, the partial vapour pressure of a substance B dissolved in a liquid A is as follows:

$x_B$	0.010	0.015	0.020
$p_B/\text{kPa}$	82.0	122.0	166.1

Show that the solution obeys Henry's law in this range of mole fractions, and calculate Henry's law constant at 310 K.

**5A.10(a)** Calculate the molar solubility of nitrogen in benzene exposed to air at 25 °C; partial pressures were calculated in *Example 1A.3* of Topic 1A.

**5A.10(b)** Calculate the molar solubility of methane at 1.0 bar in benzene at 25 °C.

**5A.11(a)** Use Henry's law and the data in Table 5A.1 to calculate the solubility (as a molality) of CO<sub>2</sub> in water at 25 °C when its partial pressure is (i) 0.10 atm, (ii) 1.00 atm.

**5A.11(b)** The mole fractions of N<sub>2</sub> and O<sub>2</sub> in air at sea level are approximately 0.78 and 0.21. Calculate the molalities of the solution formed in an open flask of water at 25 °C.

## Problems

**5A.1** The experimental values of the partial molar volume of a salt in water are found to fit the expression  $v_B = 5.117 + 19.121x^{1/2}$ , where  $v_B = V_B/(\text{cm}^3 \text{mol}^{-1})$  and  $x$  is the numerical value of the molality of B ( $x = b/b^\ominus$ ). Use the Gibbs–Duhem equation to derive an equation for the molar volume of water in the solution. The molar volume of pure water at the same temperature is  $18.079 \text{ cm}^3 \text{mol}^{-1}$ .

**5A.2** The compound *p*-azoxyanisole forms a liquid crystal. 5.0 g of the solid was placed in a tube, which was then evacuated and sealed. Use the phase rule to prove that the solid will melt at a definite temperature and that the liquid crystal phase will make a transition to a normal liquid phase at a definite temperature.

**5A.3** The following table gives the mole fraction of methylbenzene (A) in liquid and gaseous mixtures ( $x_A$  and  $y_A$ , respectively) with butanone at equilibrium at 303.15 K and the total pressure  $p$ . Take the vapour to be perfect and calculate the partial pressures of the two components. Plot them against their respective mole fractions in the liquid mixture and find the Henry's law constants for the two components.

$x_A$	0	0.0898	0.2476	0.3577	0.5194	0.6036
$y_A$	0	0.0410	0.1154	0.1762	0.2772	0.3393
$p/\text{kPa}$	36.066	34.121	30.900	28.626	25.239	23.402

**5A.12(a)** A water carbonating plant is available for use in the home and operates by providing carbon dioxide at 5.0 atm. Estimate the molar concentration of the soda water it produces.

**5A.12(b)** After some weeks of use, the pressure in the water carbonating plant mentioned in the previous exercise has fallen to 2.0 atm. Estimate the molar concentration of the soda water it produces at this stage.

$x_A$	0.7188	0.8019	0.9105	1
$y_A$	0.4450	0.5435	0.7284	1
$p/\text{kPa}$	20.6984	18.592	15.496	12.295

**5A.4** The densities of aqueous solutions of copper(II) sulfate at 20 °C were measured as set out below. Determine and plot the partial molar volume of CuSO<sub>4</sub> in the range of the measurements.

$m(\text{CuSO}_4)/\text{g}$	5	10	15	20
$\rho/(\text{g cm}^{-3})$	1.051	1.107	1.167	1.230

where  $m(\text{CuSO}_4)$  is the mass of CuSO<sub>4</sub> dissolved in 100 g of solution.

**5A.5** Haemoglobin, the red blood protein responsible for oxygen transport, binds about 1.34 cm<sup>3</sup> of oxygen per gram. Normal blood has a haemoglobin concentration of 150 g dm<sup>-3</sup>. Haemoglobin in the lungs is about 97 per cent saturated with oxygen, but in the capillary is only about 75 per cent saturated. What volume of oxygen is given up by 100 cm<sup>3</sup> of blood flowing from the lungs in the capillary?

**5A.6** Use the data from *Example 5A.1* to determine the value of  $b$  at which  $V_E$  has a minimum value.

## TOPIC 5B The properties of solutions

### Discussion questions

**5B.1** Explain what is meant by a regular solution; what additional features distinguish a real solution from a regular solution?

**5B.2** Explain the physical origin of colligative properties.

**5B.3** Colligative properties are independent of the identity of the solute. Why, then, can osmometry be used to determine the molar mass of a solute?

### Exercises

**5B.1(a)** Predict the partial vapour pressure of HCl above its solution in liquid germanium tetrachloride of molality 0.10 mol kg<sup>-1</sup>. For data, see Exercise 5A.10(a).

**5B.1(b)** Predict the partial vapour pressure of the component B above its solution in A in Exercise 5A.10(b) when the molality of B is 0.25 mol kg<sup>-1</sup>. The molar mass of A is 74.1 g mol<sup>-1</sup>.

**5B.2(a)** The vapour pressure of benzene is 53.3 kPa at 60.6 °C, but it fell to 51.5 kPa when 19.0 g of a non-volatile organic compound was dissolved in 500 g of benzene. Calculate the molar mass of the compound.

**5B.2(b)** The vapour pressure of 2-propanol is 50.00 kPa at 338.8 K, but it fell to 49.62 kPa when 8.69 g of a non-volatile organic compound was dissolved in 250 g of 2-propanol. Calculate the molar mass of the compound.

**5B.3(a)** The addition of 100 g of a compound to 750 g of CCl<sub>4</sub> lowered the freezing point of the solvent by 10.5 K. Calculate the molar mass of the compound.

**5B.3(b)** The addition of 5.00 g of a compound to 250 g of naphthalene lowered the freezing point of the solvent by 0.780 K. Calculate the molar mass of the compound.

**5B.4(a)** The osmotic pressure of an aqueous solution at 300 K is 120 kPa. Calculate the freezing point of the solution.

**5B.4(b)** The osmotic pressure of an aqueous solution at 288 K is 99.0 kPa. Calculate the freezing point of the solution.

**5B.5(a)** Calculate the Gibbs energy, entropy, and enthalpy of mixing when 0.50 mol  $C_6H_{14}$  (hexane) is mixed with 2.00 mol  $C_7H_{16}$  (heptane) at 298 K; treat the solution as ideal.

**5B.5(b)** Calculate the Gibbs energy, entropy, and enthalpy of mixing when 1.00 mol  $C_6H_{14}$  (hexane) is mixed with 1.00 mol  $C_7H_{16}$  (heptane) at 298 K; treat the solution as ideal.

**5B.6(a)** What proportions of hexane and heptane should be mixed (i) by mole fraction, (ii) by mass in order to achieve the greatest entropy of mixing?

**5B.6(b)** What proportions of benzene and ethylbenzene should be mixed (i) by mole fraction, (ii) by mass in order to achieve the greatest entropy of mixing?

**5B.7(a)** The enthalpy of fusion of anthracene is  $28.8 \text{ kJ mol}^{-1}$  and its melting point is  $217^\circ\text{C}$ . Calculate its ideal solubility in benzene at  $25^\circ\text{C}$ .

**5B.7(b)** Predict the ideal solubility of lead in bismuth at  $280^\circ\text{C}$  given that its melting point is  $327^\circ\text{C}$  and its enthalpy of fusion is  $5.2 \text{ kJ mol}^{-1}$ .

**5B.8(a)** The osmotic pressure of solutions of polystyrene in toluene were measured at  $25^\circ\text{C}$  and the pressure was expressed in terms of the height of the solvent of density  $1.004 \text{ g cm}^{-3}$ :

$c/(\text{g dm}^{-3})$	2.042	6.613	9.521	12.602
$h/\text{cm}$	0.592	1.910	2.750	3.600

Calculate the molar mass of the polymer.

**5B.8(b)** The molar mass of an enzyme was determined by dissolving it in water, measuring the osmotic pressure at  $20^\circ\text{C}$ , and extrapolating the data to zero concentration. The following data were obtained:

$c/(\text{mg cm}^{-3})$	3.221	4.618	5.112	6.722
$h/\text{cm}$	5.746	8.238	9.119	11.990

Calculate the molar mass of the enzyme.

**5B.9(a)** A dilute solution of bromine in carbon tetrachloride behaves as an ideal dilute solution. The vapour pressure of pure  $\text{CCl}_4$  is 33.85 Torr at 298 K. The Henry's law constant when the concentration of  $\text{Br}_2$  is expressed as a mole fraction is 122.36 Torr. Calculate the vapour pressure of each component, the total pressure, and the composition of the vapour phase when the mole fraction of  $\text{Br}_2$  is 0.050, on the assumption that the conditions of the ideal dilute solution are satisfied at this concentration.

## Problems

**5B.1** Potassium fluoride is very soluble in glacial acetic acid and the solutions have a number of unusual properties. In an attempt to understand them, freezing point depression data were obtained by taking a solution of known molality and then diluting it several times (J. Emsley, *J. Chem. Soc. A*, 2702 (1971)). The following data were obtained:

$b/(\text{mol kg}^{-1})$	0.015	0.037	0.077	0.295	0.602
$\Delta T/\text{K}$	0.115	0.295	0.470	1.381	2.67

Calculate the apparent molar mass of the solute and suggest an interpretation. Use  $\Delta_{\text{fus}}H = 11.4 \text{ kJ mol}^{-1}$  and  $T_f^* = 290 \text{ K}$ .

**5B.2** In a study of the properties of an aqueous solution of  $\text{Th}(\text{NO}_3)_4$  (by A. Apelblat, D. Azoulay, and A. Sahar, *J. Chem. Soc. Faraday Trans., I*, 1618 (1973)), a freezing point depression of  $0.0703 \text{ K}$  was observed for an aqueous solution of molality  $9.6 \text{ mmol kg}^{-1}$ . What is the apparent number of ions per formula unit?

**5B.9(b)** The vapour pressure of a pure liquid A is 23 kPa at  $20^\circ\text{C}$  and its Henry's law constant in liquid B is 73 kPa. Calculate the vapour pressure of each component, the total pressure, and the composition of the vapour phase when the mole fraction of A is 0.066 on the assumption that the conditions of the ideal dilute solution are satisfied at this concentration.

**5B.10(a)** At  $90^\circ\text{C}$ , the vapour pressure of methylbenzene is 53.3 kPa and that of 1,2-dimethylbenzene is 20.0 kPa. What is the composition of a liquid mixture that boils at  $90^\circ\text{C}$  when the pressure is 0.50 atm? What is the composition of the vapour produced?

**5B.10(b)** At  $90^\circ\text{C}$ , the vapour pressure of 1,2-dimethylbenzene is 20 kPa and that of 1,3-dimethylbenzene is 18 kPa. What is the composition of a liquid mixture that boils at  $90^\circ\text{C}$  when the pressure is 19 kPa? What is the composition of the vapour produced?

**5B.11(a)** The vapour pressure of pure liquid A at 300 K is 76.7 kPa and that of pure liquid B is 52.0 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.350. Calculate the total pressure of the vapour and the composition of the liquid mixture.

**5B.11(b)** The vapour pressure of pure liquid A at 293 K is 68.8 kPa and that of pure liquid B is 82.1 kPa. These two compounds form ideal liquid and gaseous mixtures. Consider the equilibrium composition of a mixture in which the mole fraction of A in the vapour is 0.612. Calculate the total pressure of the vapour and the composition of the liquid mixture.

**5B.12(a)** It is found that the boiling point of a binary solution of A and B with  $x_A = 0.6589$  is  $88^\circ\text{C}$ . At this temperature the vapour pressures of pure A and B are 127.6 kPa and 50.60 kPa, respectively. (i) Is this solution ideal? (ii) What is the initial composition of the vapour above the solution?

**5B.12(b)** It is found that the boiling point of a binary solution of A and B with  $x_A = 0.4217$  is  $96^\circ\text{C}$ . At this temperature the vapour pressures of pure A and B are 110.1 kPa and 76.5 kPa, respectively. (i) Is this solution ideal? (ii) What is the initial composition of the vapour above the solution?

**5B.13(a)** Dibromoethene (DE,  $p_{\text{DE}}^* = 22.9 \text{ kPa}$  at 358 K) and dibromopropene (DP,  $p_{\text{DP}}^* = 17.1 \text{ kPa}$  at 358 K) form a nearly ideal solution. If  $x_{\text{DE}} = 0.60$ , what is (i)  $p_{\text{total}}$  when the system is all liquid, (ii) the composition of the vapour when the system is still almost all liquid.

**5B.13(b)** Benzene and toluene form nearly ideal solutions. Consider an equimolar solution of benzene and toluene. At  $20^\circ\text{C}$  the vapour pressures of pure benzene and toluene are 9.9 kPa and 2.9 kPa, respectively. The solution is boiled by reducing the external pressure below the vapour pressure. Calculate (i) the pressure when boiling begins, (ii) the composition of each component in the vapour, and (iii) the vapour pressure when only a few drops of liquid remain. Assume that the rate of vaporization is low enough for the temperature to remain constant at  $20^\circ\text{C}$ .

**5B.3\*** Aminabhavi et al. examined mixtures of cyclohexane with various long-chain alkanes (T.M. Aminabhavi et al., *J. Chem. Eng. Data* 41, 526 (1996)). Among their data are the following measurements of the density of a mixture of cyclohexane and pentadecane as a function of mole fraction of cyclohexane ( $x_c$ ) at 298.15 K:

$x_c$	0.6965	0.7988	0.9004
$\rho/(\text{g cm}^{-3})$	0.7661	0.7674	0.7697

Compute the partial molar volume for each component in a mixture which has a mole fraction of cyclohexane of 0.7988.

**5B.4\*** Comelli and Francesconi examined mixtures of propionic acid with various other organic liquids at 313.15 K (F. Comelli and R. Francesconi, *J. Chem. Eng. Data* 41, 101 (1996)). They report the excess volume of mixing

\* These problems were provided by Charles Trapp and Carmen Giunta.

propionic acid with oxane as  $V^E = x_1x_2\{a_0 + a_1(x_1 - x_2)\}$ , where  $x_1$  is the mole fraction of propionic acid,  $x_2$  that of oxane,  $a_0 = -2.4697 \text{ cm}^3 \text{ mol}^{-1}$  and  $a_1 = 0.0608 \text{ cm}^3 \text{ mol}^{-1}$ . The density of propionic acid at this temperature is  $0.97174 \text{ g cm}^{-3}$ ; that of oxane is  $0.86398 \text{ g cm}^{-3}$ . (a) Derive an expression for the partial molar volume of each component at this temperature. (b) Compute the partial molar volume for each component in an equimolar mixture.

**5B.5\*** Equation 5B.15 indicates, after it has been converted into an expression for  $x_B$ , that solubility is an exponential function of temperature. The data in the table below gives the solubility,  $S$ , of calcium acetate in water as a function of temperature.

$\theta/^\circ\text{C}$	0	20	40	60	80
$S/(\text{g (100 g solvent)}^{-1})$	36.4	34.9	33.7	32.7	31.7

Determine the extent to which the data fit the exponential  $S = S_0 e^{\tau/T}$  and obtain values for  $S_0$  and  $\tau$ . Express these constants in terms of properties of the solute.

**5B.6** The excess Gibbs energy of solutions of methylcyclohexane (MCH) and tetrahydrofuran (THF) at 303.15 K were found to fit the expression

$$G^E = RTx(1-x)\{0.4857 - 0.1077(2x-1) + 0.0191(2x-1)^2\}$$

where  $x$  is the mole fraction of the methylcyclohexane. Calculate the Gibbs energy of mixing when a mixture of 1.00 mol of MCH and 3.00 mol of THF is prepared.

**5B.7\*** Figure 5.1 shows  $\Delta_{\text{mix}}G(x_{\text{Pb}}, T)$  for a mixture of copper and lead. (a) What does the graph reveal about the miscibility of copper and lead and the spontaneity of solution formation? What is the variance ( $F$ ) at (i) 1500 K, (ii) 1100 K? (b) Suppose that at 1500 K a mixture of composition (i)  $x_{\text{Pb}} = 0.1$ , (ii)  $x_{\text{Pb}} = 0.7$ , is slowly cooled to 1100 K. What is the equilibrium composition of the final mixture? Include an estimate of the relative amounts of each phase. (c) What is the solubility of (i) lead in copper, (ii) copper in lead at 1100 K?

Figure 5.1 The Gibbs energy of mixing of copper and lead.

**5B.8** The excess Gibbs energy of a certain binary mixture is equal to  $gRTx(1-x)$  where  $g$  is a constant and  $x$  is the mole fraction of a solute A. Find an expression for the chemical potential of A in the mixture and sketch its dependence on the composition.

**5B.9** Use the Gibbs–Helmholtz equation to find an expression for  $d \ln x_A$  in terms of  $dT$ . Integrate  $d \ln x_A$  from  $x_A = 0$  to the value of interest, and

integrate the right-hand side from the transition temperature for the pure liquid A to the value in the solution. Show that, if the enthalpy of transition is constant, then eqns 5B.9 and 5B.12 are obtained.

**5B.10\*** Polymer scientists often report their data in a variety of units. For example, in the determination of molar masses of polymers in solution by osmometry, osmotic pressures are often reported in grams per square centimetre ( $\text{g cm}^{-2}$ ) and concentrations in grams per cubic centimetre ( $\text{g cm}^{-3}$ ). (a) With these choices of units, what would be the units of  $R$  in the van 't Hoff equation? (b) The data in the table below on the concentration dependence of the osmotic pressure of polyisobutene in chlorobenzene at  $25^\circ\text{C}$  have been adapted from J. Leonard and H. Daoust (*J. Polymer Sci.* 57, 53 (1962)). From these data, determine the molar mass of polyisobutene by plotting  $\Pi/c$  against  $c$ . (c) 'Theta solvents' are solvents for which the second osmotic coefficient is zero; for 'poor' solvents the plot is linear and for good solvents the plot is nonlinear. From your plot, how would you classify chlorobenzene as a solvent for polyisobutene? Rationalize the result in terms of the molecular structure of the polymer and solvent. (d) Determine the second and third osmotic virial coefficients by fitting the curve to the virial form of the osmotic pressure equation. (e) Experimentally, it is often found that the virial expansion can be represented as

$$\Pi/c = RT/M(1 + B'_c + gB'^2c^2 + \dots)$$

and in good solvents, the parameter  $g$  is often about 0.25. With terms beyond the second power ignored, obtain an equation for  $(\Pi/c)^{1/2}$  and plot this quantity against  $c$ . Determine the second and third virial coefficients from the plot and compare to the values from the first plot. Does this plot confirm the assumed value of  $g$ ?

$10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$	2.6	2.9	3.6	4.3	6.0	12.0
$c/(\text{g cm}^{-3})$	0.0050	0.010	0.020	0.033	0.057	0.10
$10^{-2}(\Pi/c)/(\text{g cm}^{-2}/\text{g cm}^{-3})$	19.0	31.0	38.0	52	63	
$c/(\text{g cm}^{-3})$	0.145	0.195	0.245	0.27	0.29	

**5B.11\*** K. Sato, F.R. Eirich, and J.E. Mark (*J. Polymer Sci., Polym. Phys.* 14, 619 (1976)) have reported the data in the table below for the osmotic pressures of polychloroprene ( $\rho = 1.25 \text{ g cm}^{-3}$ ) in toluene ( $\rho = 0.858 \text{ g cm}^{-3}$ ) at  $30^\circ\text{C}$ . Determine the molar mass of polychloroprene and its second osmotic virial coefficient.

$c/(\text{mg cm}^{-3})$	1.33	2.10	4.52	7.18	9.87
$\Pi/(\text{N m}^{-2})$	30	51	132	246	390

**5B.12** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to draw graphs of  $\Delta_{\text{mix}}G$  against  $x_A$  at different temperatures in the range 298 K to 500 K. For what value of  $x_A$  does  $\Delta_{\text{mix}}G$  depend on temperature most strongly?

**5B.13** Using the graph in Fig. 5B.4, fix  $\xi$  and vary the temperature. For what value of  $x_A$  does the excess enthalpy depend on temperature most strongly?

**5B.14** Derive an expression for the temperature coefficient of the solubility,  $dx_B/dT$ , and plot it as a function of temperature for several values of the enthalpy of fusion.

**5B.15** Calculate the osmotic virial coefficient  $B$  from the data in *Example 5B.2*.

## TOPIC 5C Phase diagrams of binary systems

### Discussion questions

**5C.1** Draw phase diagrams for the following types of systems. Label the regions of the diagrams, stating what materials (possibly compounds or azeotropes) are present and whether they are solid liquid or gas:

(a) two-component, temperature–composition, solid–liquid diagram, one compound AB formed that melts congruently, negligible solid–solid solubility;

(b) two-component, temperature–composition, solid–liquid diagram, one compound of formula  $AB_2$  that melts incongruently, negligible solid–solid solubility;

(c) two-component, constant temperature–composition, liquid–vapour diagram, formation of an azeotrope at  $x_B=0.333$ , complete miscibility.

## Exercises

**5C.1(a)** The following temperature–composition data were obtained for a mixture of octane (O) and methylbenzene (M) at 1.00 atm, where  $x$  is the mole fraction in the liquid and  $y$  the mole fraction in the vapour at equilibrium.

$\theta/^\circ\text{C}$	110.9	112.0	114.0	115.8	117.3	119.0	121.1	123.0
$x_M$	0.908	0.795	0.615	0.527	0.408	0.300	0.203	0.097
$y_M$	0.923	0.836	0.698	0.624	0.527	0.410	0.297	0.164

The boiling points are 110.6 °C and 125.6 °C for M and O, respectively. Plot the temperature–composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (i)  $x_M=0.250$  and (ii)  $x_O=0.250$ ?

**5C.1(b)** The following temperature–composition data were obtained for a mixture of two liquids A and B at 1.00 atm, where  $x$  is the mole fraction in the liquid and  $y$  the mole fraction in the vapour at equilibrium.

$\theta/^\circ\text{C}$	125	130	135	140	145	150
$x_A$	0.91	0.65	0.45	0.30	0.18	0.098
$y_A$	0.99	0.91	0.77	0.61	0.45	0.25

The boiling points are 124 °C for A and 155 °C for B. Plot the temperature/composition diagram for the mixture. What is the composition of the vapour in equilibrium with the liquid of composition (i)  $x_A=0.50$  and (ii)  $x_B=0.33$ ?

**5C.2(a)** Methyl ethyl ether (A) and diborane,  $B_2H_6$  (B), form a compound which melts congruently at 133 K. The system exhibits two eutectics, one at 25 mol per cent B and 123 K and a second at 90 mol per cent B and 104 K. The melting points of pure A and B are 131 K and 110 K, respectively. Sketch the phase diagram for this system. Assume negligible solid–solid solubility.

**5C.2(b)** Sketch the phase diagram of the system  $NH_3/N_2H_4$  given that the two substances do not form a compound with each other, that  $NH_3$  freezes at  $-78^\circ\text{C}$  and  $N_2H_4$  freezes at  $+2^\circ\text{C}$ , and that a eutectic is formed when the mole fraction of  $N_2H_4$  is 0.07 and that the eutectic melts at  $-80^\circ\text{C}$ .

**5C.3(a)** Figure 5.2 shows the phase diagram for two partially miscible liquids, which can be taken to be that for water (A) and 2-methyl-1-propanol (B). Describe what will be observed when a mixture of composition  $x_B=0.8$  is heated, at each stage giving the number, composition, and relative amounts of the phases present.

Figure 5.2 The phase diagram for two partially miscible liquids.

**5C.2** What molecular features determine whether a mixture of two liquids will show high- and low-boiling azeotropic behaviour?

**5C.3** What factors determine the number of theoretical plates required to achieve a desired degree of separation in fractional distillation?

**5C.3(b)** Refer to Fig. 5.2 again. Describe what will be observed when a mixture of composition  $x_B=0.3$  is heated, at each stage giving the number, composition, and relative amounts of the phases present.

**5C.4(a)** Indicate on the phase diagram in Fig. 5.3 the feature that denotes incongruent melting. What is the composition of the eutectic mixture and at what temperature does it melt?

Figure 5.3 The phase diagram referred to in Exercise 5C.4(a).

**5C.4(b)** Indicate on the phase diagram in Fig. 5.4 the feature that denotes incongruent melting. What are the compositions of any eutectic mixtures and at what temperatures do they melt?

Figure 5.4 The phase diagram referred to in Exercise 5C.4(b).

**5C.5(a)** Sketch the cooling curves for the isopleths  $a$  and  $b$  in Fig. 5.3.

**5C.5(b)** Sketch the cooling curves for the isopleths  $a$  and  $b$  in Fig. 5.4.

**5C.6(a)** Use the phase diagram in Fig. 5.3 to state (i) the solubility of Ag in Sn at  $800^\circ\text{C}$  and (ii) the solubility of  $Ag_3Sn$  in Ag at  $460^\circ\text{C}$ , (iii) the solubility of  $Ag_3Sn$  in Ag at  $300^\circ\text{C}$ .

**5C.6(b)** Use the phase diagram in Fig. 5.3 to state (i) the solubility of B in A at  $500^\circ\text{C}$  and (ii) the solubility of B in A at  $390^\circ\text{C}$ , (iii) the solubility of  $AB_2$  in B at  $300^\circ\text{C}$ .

**5C.7(a)** Figure 5.5 shows the experimentally determined phase diagrams for the nearly ideal solution of hexane and heptane. (i) Label the regions of the

diagrams to which phases are present. (ii) For a solution containing 1 mol each of hexane and heptane molecules, estimate the vapour pressure at 70 °C when vaporization on reduction of the external pressure just begins. (iii) What is the vapour pressure of the solution at 70 °C when just one drop of liquid remains. (iv) Estimate from the figures the mole fraction of hexane in the liquid and vapour phases for the conditions of part b. (v) What are the mole fractions for the conditions of part c? (vi) At 85 °C and 760 Torr, what are the amounts substance in the liquid and vapour phases when  $z_{\text{heptane}} = 0.40$ ?

Figure 5.5 Phase diagrams for the nearly ideal solution of hexane and heptane.

## Problems

**5C.1\*** 1-Butanol and chlorobenzene form a minimum-boiling azeotropic system. The mole fraction of 1-butanol in the liquid ( $x$ ) and vapour ( $y$ ) phases at 1.000 atm is given below for a variety of boiling temperatures (H. Artigas et al., *J. Chem. Eng. Data* **42**, 132 (1997)).

$T/\text{K}$	396.57	393.94	391.60	390.15	389.03	388.66	388.57
$x$	0.1065	0.1700	0.2646	0.3687	0.5017	0.6091	0.7171
$y$	0.2859	0.3691	0.4505	0.5138	0.5840	0.6409	0.7070

Pure chlorobenzene boils at 404.86 K. (a) Construct the chlorobenzene-rich portion of the phase diagram from the data. (b) Estimate the temperature at which a solution for which the mole fraction of 1-butanol is 0.300 begins to boil. (c) State the compositions and relative proportions of the two phases present after a solution initially 0.300 1-butanol is heated to 393.94 K.

**5C.2\*** An, Zhao, Jiang, and Shen investigated the liquid–liquid coexistence curve of *N,N*-dimethylacetamide and heptane (X. An et al., *J. Chem. Thermodynamics* **28**, 1221 (1996)). Mole fractions of *N,N*-dimethylacetamide in the upper ( $x_1$ ) and lower ( $x_2$ ) phases of a two-phase region are given opposite as a function of temperature:

**5C.7(b)** Uranium tetrafluoride and zirconium tetrafluoride melt at 1035 °C and 912 °C respectively. They form a continuous series of solid solutions with a minimum melting temperature of 765 °C and composition  $x(\text{ZrF}_4) = 0.77$ . At 900 °C, the liquid solution of composition  $x(\text{ZrF}_4) = 0.28$  is in equilibrium with a solid solution of composition  $x(\text{ZrF}_4) = 0.14$ . At 850 °C the two compositions are 0.87 and 0.90, respectively. Sketch the phase diagram for this system and state what is observed when a liquid of composition  $x(\text{ZrF}_4) = 0.40$  is cooled slowly from 900 °C to 500 °C.

**5C.8(a)** Methane (melting point 91 K) and tetrafluoromethane (melting point 89 K) do not form solid solutions with each other, and as liquids they are only partially miscible. The upper critical temperature of the liquid mixture is 94 K at  $x(\text{CF}_4) = 0.43$  and the eutectic temperature is 84 K at  $x(\text{CF}_4) = 0.88$ . At 86 K, the phase in equilibrium with the tetrafluoromethane-rich solution changes from solid methane to a methane-rich liquid. At that temperature, the two liquid solutions that are in mutual equilibrium have the compositions  $x(\text{CF}_4) = 0.10$  and  $x(\text{CF}_4) = 0.80$ . Sketch the phase diagram.

**5C.8(b)** Describe the phase changes that take place when a liquid mixture of 4.0 mol  $\text{B}_2\text{H}_6$  (melting point 131 K) and 1.0 mol  $\text{CH}_3\text{OCH}_3$  (melting point 135 K) is cooled from 140 K to 90 K. These substances form a compound  $(\text{CH}_3)_2\text{OB}_2\text{H}_6$  that melts congruently at 133 K. The system exhibits one eutectic at  $x(\text{B}_2\text{H}_6) = 0.25$  and 123 K and another at  $x(\text{B}_2\text{H}_6) = 0.90$  and 104 K.

**5C.9(a)** Refer to the information in Exercise 5C.8(a) and sketch the cooling curves for liquid mixtures in which  $x(\text{CF}_4)$  is (i) 0.10, (ii) 0.30, (iii) 0.50, (iv) 0.80, and (v) 0.95.

**5C.9(b)** Refer to the information in Exercise 5C.8(b) and sketch the cooling curves for liquid mixtures in which  $x(\text{B}_2\text{H}_6)$  is (i) 0.10, (ii) 0.30, (iii) 0.50, (iv) 0.80, and (v) 0.95.

**5C.10(a)** Hexane and perfluorohexane show partial miscibility below 22.70 °C. The critical concentration at the upper critical temperature is  $x = 0.355$ , where  $x$  is the mole fraction of  $\text{C}_6\text{F}_{14}$ . At 22.0 °C the two solutions in equilibrium have  $x = 0.24$  and  $x = 0.48$ , respectively, and at 21.5 °C the mole fractions are 0.22 and 0.51. Sketch the phase diagram. Describe the phase changes that occur when perfluorohexane is added to a fixed amount of hexane at (i) 23 °C, (ii) 22 °C.

**5C.10(b)** Two liquids, A and B, show partial miscibility below 52.4 °C. The critical concentration at the upper critical temperature is  $x = 0.459$ , where  $x$  is the mole fraction of A. At 40.0 °C the two solutions in equilibrium have  $x = 0.22$  and  $x = 0.60$ , respectively, and at 42.5 °C the mole fractions are 0.24 and 0.48. Sketch the phase diagram. Describe the phase changes that occur when B is added to a fixed amount of A at (i) 48 °C, (ii) 52.4 °C.

$T/\text{K}$	309.820	309.422	309.031	308.006	306.686
$x_1$	0.473	0.400	0.371	0.326	0.239
$x_2$	0.529	0.601	0.625	0.657	0.690

$T/\text{K}$	304.553	301.803	299.097	296.000	294.534
$x_1$	0.255	0.218	0.193	0.168	0.157
$x_2$	0.724	0.758	0.783	0.804	0.814

(a) Plot the phase diagram. (b) State the proportions and compositions of the two phases that form from mixing 0.750 mol of *N,N*-dimethylacetamide with 0.250 mol of heptane at 296.0 K. To what temperature must the mixture be heated to form a single-phase mixture?

**5C.3** Phosphorus and sulfur form a series of binary compounds. The best characterized are  $\text{P}_4\text{S}_3$ ,  $\text{P}_4\text{S}_7$ , and  $\text{P}_4\text{S}_{10}$ , all of which melt congruently. Assuming that only these three binary compounds of the two elements exist, (a) draw schematically only the P/S phase diagram. Label each region of the diagram with the substance that exists in that region and indicate its

phase. Label the horizontal axis as  $x_S$  and give the numerical values of  $x_S$  that correspond to the compounds. The melting point of pure phosphorus is 44°C and that of pure sulfur is 119°C. (b) Draw, schematically, the cooling curve for a mixture of composition  $x_S = 0.28$ . Assume that a eutectic occurs at  $x_S = 0.2$  and negligible solid–solid solubility.

**5C.4** The following table gives the break and halt temperatures found in the cooling curves of two metals A and B. Construct a phase diagram consistent with the data of these curves. Label the regions of the diagram, stating what phases and substances are present. Give the probable formulas of any compounds that form.

$100x_B$	$\theta_{\text{break}}/^\circ\text{C}$	$\theta_{\text{halt},1}/^\circ\text{C}$	$\theta_{\text{halt},2}/^\circ\text{C}$
0		1100	
10.0	1060	700	
20.0	1000	700	
30.0	940	700	400
40.0	850	700	400
50.0	750	700	400
60.0	670	400	
70.0	550	400	
80.0		400	
90.0	450	400	
100.0		500	

**5C.5** Consider the phase diagram in Fig. 5.6, which represents a solid–liquid equilibrium. Label all regions of the diagram according to the chemical species that exist in that region and their phases. Indicate the number of species and phases present at the points labelled *b*, *d*, *e*, *f*, *g*, and *k*. Sketch cooling curves for compositions  $x_B = 0.16$ , 0.23, 0.57, 0.67, and 0.84.

Figure 5.6 The phase diagram referred to in Problem 5C.5.

**5C.6** Sketch the phase diagram for the Mg/Cu system using the following information:  $\theta_f(\text{Mg}) = 648^\circ\text{C}$ ,  $\theta_f(\text{Cu}) = 1085^\circ\text{C}$ ; two intermetallic compounds are formed with  $\theta_f(\text{MgCu}_2) = 800^\circ\text{C}$  and  $\theta_f(\text{Mg}_2\text{Cu}) = 580^\circ\text{C}$ ; eutectics of mass percentage Mg composition and melting points 10 per cent (690°C), 33 per cent (560°C), and 65 per cent (380°C). A sample of Mg/Cu alloy containing 25 per cent Mg by mass was prepared in a crucible heated to 800°C in an

inert atmosphere. Describe what will be observed if the melt is cooled slowly to room temperature. Specify the composition and relative abundances of the phases and sketch the cooling curve.

**5C.7\*** The temperature–composition diagram for the Ca/Si binary system is shown in Fig. 5.7. (a) Identify eutectics, congruent melting compounds, and incongruent melting compounds. (b) If a 20 per cent by atom composition melt of silicon at 1500°C is cooled to 1000°C, what phases (and phase composition) would be at equilibrium? Estimate the relative amounts of each phase. (c) Describe the equilibrium phases observed when an 80 per cent by atom composition Si melt is cooled to 1030°C. What phases, and relative amounts, would be at equilibrium at a temperature (i) slightly higher than 1030°C, (ii) slightly lower than 1030°C? Draw a graph of the mole percentages of both Si(s) and CaSi<sub>2</sub>(s) as a function of mole percentage of melt that is freezing at 1030°C.

Figure 5.7 The temperature–composition diagram for the Ca/Si binary system.

**5C.8** Iron(II) chloride (melting point 677°C) and potassium chloride (melting point 776°C) form the compounds KFeCl<sub>3</sub> and K<sub>2</sub>FeCl<sub>4</sub> at elevated temperatures. KFeCl<sub>3</sub> melts congruently at 380°C and K<sub>2</sub>FeCl<sub>4</sub> melts incongruently at 399°C. Eutectics are formed with compositions  $x = 0.38$  (melting point 351°C) and  $x = 0.54$  (melting point 393°C), where  $x$  is the mole fraction of FeCl<sub>2</sub>. The KCl solubility curve intersects the K<sub>2</sub>FeCl<sub>4</sub> curve at  $x = 0.34$ . Sketch the phase diagram. State the phases that are in equilibrium when a mixture of composition  $x = 0.36$  is cooled from 400°C to 300°C.

**5C.9** To reproduce the results of Fig. 5C.2, first rearrange eqn 5C.4 so that  $y_A$  is expressed as a function of  $x_A$  and the ratio  $p_A^*/p_B^*$ . Then plot  $y_A$  against  $x_A$  for several values of ratio  $p_A^*/p_B^* > 1$ .

**5C.10** To reproduce the results of Fig. 5C.3, first rearrange eqn 5C.5 so that the ratio  $p_A^*/p_B^*$  is expressed as a function of  $y_A$  and the ratio  $p_A^*/p_B^*$ . Then plot  $p_A^*/p_B^*$  against  $y_A$  for several values of  $p_A^*/p_B^* > 1$ .

**5C.11** Working from eqn 5B.7, write an expression for  $T_{\text{min}}$ , the temperature at which  $\Delta_{\text{mix}}G$  has a minimum, as a function of  $\xi$  and  $x_A$ . Then, plot  $T_{\text{min}}$  against  $x_A$  for several values of  $\xi$ . Provide a physical interpretation for any maxima or minima that you observe in these plots.

**5C.12** Use eqn 5C.7 to generate plots of  $\xi$  against  $x_A$  by one of two methods: (a) solve the transcendental equation  $\ln\{x/(1-x)\} + \xi(1-2x) = 0$  numerically, or (b) plot the first term of the transcendental equation against the second and identify the points of intersection as  $\xi$  is changed.

## TOPIC 5D Phase diagrams of ternary systems

### Discussion questions

**5D.1** What is the maximum number of phases that can be in equilibrium in a ternary system?

**5D.2** Does the lever rule apply to a ternary system?

**5D.3** Could a regular tetrahedron be used to depict the properties of a four-component system?

## Exercises

**5D.1(a)** Mark the following features on triangular coordinates: (i) the point (0.2, 0.2, 0.6), (ii) the point (0, 0.2, 0.8), (iii) the point at which all three mole fractions are the same.

**5D.1(b)** Mark the following features on triangular coordinates: (i) the point (0.6, 0.2, 0.2), (ii) the point (0.8, 0.2, 0), (iii) the point (0.25, 0.25, 0.50).

**5D.2(a)** Mark the following points on a ternary phase diagram for the system  $\text{NaCl}/\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}/\text{H}_2\text{O}$ : (i) 25 per cent by mass  $\text{NaCl}$ , 25 per cent  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ , and the rest  $\text{H}_2\text{O}$ ; (ii) the line denoting the same relative composition of the two salts but with changing amounts of water.

**5D.2(b)** Mark the following points on a ternary phase diagram for the system  $\text{NaCl}/\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}/\text{H}_2\text{O}$ : (i) 33 per cent by mass  $\text{NaCl}$ , 33 per cent  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ , and the rest  $\text{H}_2\text{O}$ ; (ii) the line denoting the same relative composition of the two salts but with changing amounts of water.

**5D.3(a)** Refer to the ternary phase diagram in Fig. 5D.4. How many phases are present, and what are their compositions and relative abundances, in a mixture that contains 2.3 g of water, 9.2 g of chloroform, and 3.1 g of acetic acid? Describe what happens when (i) water, (iii) acetic acid is added to the mixture.

**5D.3(b)** Refer to the ternary phase diagram in Fig. 5D.4. How many phases are present, and what are their compositions and relative abundances, in a mixture that contains 55.0 g of water, 8.8 g of chloroform, and 3.7 g of acetic acid? Describe what happens when (i) water, (ii) acetic acid is added to the mixture.

**5D.4(a)** Figure 5.8 shows the phase diagram for the ternary system  $\text{NH}_4\text{Cl}/(\text{NH}_4)_2\text{SO}_4/\text{H}_2\text{O}$  at 25 °C. Identify the number of phases present for mixtures of compositions (i) (0.2, 0.4, 0.4), (ii) (0.4, 0.4, 0.2), (iii) (0.2, 0.1, 0.7), (iv) (0.4, 0.16, 0.44). The numbers are mole fractions of the three components in the order  $(\text{NH}_4\text{Cl}, (\text{NH}_4)_2\text{SO}_4, \text{H}_2\text{O})$ .

Figure 5.8 The phase diagram for the ternary system  $\text{NH}_4\text{Cl}/(\text{NH}_4)_2\text{SO}_4/\text{H}_2\text{O}$  at 25 °C.

**5D.4(b)** Refer to Fig. 5.8 and identify the number of phases present for mixtures of compositions (i) (0.4, 0.1, 0.5), (ii) (0.8, 0.1, 0.1), (iii) (0, 0.3, 0.7), (iv) (0.33, 0.33, 0.34). The numbers are mole fractions of the three components in the order  $(\text{NH}_4\text{Cl}, (\text{NH}_4)_2\text{SO}_4, \text{H}_2\text{O})$ .

**5D.5(a)** Referring to Fig. 5.8, deduce the molar solubility of (i)  $\text{NH}_4\text{Cl}$ , (ii)  $(\text{NH}_4)_2\text{SO}_4$  in water at 25 °C.

**5D.5(b)** Describe what happens when (i)  $(\text{NH}_4)_2\text{SO}_4$  is added to a saturated solution of  $\text{NH}_4\text{Cl}$  in water in the presence of excess  $\text{NH}_4\text{Cl}$ , (ii) water is added to a mixture of 25 g of  $\text{NH}_4\text{Cl}$  and 75 g of  $(\text{NH}_4)_2\text{SO}_4$ .

## Problems

**5D.1** At a certain temperature, the solubility of  $\text{I}_2$  in liquid  $\text{CO}_2$  is  $x(\text{I}_2) = 0.03$ . At the same temperature its solubility in nitrobenzene is 0.04. Liquid carbon dioxide and nitrobenzene are miscible in all proportions, and the solubility of  $\text{I}_2$  in the mixture varies linearly with the proportion of nitrobenzene. Sketch a phase diagram for the ternary system.

**5D.2** The binary system nitroethane/decahydronaphthalene (DEC) shows partial miscibility, with the two-phase region lying between  $x = 0.08$  and  $x = 0.84$ , where  $x$  is the mole fraction of nitroethane. The binary system liquid carbon dioxide/DEC is also partially miscible, with its two-phase region lying between  $y = 0.36$  and  $y = 0.80$ , where  $y$  is the mole fraction of DEC. Nitroethane and liquid carbon dioxide are miscible in all proportions.

The addition of liquid carbon dioxide to mixtures of nitroethane and DEC increases the range of miscibility, and the plait point is reached when  $z$ , the mole fraction of  $\text{CO}_2$ , is 0.18 and  $x = 0.53$ . The addition of nitroethane to mixtures of carbon dioxide and DEC also results in another plait point at  $x = 0.08$  and  $y = 0.52$ . (a) Sketch the phase diagram for the ternary system, (b) For some binary mixtures of nitroethane and liquid carbon dioxide the addition of arbitrary amounts of DEC will not cause phase separation. Find the range of concentration for such binary mixtures.

**5D.3** Prove that a straight line from the apex A of a ternary phase diagram to the opposite edge BC represents mixtures of constant ratio of B and C, however much A is present.

## TOPIC 5E Activities

## Discussion questions

**5E.1** What are the contributions that account for the difference between activity and concentration?

**5E.2** How is Raoult's law modified so as to describe the vapour pressure of real solutions?

**5E.3** Summarize the ways in which activities may be measured.

## Exercises

**5E.1(a)** Substances A and B are both volatile liquids with  $p_A^* = 300$  Torr,  $p_B^* = 250$  Torr, and  $K_B = 200$  Torr (concentration expressed in mole fraction). When  $x_A = 0.9$ ,  $b_B = 2.22$  mol kg<sup>-1</sup>,  $p_A = 250$  Torr, and  $p_B = 25$  Torr. Calculate the

activities and activity coefficients of A and B. Use the mole fraction, Raoult's law basis system for A and the Henry's law basis system (both mole fractions and molalities) for B.

**5E.1(b)** Given that  $p^*(\text{H}_2\text{O}) = 0.02308$  atm and  $p(\text{H}_2\text{O}) = 0.02239$  atm in a solution in which 0.122 kg of a volatile solute ( $M = 241$  g mol<sup>-1</sup>) is dissolved in 0.920 kg water at 293 K, calculate the activity and activity coefficient of water in the solution.

**5E.2(a)** By measuring the equilibrium between liquid and vapour phases of an acetone(A)/methanol(M) solution at 57.2 °C at 1.00 atm, it was found that  $x_A = 0.400$  when  $y_A = 0.516$ . Calculate the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are:  $p_A^* = 105$  kPa and  $p_M^* = 73.5$  kPa. ( $x_A$  is the mole fraction in the liquid and  $y_A$  the mole fraction in the vapour.)

**5E.2(b)** By measuring the equilibrium between liquid and vapour phases of a solution at 30 °C at 1.00 atm, it was found that  $x_A = 0.220$  when  $y_A = 0.314$ .

## Problems

**5E.1\*** Francesconi, Lunelli, and Comelli studied the liquid–vapour equilibria of trichloromethane and 1,2-epoxybutane at several temperatures (Francesconi et al., *J. Chem. Eng. Data* 41, 310 (1996)). Among their data are the following measurements of the mole fractions of trichloromethane in the liquid phase ( $x_T$ ) and the vapour phase ( $y_T$ ) at 298.15 K as a function of pressure.

$p/\text{kPa}$	23.40	21.75	20.25	18.75	18.15	20.25	22.50	26.30
$x$	0	0.129	0.228	0.353	0.511	0.700	0.810	1
$y$	0	0.065	0.145	0.285	0.535	0.805	0.915	1

Compute the activity coefficients of both components on the basis of Raoult's law.

**5E.2** The *osmotic coefficient*  $\phi$  is defined as  $\phi = -(x_A/x_B) \ln a_A$ . By writing  $r = x_B/x_A$ , and using the Gibbs–Duhem equation, show that we can calculate

the activities and activity coefficients of both components in this solution on the Raoult's law basis. The vapour pressures of the pure components at this temperature are:  $p_A^* = 73.0$  kPa and  $p_B^* = 92.1$  kPa. ( $x_A$  is the mole fraction in the liquid and  $y_A$  the mole fraction in the vapour.)

**5E.3(a)** Find the relation between the standard and biological standard Gibbs energies of a reaction of the form  $A \rightarrow 2B + 2 \text{H}^+(\text{aq})$ .

**5E.3(b)** Find the relation between the standard and biological standard Gibbs energies of a reaction of the form  $2A \rightarrow B + 4 \text{H}^+(\text{aq})$ .

**5E.4(a)** Suppose it is found that for a hypothetical regular solution that  $\xi = 1.40$ ,  $p_A^* = 15.0$  kPa and  $p_B^* = 11.6$  kPa. Draw the vapour-pressure diagram.

**5E.4(b)** Suppose it is found that for a hypothetical regular solution that  $\xi = -1.40$ ,  $p_A^* = 15.0$  kPa and  $p_B^* = 11.6$  kPa. Draw the vapour-pressure diagram.

the activity of B from the activities of A over a composition range by using the formula

$$\ln \frac{a_B}{r} = \phi - \phi(0) + \int_0^r \frac{\phi - 1}{r} dr$$

**5E.3** Show that the osmotic pressure of a real solution is given by  $\Pi V = -RT \ln a_A$ . Go on to show that, provided the concentration of the solution is low, this expression takes the form  $\Pi V = \phi RT [B]$  and hence that the osmotic coefficient  $\phi$  (which is defined in Problem 5E.2) may be determined from osmometry.

**5E.4** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to plot  $p_A/p_A^*$  against  $x_A$  with  $\xi = 2.5$  by using eqn 5E.19 and then eqn 5E.20. Above what value of  $x_A$  do the values of  $p_A/p_A^*$  given by these equations differ by more than 10 per cent?

## TOPIC 5F The activities of ions

### Discussion questions

**5F.1** Why do the activity coefficients of ions in solution differ from 1? Why are they less than 1 in dilute solutions?

**5F.2** Describe the general features of the Debye–Hückel theory of electrolyte solutions.

### Exercises

**5F.1(a)** Calculate the ionic strength of a solution that is 0.10 mol kg<sup>-1</sup> in KCl(aq) and 0.20 mol kg<sup>-1</sup> in CuSO<sub>4</sub>(aq).

**5F.1(b)** Calculate the ionic strength of a solution that is 0.040 mol kg<sup>-1</sup> in K<sub>3</sub>[Fe(CN)<sub>6</sub>](aq), 0.030 mol kg<sup>-1</sup> in KCl(aq), and 0.050 mol kg<sup>-1</sup> in NaBr(aq).

**5F.2(a)** Calculate the masses of (i) Ca(NO<sub>3</sub>)<sub>2</sub> and, separately, (ii) NaCl to add to a 0.150 mol kg<sup>-1</sup> solution of KNO<sub>3</sub>(aq) containing 500 g of solvent to raise its ionic strength to 0.250.

**5F.2(b)** Calculate the masses of (i) KNO<sub>3</sub> and, separately, (ii) Ba(NO<sub>3</sub>)<sub>2</sub> to add to a 0.110 mol kg<sup>-1</sup> solution of KNO<sub>3</sub>(aq) containing 500 g of solvent to raise its ionic strength to 1.00.

### Problems

**5F.1** The mean activity coefficients for aqueous solutions of NaCl at 25 °C are given opposite. Confirm that they support the Debye–Hückel limiting law and that an improved fit is obtained with the Davies equation.

**5F.3** Suggest an interpretation of the additional terms in extended versions of the Debye–Hückel limiting law.

**5F.3(a)** Estimate the mean ionic activity coefficient and activity of a solution at 25 °C that is 0.010 mol kg<sup>-1</sup> CaCl<sub>2</sub>(aq) and 0.030 mol kg<sup>-1</sup> NaF(aq).

**5F.3(b)** Estimate the mean ionic activity coefficient and activity of a solution at 25 °C that is 0.020 mol kg<sup>-1</sup> NaCl(aq) and 0.035 mol kg<sup>-1</sup> Ca(NO<sub>3</sub>)<sub>2</sub>(aq).

**5F.4(a)** The mean activity coefficients of HBr in three dilute aqueous solutions at 25 °C are 0.930 (at 5.0 mmol kg<sup>-1</sup>), 0.907 (at 10.0 mmol kg<sup>-1</sup>), and 0.879 (at 20.0 mmol kg<sup>-1</sup>). Estimate the value of  $B$  in eqn 5F.11a.

**5F.4(b)** The mean activity coefficients of KCl in three dilute aqueous solutions at 25 °C are 0.927 (at 5.0 mmol kg<sup>-1</sup>), 0.902 (at 10.0 mmol kg<sup>-1</sup>), and 0.816 (at 50.0 mmol kg<sup>-1</sup>). Estimate the value of  $B$  in eqn 5F.11a.

$b/(\text{mmol kg}^{-1})$	1.0	2.0	5.0	10.0	20.0
$\gamma_{\pm}$	0.9649	0.9519	0.9275	0.9024	0.8712

**5F2** Consider the plot of  $\log \gamma_{\pm}$  against  $I^{1/2}$  with  $B=1.50$  and  $C=0$  in the Davies equation as a representation of experimental data for a certain MX electrolyte. Over what range of ionic strengths does the application of the

limiting law lead to an error in the value of the activity coefficient of less than 10 per cent of the value predicted by the extended law?

## Integrated activities

**5.1** The table below lists the vapour pressures of mixtures of iodoethane (I) and ethyl acetate (A) at 50 °C. Find the activity coefficients of both components on (a) the Raoult's law basis, (b) the Henry's law basis with iodoethane as solute.

$x_I$	0	0.0579	0.1095	0.1918	0.2353	0.3718
$p_I/\text{kPa}$	0	3.73	7.03	11.7	14.05	20.72
$p_A/\text{kPa}$	37.38	35.48	33.64	30.85	29.44	25.05
$x_I$	0.5478	0.6349	0.8253	0.9093	1.0000	
$p_I/\text{kPa}$	28.44	31.88	39.58	43.00	47.12	
$p_A/\text{kPa}$	19.23	16.39	8.88	5.09	0	

**5.2** Plot the vapour pressure data for a mixture of benzene (B) and acetic acid (A) given below and plot the vapour pressure/composition curve for the mixture at 50 °C. Then confirm that Raoult's and Henry's laws are obeyed in the appropriate regions. Deduce the activities and activity coefficients of the components on the Raoult's law basis and then, taking B as the solute, its activity and activity coefficient on a Henry's law basis. Finally, evaluate the excess Gibbs energy of the mixture over the composition range spanned by the data.

$x_A$	0.0160	0.0439	0.0835	0.1138	0.1714	
$p_A/\text{kPa}$	0.484	0.967	1.535	1.89	2.45	
$p_B/\text{kPa}$	35.05	34.29	33.28	32.64	30.90	
$x_A$	0.2973	0.3696	0.5834	0.6604	0.8437	0.9931
$p_A/\text{kPa}$	3.31	3.83	4.84	5.36	6.76	7.29
$p_B/\text{kPa}$	28.16	26.08	20.42	18.01	10.0	0.47

**5.3\*** Chen and Lee studied the liquid–vapour equilibria of cyclohexanol with several gases at elevated pressures (J.-T. Chen and M.-J. Lee, *J. Chem. Eng. Data* **41**, 339 (1996)). Among their data are the following measurements of the mole fractions of cyclohexanol in the vapour phase ( $y$ ) and the liquid phase ( $x$ ) at 393.15 K as a function of pressure.

$p/\text{bar}$	10.0	20.0	30.0	40.0	60.0	80.0
$y_{\text{cyc}}$	0.0267	0.0149	0.0112	0.00947	0.00835	0.00921
$x_{\text{cyc}}$	0.9741	0.9464	0.9204	0.892	0.836	0.773

Determine the Henry's law constant of  $\text{CO}_2$  in cyclohexanol, and compute the activity coefficient of  $\text{CO}_2$ .

**5.4\*** The following data have been obtained for the liquid–vapour equilibrium compositions of mixtures of nitrogen and oxygen at 100 kPa.

$T/\text{K}$	77.3	78	80	82	84	86	88	90.2
$x(\text{O}_2)$	0	10	34	54	70	82	92	100
$y(\text{O}_2)$	0	2	11	22	35	52	73	100
$p^*(\text{O}_2)/\text{Torr}$	154	171	225	294	377	479	601	760

Plot the data on a temperature–composition diagram and determine the extent to which it fits the predictions for an ideal solution by calculating the activity coefficients of  $\text{O}_2$  at each composition.

**5.5** Use the Gibbs–Duhem equation to derive the *Gibbs–Duhem–Margules equation*

$$\left(\frac{\partial \ln f_A}{\partial \ln x_A}\right)_{p,T} = \left(\frac{\partial \ln f_B}{\partial \ln x_B}\right)_{p,T}$$

where  $f$  is the fugacity. Use the relation to show that when the fugacities are replaced by pressures, that if Raoult's law applies to one component in a mixture it must also apply to the other.

**5.6** Use the Gibbs–Duhem equation to show that the partial molar volume (or any partial molar property) of a component B can be obtained if the partial molar volume (or other property) of A is known for all compositions up to the one of interest. Do this by proving that

$$V_B = V_B^* - \int_{V_A^*}^{V_A} \frac{x_A}{1-x_A} dV_A$$

where the  $x_A$  are functions of the  $V_A$ . Use the following data (which are for 298 K) to evaluate the integral graphically to find the partial molar volume of acetone at  $x=0.500$ .

$x(\text{CHCl}_3)$	0	0.194	0.385	0.559	0.788	0.889	1.000
$V_m/(\text{cm}^3 \text{mol}^{-1})$	73.99	75.29	76.50	77.55	79.08	79.82	80.67

**5.7** Show that the freezing-point depression of a real solution in which the solvent of molar mass  $M$  has activity  $a_A$  obeys

$$\frac{d \ln a_A}{d(\Delta T)} = -\frac{M}{K_f}$$

and use the Gibbs–Duhem equation to show that

$$\frac{d \ln a_B}{d(\Delta T)} = -\frac{1}{b_B K_f}$$

where  $a_B$  is the solute activity and  $b_B$  is its molality. Use the Debye–Hückel limiting law to show that the osmotic coefficient ( $\phi$ , Problem 5E.2) is given by  $\phi = 1 - \frac{1}{3} A' I$  with  $A' = 2.303A$  and  $I = b/b^\ominus$ .

**5.8** For the calculation of the solubility  $c$  of a gas in a solvent, it is often convenient to use the expression  $c = Kp$ , where  $K$  is the Henry's law constant. Breathing air at high pressures, such as in scuba diving, results in an increased concentration of dissolved nitrogen. The Henry's law constant for the solubility of nitrogen is  $0.18 \mu\text{g}/(\text{g H}_2\text{O atm})$ . What mass of nitrogen is dissolved in 100 g of water saturated with air at 4.0 atm and 20 °C? Compare your answer to that for 100 g of water saturated with air at 1.0 atm. (Air is 78.08 mole per cent  $\text{N}_2$ .) If nitrogen is four times as soluble in fatty tissues as in water, what is the increase in nitrogen concentration in fatty tissue in going from 1 atm to 4 atm?

**5.9** Dialysis may be used to study the binding of small molecules to macromolecules, such as an inhibitor to an enzyme, an antibiotic to DNA, and any other instance of cooperation or inhibition by small molecules attaching to large ones. To see how this is possible, suppose inside the dialysis bag the molar concentration of the macromolecule M is  $[M]$  and the total concentration of small molecule A is  $[A]_{\text{in}}$ . This total concentration is the sum of the concentrations of free A and bound A, which we write  $[A]_{\text{free}}$  and  $[A]_{\text{bound}}$ , respectively. At equilibrium,  $\mu_{A,\text{free}} = \mu_{A,\text{out}}$ , which implies that  $[A]_{\text{free}} = [A]_{\text{out}}$ , provided the activity coefficient of A is the same in both solutions. Therefore, by measuring the concentration of A in the solution outside the bag, we can find the concentration of unbound A in the macromolecule solution and, from the difference  $[A]_{\text{in}} - [A]_{\text{free}} = [A]_{\text{in}} - [A]_{\text{out}}$ , the concentration of bound A. Now we explore the quantitative consequences of the experimental arrangement just described.

(a) The average number of A molecules bound to M molecules,  $\nu$ , is

$$\nu = \frac{[A]_{\text{bound}}}{[M]} = \frac{[A]_{\text{in}} - [A]_{\text{out}}}{[M]}$$

The bound and unbound A molecules are in equilibrium,  $M + A \rightleftharpoons MA$ . Recall from introductory chemistry that we may write the equilibrium constant for binding,  $K$ , as

$$K = \frac{[MA]}{[M]_{\text{free}}[A]_{\text{free}}}$$

Now show that

$$K = \frac{\nu}{(1-\nu)[A]_{\text{out}}}$$

(b) If there are  $N$  identical and independent binding sites on each macromolecule, each macromolecule behaves like  $N$  separate smaller macromolecules, with the same value of  $K$  for each site. It follows that the average number of A molecules per site is  $\nu/N$ . Show that, in this case, we may write the *Scatchard equation*:

$$\frac{\nu}{[A]_{\text{out}}} = KN - K\nu$$

(c) To apply the Scatchard equation, consider the binding of ethidium bromide ( $E^-$ ) to a short piece of DNA by a process called *intercalation*, in which the aromatic ethidium cation fits between two adjacent DNA base pairs. An equilibrium dialysis experiment was used to study the binding of ethidium bromide (EB) to a short piece of DNA. A  $1.00 \mu\text{mol dm}^{-3}$  aqueous solution of the DNA sample was dialysed against an excess of EB. The following data were obtained for the total concentration of EB:

[EB]/( $\mu\text{mol dm}^{-3}$ )					
Side without DNA	0.042	0.092	0.204	0.526	1.150
Side with DNA	0.292	0.590	1.204	2.531	4.150

From these data, make a Scatchard plot and evaluate the intrinsic equilibrium constant,  $K$ , and total number of sites per DNA molecule. Is the identical and independent sites model for binding applicable?

**5.10** The form of the Scatchard equation given Problem 5.9 applies only when the macromolecule has identical and independent binding sites. For non-identical independent binding sites, the Scatchard equation is

$$\frac{\nu}{[A]_{\text{out}}} = \sum_i \frac{N_i K_i}{1 + K_i [A]_{\text{out}}}$$

Plot  $\nu/[A]$  for the following cases. (a) There are four independent sites on an enzyme molecule and the intrinsic binding constant is  $K = 1.0 \times 10^7$ . (b) There are a total of six sites per polymer. Four of the sites are identical and have an intrinsic binding constant of  $1 \times 10^5$ . The binding constants for the other two sites are  $2 \times 10^6$ .

**5.11** The addition of a small amount of a salt, such as  $(\text{NH}_4)_2\text{SO}_4$ , to a solution containing a charged protein increases the solubility of the protein in water. This observation is called the *salting-in effect*. However, the addition of large amounts of salt can decrease the solubility of the protein to such an extent that the protein precipitates from solution. This observation is called the *salting-out effect* and is used widely by biochemists to isolate and purify proteins. Consider the equilibrium  $\text{PX}_\nu(\text{s}) \rightleftharpoons \text{P}^{\nu+}(\text{aq}) + \nu \text{X}^-(\text{aq})$ , where  $\text{P}^{\nu+}$  is a polycationic protein of charge  $\nu+$  and  $\text{X}^-$  is its counter ion. Use Le Chatelier's principle and the physical principles behind the Debye-Hückel theory to provide a molecular interpretation for the salting-in and salting-out effects.

**5.12** Some polymers can form liquid crystal mesophases with unusual physical properties. For example, liquid crystalline Kevlar (1) is strong enough to be the material of choice for bulletproof vests and is stable at temperatures up to 600 K. What molecular interactions contribute to the formation, thermal stability, and mechanical strength of liquid crystal mesophases in Kevlar?

1 Kevlar

# CHAPTER 6

## Chemical equilibrium

Chemical reactions tend to move towards a dynamic equilibrium in which both reactants and products are present but have no further tendency to undergo net change. In some cases, the concentration of products in the equilibrium mixture is so much greater than that of the unchanged reactants that for all practical purposes the reaction is 'complete'. However, in many important cases the equilibrium mixture has significant concentrations of both reactants and products.

### 6A The equilibrium constant

This Topic develops the concept of chemical potential and shows how it is used to account for the equilibrium composition of chemical reactions. The equilibrium composition corresponds to a minimum in the Gibbs energy plotted against the extent of reaction. By locating this minimum we establish the relation between the equilibrium constant and the standard Gibbs energy of reaction.

### 6B The response of equilibria to the conditions

The thermodynamic formulation of equilibrium enables us to establish the quantitative effects of changes in the conditions. One very important aspect of equilibrium is the control that can be exercised by varying the conditions, such as the pressure or temperature.

### 6C Electrochemical cells

Because many reactions involve the transfer of electrons, they can be studied (and utilized) by allowing them to take place in a cell equipped with electrodes, with the spontaneous reaction

forcing electrons through an external circuit. We shall see that the electric potential of the cell is related to the reaction Gibbs energy, so providing an electrical procedure for the determination of thermodynamic quantities.

### 6D Electrode potentials

Electrochemistry is in part a major application of thermodynamic concepts to chemical equilibria as well as being of great technological importance. As elsewhere in thermodynamics, we see how to report electrochemical data in a compact form and apply it to problems of real chemical significance, especially to the prediction of the spontaneous direction of reactions and the calculation of equilibrium constants.

### What is the impact of this material?

The thermodynamic description of spontaneous reactions has numerous practical and theoretical applications. We highlight two applications. One is to the discussion of biochemical processes, where one reaction drives another (*Impact I6.1*). That, ultimately, is why we have to eat, for we see that the reaction that takes place when one substance is oxidized can drive non-spontaneous reactions, such as protein synthesis, forward. Another makes use of the great sensitivity of electrochemical processes to the concentration of electroactive materials, and we see how specially designed electrodes are used in analysis (*Impact I6.2*).

### ► Why do you need to know this material?

Equilibrium constants lie at the heart of chemistry and are a key point of contact between thermodynamics and laboratory chemistry. The material in this Topic shows how they arise and explains the thermodynamic properties that determine their values.

### ► What is the key idea?

The composition of a reaction mixture tends to change until the Gibbs energy is a minimum.

### ► What do you need to know already?

Underlying the whole discussion is the expression of the direction of spontaneous change in terms of the Gibbs energy of a system (Topic 3C). This material draws on the concept of chemical potential and its dependence on the concentration or pressure of the substance (Topic 5A). You need to know how to express the total Gibbs energy of a mixture in terms of the chemical potentials of its components (Topic 5A).

As explained in Topic 3C, the direction of spontaneous change at constant temperature and pressure is towards lower values of the Gibbs energy,  $G$ . The idea is entirely general, and in this Topic we apply it to the discussion of chemical reactions. There is a tendency of a mixture of reactants to undergo reaction until the Gibbs energy of the mixture has reached a minimum: that state corresponds to a state of chemical equilibrium. The equilibrium is dynamic in the sense that the forward and reverse reactions continue, but at matching rates. As always in the application of thermodynamics, spontaneity is a *tendency*: there might be kinetic reasons why that tendency is not realized.

## 6A.1 The Gibbs energy minimum

We locate the equilibrium composition of a reaction mixture by calculating the Gibbs energy of the reaction mixture and identifying the composition that corresponds to minimum  $G$ . Here we proceed in two steps: first, we consider a very simple equilibrium, and then we generalize it.

### (a) The reaction Gibbs energy

Consider the equilibrium  $A \rightleftharpoons B$ . Even though this reaction looks trivial, there are many examples of it, such as the isomerization of pentane to 2-methylbutane and the conversion of L-alanine to D-alanine.

Suppose an infinitesimal amount  $d\xi$  of A turns into B, then the change in the amount of A present is  $dn_A = -d\xi$  and the change in the amount of B present is  $dn_B = +d\xi$ . The quantity  $\xi$  (xi) is called the **extent of reaction**; it has the dimensions of amount of substance and is reported in moles. When the extent of reaction changes by a measurable amount  $\Delta\xi$ , the amount of A present changes from  $n_{A,0}$  to  $n_{A,0} - \Delta\xi$  and the amount of B changes from  $n_{B,0}$  to  $n_{B,0} + \Delta\xi$ . In general, the amount of a component J changes by  $\nu_J \Delta\xi$ , where  $\nu_J$  is the stoichiometric number of the species J (positive for products, negative for reactants).

#### Brief illustration 6A.1 The extent of reaction

If initially 2.0 mol A is present and we wait until  $\Delta\xi = +1.5$  mol, then the amount of A remaining will be 0.5 mol. The amount of B formed will be 1.5 mol.

**Self-test 6A.1** Suppose the reaction is  $3\text{A} \rightarrow 2\text{B}$  and that initially 2.5 mol A is present. What is the composition when  $\Delta\xi = +0.5$  mol?

Answer: 1.0 mol A, 1.0 mol B

The **reaction Gibbs energy**,  $\Delta_r G$ , is defined as the slope of the graph of the Gibbs energy plotted against the extent of reaction:

$$\Delta_r G = \left( \frac{\partial G}{\partial \xi} \right)_{p,T} \quad \text{Definition} \quad \text{Reaction Gibbs energy} \quad (6A.1)$$

Although  $\Delta$  normally signifies a *difference* in values, here it signifies a *derivative*, the slope of  $G$  with respect to  $\xi$ . However, to see that there is a close relationship with the normal usage, suppose the reaction advances by  $d\xi$ . The corresponding change in Gibbs energy is

$$dG = \mu_A dn_A + \mu_B dn_B = -\mu_A d\xi + \mu_B d\xi = (\mu_B - \mu_A) d\xi$$

This equation can be reorganized into

$$\left( \frac{\partial G}{\partial \xi} \right)_{p,T} = \mu_B - \mu_A$$

That is,

$$\Delta_r G = \mu_B - \mu_A \quad (6A.2)$$

We see that  $\Delta_r G$  can also be interpreted as the difference between the chemical potentials (the partial molar Gibbs energies) of the reactants and products *at the current composition of the reaction mixture*.

Because chemical potentials vary with composition, the slope of the plot of Gibbs energy against extent of reaction, and therefore the reaction Gibbs energy, changes as the reaction proceeds. The spontaneous direction of reaction lies in the direction of decreasing  $G$  (that is, down the slope of  $G$  plotted against  $\xi$ ). Thus we see from eqn 6A.2 that the reaction  $\text{A} \rightarrow \text{B}$  is spontaneous when  $\mu_A > \mu_B$ , whereas the reverse reaction is spontaneous when  $\mu_B > \mu_A$ . The slope is zero, and the reaction is at equilibrium and spontaneous in neither direction, when

$$\Delta_r G = 0 \quad \text{Condition of equilibrium} \quad (6A.3)$$

This condition occurs when  $\mu_B = \mu_A$  (Fig. 6A.1). It follows that, if we can find the composition of the reaction mixture that ensures  $\mu_B = \mu_A$ , then we can identify the composition of the reaction mixture at equilibrium. Note that the chemical potential is now fulfilling the role its name suggests: it represents the potential for chemical change, and equilibrium is attained when these potentials are in balance.

**Figure 6A.1** As the reaction advances (represented by motion from left to right along the horizontal axis) the slope of the Gibbs energy changes. Equilibrium corresponds to zero slope at the foot of the valley.

### (b) Exergonic and endergonic reactions

The spontaneity of a reaction at constant temperature and pressure can be expressed in terms of the reaction Gibbs energy:

- If  $\Delta_r G < 0$ , the forward reaction is spontaneous.
- If  $\Delta_r G > 0$ , the reverse reaction is spontaneous.
- If  $\Delta_r G = 0$ , the reaction is at equilibrium.

A reaction for which  $\Delta_r G < 0$  is called **exergonic** (from the Greek words for work producing). The name signifies that, because the process is spontaneous, it can be used to drive another process, such as another reaction, or used to do non-expansion work. A simple mechanical analogy is a pair of weights joined by a string (Fig. 6A.2): the lighter of the pair of weights will be pulled up as the heavier weight falls down. Although the lighter weight has a natural tendency to move downward, its coupling to the heavier weight results in it being raised. In biological cells, the oxidation of carbohydrates act as

**Figure 6A.2** If two weights are coupled as shown here, then the heavier weight will move the lighter weight in its non-spontaneous direction: overall, the process is still spontaneous. The weights are the analogues of two chemical reactions: a reaction with a large negative  $\Delta G$  can force another reaction with a smaller  $\Delta G$  to run in its non-spontaneous direction.

the heavy weight that drives other reactions forward and results in the formation of proteins from amino acids, muscle contraction, and brain activity. A reaction for which  $\Delta_r G > 0$  is called **endergonic** (signifying work consuming). The reaction can be made to occur only by doing work on it, such as electrolysing water to reverse its spontaneous formation reaction.

#### Brief illustration 6A.2 Exergonic and endergonic reactions

The standard Gibbs energy of the reaction  $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$  at 298 K is  $-237 \text{ kJ mol}^{-1}$ , so the reaction is exergonic and in a suitable device (a fuel cell, for instance) operating at constant temperature and pressure could produce 237 kJ of electrical work for each mole of  $\text{H}_2$  molecules that react. The reverse reaction, for which  $\Delta_r G^\ominus = +237 \text{ kJ mol}^{-1}$  is endergonic and at least 237 kJ of work must be done to achieve it.

**Self-test 6A.2** Classify the formation of methane from its elements as exergonic or endergonic under standard conditions at 298 K.

Answer: Endergonic

## 6A.2 The description of equilibrium

With the background established, we are now ready to see how to apply thermodynamics to the description of chemical equilibrium.

### (a) Perfect gas equilibria

When A and B are perfect gases we can use eqn 5A.14b ( $\mu = \mu^\ominus + RT \ln p$ , with  $p$  interpreted as  $p/p^\ominus$ ) to write

$$\begin{aligned} \Delta_r G &= \mu_B - \mu_A = (\mu_B^\ominus + RT \ln p_B) - (\mu_A^\ominus + RT \ln p_A) \\ &= \Delta_r G^\ominus + RT \ln \frac{p_B}{p_A} \end{aligned} \quad (6A.4)$$

If we denote the ratio of partial pressures by  $Q$ , we obtain

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q \quad Q = \frac{p_B}{p_A} \quad (6A.5)$$

The ratio  $Q$  is an example of a ‘reaction quotient’, a quantity we define more formally shortly. It ranges from 0 when  $p_B = 0$  (corresponding to pure A) to infinity when  $p_A = 0$  (corresponding to pure B). The standard reaction Gibbs energy,  $\Delta_r G^\ominus$  (Topic 3C), is the difference in the standard molar Gibbs energies of the reactants and products, so for our reaction

$$\Delta_r G^\ominus = G_m^\ominus(\text{B}) - G_m^\ominus(\text{A}) = \mu_B^\ominus - \mu_A^\ominus \quad (6A.6)$$

Note that in the definition of  $\Delta_r G^\ominus$ , the  $\Delta_r$  has its normal meaning as the difference ‘products – reactants’. In Topic 3C we saw that the difference in standard molar Gibbs energies of the products and reactants is equal to the difference in their standard Gibbs energies of formation, so in practice we calculate  $\Delta_r G^\ominus$  from

$$\Delta_r G^\ominus = \Delta_f G^\ominus(\text{B}) - \Delta_f G^\ominus(\text{A}) \quad (6A.7)$$

At equilibrium,  $\Delta_r G = 0$ . The ratio of partial pressures at equilibrium is denoted  $K$ , and eqn 6A.5 becomes

$$0 = \Delta_r G^\ominus + RT \ln K$$

which rearranges to

$$RT \ln K = -\Delta_r G^\ominus \quad K = \left( \frac{p_B}{p_A} \right)_{\text{equilibrium}} \quad (6A.8)$$

This relation is a special case of one of the most important equations in chemical thermodynamics: it is the link between tables of thermodynamic data, such as those in the *Resource section*, and the chemically important ‘equilibrium constant’,  $K$  (again, a quantity we define formally shortly).

#### Brief illustration 6A.3 The equilibrium constant

The standard Gibbs energy of the isomerization of pentane to 2-methylbutane at 298 K, the reaction  $\text{CH}_3(\text{CH}_2)_3\text{CH}_3(\text{g}) \rightarrow (\text{CH}_3)_2\text{CHCH}_2\text{CH}_3(\text{g})$ , is close to  $-6.7 \text{ kJ mol}^{-1}$  (this is an estimate based on enthalpies of formation; its actual value is not listed). Therefore, the equilibrium constant for the reaction is

$$K = e^{-(6.7 \times 10^3 \text{ J mol}^{-1}) / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = e^{2.7 \dots} = 15$$

**Self-test 6A.3** Suppose it is found that at equilibrium the partial pressures of A and B in the gas-phase reaction  $\text{A} \rightleftharpoons \text{B}$  are equal. What is the value of  $\Delta_r G^\ominus$ ?

Answer: 0

In molecular terms, the minimum in the Gibbs energy, which corresponds to  $\Delta_r G = 0$ , stems from the Gibbs energy of mixing of the two gases. To see the role of mixing, consider the reaction  $\text{A} \rightarrow \text{B}$ . If only the enthalpy were important, then  $H$  and therefore  $G$  would change linearly from its value for pure reactants to its value for pure products. The slope of this straight line is a constant and equal to  $\Delta_r G^\ominus$  at all stages of the reaction and there is no intermediate minimum in the graph (Fig. 6A.3). However, when the entropy is taken into account, there is an additional contribution to the Gibbs energy that is given by eqn 5A.16 ( $\Delta_{\text{mix}} G = nRT(x_A \ln x_A + x_B \ln x_B)$ ). This expression makes a U-shaped contribution to the total change in Gibbs energy.

**Figure 6A.3** If the mixing of reactants and products is ignored, then the Gibbs energy changes linearly from its initial value (pure reactants) to its final value (pure products) and the slope of the line is  $\Delta_r G^\ominus$ . However, as products are produced, there is a further contribution to the Gibbs energy arising from their mixing (lowest curve). The sum of the two contributions has a minimum. That minimum corresponds to the equilibrium composition of the system.

As can be seen from Fig. 6A.3, when it is included there is an intermediate minimum in the total Gibbs energy, and its position corresponds to the equilibrium composition of the reaction mixture.

We see from eqn 6A.8 that, when  $\Delta_r G^\ominus > 0$ ,  $K < 1$ . Therefore, at equilibrium the partial pressure of A exceeds that of B, which means that the reactant A is favoured in the equilibrium. When  $\Delta_r G^\ominus < 0$ ,  $K > 1$ , so at equilibrium the partial pressure of B exceeds that of A. Now the product B is favoured in the equilibrium.

*A note on good practice* A common remark is that ‘a reaction is spontaneous if  $\Delta_r G^\ominus < 0$ ’. However, whether or not a reaction is spontaneous at a particular composition depends on the value of  $\Delta_r G$  at that composition, not  $\Delta_r G^\ominus$ . It is far better to interpret the sign of  $\Delta_r G^\ominus$  as indicating whether  $K$  is greater or smaller than 1. The forward reaction is spontaneous ( $\Delta_r G < 0$ ) when  $Q < K$  and the reverse reaction is spontaneous when  $Q > K$ .

## (b) The general case of a reaction

We can now extend the argument that led to eqn 6A.8 to a general reaction. First, we note that a chemical reaction may be expressed symbolically in terms of (signed) stoichiometric numbers as

$$0 = \sum_J \nu_J J \quad \text{Symbolic form} \quad \text{Chemical equation} \quad (6A.9)$$

where  $J$  denotes the substances and the  $\nu_J$  are the corresponding stoichiometric numbers in the chemical equation. In the reaction  $2A + B \rightarrow 3C + D$ , for instance, these numbers have the

values  $\nu_A = -2$ ,  $\nu_B = -1$ ,  $\nu_C = +3$ , and  $\nu_D = +1$ . A stoichiometric number is positive for products and negative for reactants. Then we define the extent of reaction  $\xi$  so that, if it changes by  $\Delta\xi$ , then the change in the amount of any species  $J$  is  $\nu_J \Delta\xi$ .

With these points in mind and with the reaction Gibbs energy,  $\Delta_r G$ , defined in the same way as before (eqn 6A.1) we show in the following *Justification* that the Gibbs energy of reaction can always be written

$$\Delta_r G = \Delta_r G^\ominus + RT \ln Q \quad \text{Reaction Gibbs energy at an arbitrary stage} \quad (6A.10)$$

with the standard reaction Gibbs energy calculated from

$$\Delta_r G^\ominus = \sum_{\text{Products}} \nu \Delta_f G^\ominus - \sum_{\text{Reactants}} \nu \Delta_f G^\ominus \quad \text{Practical implementation} \quad \text{Reaction Gibbs energy} \quad (6A.11a)$$

where the  $\nu$  are the (positive) stoichiometric coefficients. More formally,

$$\Delta_r G^\ominus = \sum_J \nu_J \Delta_f G^\ominus (J) \quad \text{Formal expression} \quad \text{Reaction Gibbs energy} \quad (6A.11b)$$

where the  $\nu_J$  are the (signed) stoichiometric numbers. The reaction quotient,  $Q$ , has the form

$$Q = \frac{\text{activities of products}}{\text{activities of reactants}} \quad \text{General form} \quad \text{Reaction quotient} \quad (6A.12a)$$

with each species raised to the power given by its stoichiometric coefficient. More formally, to write the general expression for  $Q$  we introduce the symbol  $\Pi$  to denote the product of what follows it (just as  $\Sigma$  denotes the sum), and define  $Q$  as

$$Q = \prod_J a_J^{\nu_J} \quad \text{Definition} \quad \text{Reaction quotient} \quad (6A.12b)$$

Because reactants have negative stoichiometric numbers, they automatically appear as the denominator when the product is written out explicitly. Recall from Table 5E.1 that, for pure solids and liquids, the activity is 1, so such substances make no contribution to  $Q$  even though they may appear in the chemical equation.

### Brief illustration 6A.4 The reaction quotient

Consider the reaction  $2A + 3B \rightarrow C + 2D$ , in which case  $\nu_A = -2$ ,  $\nu_B = -3$ ,  $\nu_C = +1$ , and  $\nu_D = +2$ . The reaction quotient is then

$$Q = a_A^{-2} a_B^{-3} a_C a_D^2 = \frac{a_C a_D^2}{a_A^2 a_B^3}$$

**Self-test 6A.4** Write the reaction quotient for  $A + 2B \rightarrow 3C$ .

Answer:  $Q = a_C^3 / a_A a_B^2$

### Justification 6A.1 The dependence of the reaction Gibbs energy on the reaction quotient

Consider a reaction with stoichiometric numbers  $\nu_j$ . When the reaction advances by  $d\xi$ , the amounts of reactants and products change by  $dn_j = \nu_j d\xi$ . The resulting infinitesimal change in the Gibbs energy at constant temperature and pressure is

$$dG = \sum_j \mu_j dn_j = \sum_j \mu_j \nu_j d\xi = \left( \sum_j \mu_j \nu_j \right) d\xi$$

It follows that

$$\Delta_r G = \left( \frac{\partial G}{\partial \xi} \right)_{p,T} = \sum_j \nu_j \mu_j$$

To make progress, we note that the chemical potential of a species  $J$  is related to its activity by eqn 5E.9 ( $\mu_j = \mu_j^\ominus + RT \ln a_j$ ). When this expression is substituted into eqn 6A.11 we obtain

$$\begin{aligned} \Delta_r G &= \sum_j \nu_j \mu_j^\ominus + RT \sum_j \nu_j \ln a_j \\ &= \Delta_r G^\ominus + RT \sum_j \nu_j \ln a_j = \Delta_r G^\ominus + RT \ln \prod_j a_j^{\nu_j} \\ &= \Delta_r G^\ominus + RT \ln Q \end{aligned}$$

In the second line we use first  $a \ln x = \ln x^a$  and then  $\ln x + \ln y + \dots = \ln xy\dots$ , so

$$\sum_i \ln x_i = \ln \left( \prod_i x_i \right)$$

Now we conclude the argument, starting from eqn 6A.10. At equilibrium, the slope of  $G$  is zero:  $\Delta_r G = 0$ . The activities then have their equilibrium values and we can write

$$K = \left( \prod_j a_j^{\nu_j} \right)_{\text{equilibrium}} \quad \text{Definition} \quad \text{Equilibrium constant} \quad (6A.13)$$

This expression has the same form as  $Q$  but is evaluated using equilibrium activities. From now on, we shall not write the 'equilibrium' subscript explicitly, and will rely on the context to make it clear that for  $K$  we use equilibrium values and for  $Q$  we use the values at the specified stage of the reaction. An equilibrium constant  $K$  expressed in terms of activities (or fugacities) is called a **thermodynamic equilibrium constant**. Note that, because activities are dimensionless numbers, the thermodynamic equilibrium constant is also dimensionless. In elementary applications, the activities that occur in eqn 6A.13 are often replaced as follows:

State	Measure	Approximation for $a_j$	Definition
Solute	molality	$b_j/b_j^\ominus$	$b^\ominus = 1 \text{ mol kg}^{-1}$
	molar concentration	$[J]/c^\ominus$	$c^\ominus = 1 \text{ mol dm}^{-3}$
Gas phase	partial pressure	$p_j/p^\ominus$	$p^\ominus = 1 \text{ bar}$

In such cases, the resulting expressions are only approximations. The approximation is particularly severe for electrolyte solutions, for in them activity coefficients differ from 1 even in very dilute solutions (Topic 5F).

### Brief illustration 6A.5 The equilibrium constant

The equilibrium constant for the heterogeneous equilibrium  $\text{CaCO}_3(\text{s}) \rightleftharpoons \text{CaO}(\text{s}) + \text{CO}_2(\text{g})$  is

$$K = a_{\text{CaCO}_3(\text{s})}^{-1} a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})} = \frac{a_{\text{CaO}(\text{s})} a_{\text{CO}_2(\text{g})}}{a_{\text{CaCO}_3(\text{s})}} = a_{\text{CO}_2(\text{g})}$$

Provided the carbon dioxide can be treated as a perfect gas, we can go on to write

$$K = p_{\text{CO}_2}/p^\ominus$$

and conclude that in this case the equilibrium constant is the numerical value of the decomposition vapour pressure of calcium carbonate.

**Self-test 6A.5** Write the equilibrium constant for the reaction  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$ , with the gases treated as perfect.

$$\text{Answer: } K = a_{\text{NH}_3}^2 / a_{\text{N}_2} a_{\text{H}_2}^3 = p_{\text{NH}_3}^2 p^{\ominus 2} / p_{\text{N}_2} p_{\text{H}_2}^3$$

At this point we set  $\Delta_r G = 0$  in eqn 6A.10 and replace  $Q$  by  $K$ . We immediately obtain

$$\Delta_r G^\ominus = -RT \ln K \quad \text{Thermodynamic equilibrium constant} \quad (6A.14)$$

This is an exact and highly important thermodynamic relation, for it enables us to calculate the equilibrium constant of any reaction from tables of thermodynamic data, and hence to predict the equilibrium composition of the reaction mixture. In Topic 15F we see that the right-hand side of eqn 6A.14 may be expressed in terms of spectroscopic data for gas-phase species; so this expression also provides a link between spectroscopy and equilibrium composition.

### Example 6A.1 Calculating an equilibrium constant

Calculate the equilibrium constant for the ammonia synthesis reaction,  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$ , at 298 K and show how  $K$  is related to the partial pressures of the species at equilibrium

when the overall pressure is low enough for the gases to be treated as perfect.

**Method** Calculate the standard reaction Gibbs energy from eqn 6A.10 and convert it to the value of the equilibrium constant by using eqn 6A.14. The expression for the equilibrium constant is obtained from eqn 6A.13, and because the gases are taken to be perfect, we replace each activity by the ratio  $p_i/p^\ominus$ , where  $p_i$  is the partial pressure of species  $i$ .

**Answer** The standard Gibbs energy of the reaction is

$$\begin{aligned}\Delta_r G^\ominus &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) - \{\Delta_f G^\ominus(\text{N}_2, \text{g}) + 3\Delta_f G^\ominus(\text{H}_2, \text{g})\} \\ &= 2\Delta_f G^\ominus(\text{NH}_3, \text{g}) = 2 \times (-16.45 \text{ kJ mol}^{-1})\end{aligned}$$

Then,

$$\ln K = -\frac{2 \times (-1.645 \times 10^4 \text{ J mol}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = \frac{2 \times 1.645 \times 10^4}{8.3145 \times 298} = 13.2 \dots$$

Hence,  $K = 5.8 \times 10^5$ . This result is thermodynamically exact. The thermodynamic equilibrium constant for the reaction is

$$K = \frac{a_{\text{NH}_3}^2}{a_{\text{N}_2} a_{\text{H}_2}^3}$$

and this ratio has the value we have just calculated. At low overall pressures, the activities can be replaced by the ratios  $p_i/p^\ominus$  and an approximate form of the equilibrium constant is

$$K = \frac{(p_{\text{NH}_3}/p^\ominus)^2}{(p_{\text{N}_2}/p^\ominus)(p_{\text{H}_2}/p^\ominus)^3} = \frac{p_{\text{NH}_3}^2 p^{\ominus 2}}{p_{\text{N}_2} p_{\text{H}_2}^3}$$

**Self-test 6A.6** Evaluate the equilibrium constant for  $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$  at 298 K.

Answer:  $K = 0.15$

### Example 6A.2 Estimating the degree of dissociation at equilibrium

The *degree of dissociation* (or *extent of dissociation*,  $\alpha$ ) is defined as the fraction of reactant that has decomposed; if the initial amount of reactant is  $n$  and the amount at equilibrium is  $n_{\text{eq}}$ , then  $\alpha = (n - n_{\text{eq}})/n$ . The standard reaction Gibbs energy for the decomposition  $\text{H}_2\text{O}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g})$  is  $+118.08 \text{ kJ mol}^{-1}$  at 2300 K. What is the degree of dissociation of  $\text{H}_2\text{O}$  at 2300 K and 1.00 bar?

**Method** The equilibrium constant is obtained from the standard Gibbs energy of reaction by using eqn 6A.11, so the task is to relate the degree of dissociation,  $\alpha$ , to  $K$  and then to find its numerical value. Proceed by expressing the equilibrium compositions in terms of  $\alpha$ , and solve for  $\alpha$  in terms of  $K$ . Because the standard reaction Gibbs energy is large and positive, we can anticipate that  $K$  will be small, and hence that  $\alpha \ll 1$ ,

which opens the way to making approximations to obtain its numerical value.

**Answer** The equilibrium constant is obtained from eqn 6A.14 in the form

$$\begin{aligned}\ln K &= -\frac{\Delta_r G^\ominus}{RT} = -\frac{1.1808 \times 10^5 \text{ J mol}^{-1}}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (2300 \text{ K})} \\ &= -\frac{1.1808 \times 10^5}{8.3145 \times 2300} = -6.17 \dots\end{aligned}$$

It follows that  $K = 2.08 \times 10^{-3}$ . The equilibrium composition can be expressed in terms of  $\alpha$  by drawing up the following table:

	$\text{H}_2\text{O}$	$\text{H}_2$	$+\frac{1}{2}\text{O}_2$	
Initial amount	$n$	0	0	
Change to reach equilibrium	$-\alpha n$	$+\alpha n$	$+\frac{1}{2}\alpha n$	
Amount at equilibrium	$(1-\alpha)n$	$\alpha n$	$\frac{1}{2}\alpha n$	Total: $(1+\frac{1}{2}\alpha)n$
Mole fraction, $x_i$	$\frac{1-\alpha}{1+\frac{1}{2}\alpha}$	$\frac{\alpha}{1+\frac{1}{2}\alpha}$	$\frac{\frac{1}{2}\alpha}{1+\frac{1}{2}\alpha}$	
Partial pressure, $p_i$	$\frac{(1-\alpha)p}{1+\frac{1}{2}\alpha}$	$\frac{\alpha p}{1+\frac{1}{2}\alpha}$	$\frac{\frac{1}{2}\alpha p}{1+\frac{1}{2}\alpha}$	

where, for the entries in the last row, we have used  $p_i = x_i p$  (eqn 1A.8). The equilibrium constant is therefore

$$K = \frac{p_{\text{H}_2} p_{\text{O}_2}^{1/2}}{p_{\text{H}_2\text{O}}} = \frac{\alpha^{3/2} p^{1/2}}{(1-\alpha)(2+\alpha)^{1/2}}$$

In this expression, we have written  $p$  in place of  $p/p^\ominus$ , to simplify its appearance. Now make the approximation that  $\alpha \ll 1$ , and hence obtain

$$K \approx \frac{\alpha^{3/2} p^{1/2}}{2^{1/2}}$$

Under the stated condition,  $p = 1.00 \text{ bar}$  (that is,  $p/p^\ominus = 1.00$ ), so  $\alpha \approx (2^{1/2} K)^{2/3} = 0.0205$ . That is, about 2 per cent of the water has decomposed.

*A note on good practice* Always check that the approximation is consistent with the final answer. In this case  $\alpha \ll 1$ , in accord with the original assumption.

**Self-test 6A.7** Given that the standard Gibbs energy of reaction at 2000 K is  $+135.2 \text{ kJ mol}^{-1}$  for the same reaction, suppose that steam at 200 kPa is passed through a furnace tube at that temperature. Calculate the mole fraction of  $\text{O}_2$  present in the output gas stream.

Answer: 0.00221

### (c) The relation between equilibrium constants

Equilibrium constants in terms of activities are exact, but it is often necessary to relate them to concentrations. Formally, we need to know the activity coefficients, and then to use  $a_j = \gamma_j x_j$ ,  $a_j = \gamma_j b_j / b^\ominus$ , or  $a_j = [J] / c^\ominus$ , where  $x_j$  is a mole fraction,  $b_j$  is a molality, and  $[J]$  is a molar concentration. For example, if we were interested in the composition in terms of molality for an equilibrium of the form  $A + B \rightleftharpoons C + D$ , where all four species are solutes, we would write

$$K = \frac{a_C a_D}{a_A a_B} = \frac{\gamma_C \gamma_D}{\gamma_A \gamma_B} \times \frac{b_C b_D}{b_A b_B} = K_\gamma K_b \quad (6A.15)$$

The activity coefficients must be evaluated at the equilibrium composition of the mixture (for instance, by using one of the Debye–Hückel expressions, Topic 5F), which may involve a complicated calculation, because the activity coefficients are known only if the equilibrium composition is already known. In elementary applications, and to begin the iterative calculation of the concentrations in a real example, the assumption is often made that the activity coefficients are all so close to unity that  $K_\gamma = 1$ . Then we obtain the result widely used in elementary chemistry that  $K \approx K_b$ , and equilibria are discussed in terms of molalities (or molar concentrations) themselves.

A special case arises when we need to express the equilibrium constant of a gas-phase reaction in terms of molar concentrations instead of the partial pressures that appear in the thermodynamic equilibrium constant. Provided we can treat the gases as perfect, the  $p_j$  that appear in  $K$  can be replaced by  $[J]RT$ , and

$$\begin{aligned} K &= \prod_j a_j^{\nu_j} = \prod_j \left( \frac{p_j}{p^\ominus} \right)^{\nu_j} = \prod_j [J]^{\nu_j} \left( \frac{RT}{p^\ominus} \right)^{\nu_j} \\ &= \prod_j [J]^{\nu_j} \times \prod_j \left( \frac{RT}{p^\ominus} \right)^{\nu_j} \end{aligned}$$

(Products can always be factorized like that:  $abcdef$  is the same as  $abc \times def$ .) The (dimensionless) equilibrium constant  $K_c$  is defined as

$$K_c = \prod_j \left( \frac{[J]}{c^\ominus} \right)^{\nu_j} \quad \text{Definition } K_c \text{ for gas-phase reactions} \quad (6A.16)$$

It follows that

$$K = K_c \times \prod_j \left( \frac{c^\ominus RT}{p^\ominus} \right)^{\nu_j} \quad (6A.17a)$$

If now we write  $\Delta \nu = \sum_j \nu_j$ , which is easier to think of as  $\nu(\text{products}) - \nu(\text{reactants})$ , then the relation between  $K$  and  $K_c$  for a gas-phase reaction is

$$K = K_c \times \left( \frac{c^\ominus RT}{p^\ominus} \right)^{\Delta \nu} \quad \text{Relation between } K \text{ and } K_c \text{ for gas-phase reactions} \quad (6A.17b)$$

The term in parentheses works out as  $T/(12.03 \text{ K})$ .

#### Brief illustration 6A.6 The relation between equilibrium constants

For the reaction  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightarrow 2 \text{NH}_3(\text{g})$ ,  $\Delta \nu = 2 - 4 = -2$ , so

$$K = K_c \times \left( \frac{T}{12.03 \text{ K}} \right)^{-2} = K_c \times \left( \frac{12.03 \text{ K}}{T} \right)^2$$

At 298.15 K the relation is

$$K = K_c \times \left( \frac{12.03 \text{ K}}{298.15 \text{ K}} \right)^2 = \frac{K_c}{614.2}$$

so  $K_c = 614.2K$ . Note that both  $K$  and  $K_c$  are dimensionless.

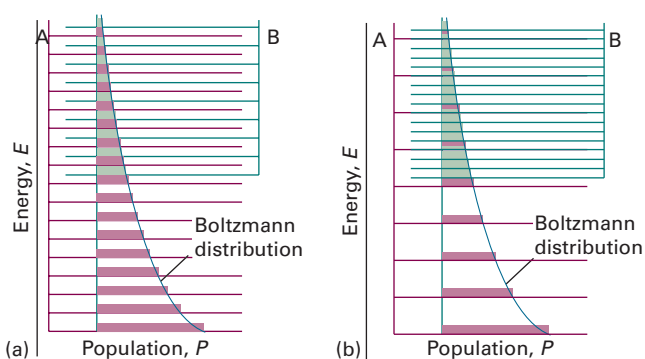

**Self-test 6A.8** Find the relation between  $K$  and  $K_c$  for the equilibrium  $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$  at 298 K.

Answer:  $K_c = 123K$

### (d) Molecular interpretation of the equilibrium constant

Deeper insight into the origin and significance of the equilibrium constant can be obtained by considering the Boltzmann distribution of molecules over the available states of a system composed of reactants and products (Foundations B). When atoms can exchange partners, as in a reaction, the available states of the system include arrangements in which the atoms are present in the form of reactants and in the form of products: these arrangements have their characteristic sets of energy levels, but the Boltzmann distribution does not distinguish between their identities, only their energies. The atoms distribute themselves over both sets of energy levels in accord with the Boltzmann distribution (Fig. 6A.4). At a given temperature, there will be a specific distribution of populations, and hence a specific composition of the reaction mixture.

It can be appreciated from the illustration that, if the reactants and products both have similar arrays of molecular energy levels, then the dominant species in a reaction mixture at equilibrium will be the species with the lower set of energy levels. However, the fact that the Gibbs energy occurs in the expression is a signal that entropy plays a role as well as energy. Its role can be appreciated by referring to Fig. 6A.4. In Fig. 6A.4b we see that, although the B energy levels lie higher than the A energy levels, in this instance they are much more closely spaced. As a result, their total population may be considerable and B could even dominate in the reaction mixture at equilibrium. Closely spaced energy levels correlate with a high

**Figure 6A.4** The Boltzmann distribution of populations over the energy levels of two species A and B with similar densities of energy levels. The reaction  $A \rightarrow B$  is endothermic in this example. (a) The bulk of the population is associated with the species A, so that species is dominant at equilibrium. (b) Even though the reaction  $A \rightarrow B$  is endothermic, the density of energy levels in B is so much greater than that in A that the population associated with B is greater than that associated with A, so B is dominant at equilibrium.

entropy (Topic 15E), so in this case we see that entropy effects dominate adverse energy effects. This competition is mirrored in eqn 6A.14, as can be seen most clearly by using  $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$  and writing it in the form

$$K = e^{-\Delta_r H^\ominus/RT} e^{\Delta_r S^\ominus/R} \quad (6A.18)$$

Note that a positive reaction enthalpy results in a lowering of the equilibrium constant (that is, an endothermic reaction can be expected to have an equilibrium composition that favours the reactants). However, if there is positive reaction entropy, then the equilibrium composition may favour products, despite the endothermic character of the reaction.

#### Brief illustration 6A.7 Contributions to $K$

In *Example 6A.1* it is established that  $\Delta_r G^\ominus = -33.0 \text{ kJ mol}^{-1}$  for the reaction  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$  at 298 K. From the tables of data in the *Resource section*, we can find that  $\Delta_r H^\ominus = -92.2 \text{ kJ mol}^{-1}$  and  $\Delta_r S^\ominus = -198.8 \text{ J K}^{-1} \text{ mol}^{-1}$ . The contributions to  $K$  are therefore

$$\begin{aligned} K &= e^{-(9.22 \times 10^4 \text{ J mol}^{-1})/(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} \\ &\quad \times e^{(-198.8 \text{ J K}^{-1} \text{ mol}^{-1})/(8.3145 \text{ J K}^{-1} \text{ mol}^{-1})} \\ &= e^{37.2\dots} \times e^{-23.9\dots} \end{aligned}$$

We see that the exothermic character of the reaction encourages the formation of products (it results in a large increase in entropy of the surroundings) but the decrease in entropy of the system as H atoms are pinned to N atoms opposes their formation.

**Self-test 6A.9** Analyse the equilibrium  $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$  similarly.

Answer:  $K = e^{-26.7\dots} \times e^{21.1\dots}$ ; enthalpy opposes, entropy encourages

## Checklist of concepts

1. The **reaction Gibbs energy** is the slope of the plot of Gibbs energy against extent of reaction.
2. Reactions are either **exergonic** or **endergonic**.
3. The reaction Gibbs energy depends logarithmically on the **reaction quotient**.
4. When the reaction Gibbs energy is zero the reaction quotient has a value called the **equilibrium constant**.
5. Under ideal conditions, the thermodynamic equilibrium constant may be approximated by expressing it in terms of concentrations and partial pressures.

## Checklist of equations

### ► Why do you need to know this material?

Chemists, and chemical engineers designing a chemical plant, need to know how an equilibrium will respond to changes in the conditions, such as a change in pressure or temperature. The variation with temperature also provides a way to determine the enthalpy and entropy of a reaction.

### ► What is the key idea?

A system at equilibrium, when subjected to a disturbance, responds in a way that tends to minimize the effect of the disturbance.

### ► What do you need to know already?

This Topic builds on the relation between the equilibrium constant and the standard Gibbs energy of reaction (Topic 6A). To express the temperature dependence of  $K$  it draws on the Gibbs–Helmholtz equation (Topic 3D).

The equilibrium constant for a reaction is not affected by the presence of a catalyst or an enzyme (a biological catalyst). As explained in detail in Topics 20H and 22C, catalysts increase the rate at which equilibrium is attained but do not affect its position. However, it is important to note that in industry reactions rarely reach equilibrium, partly on account of the rates at which reactants mix. The equilibrium constant is also independent of pressure, but as we shall see, that does not necessarily mean

that the composition at equilibrium is independent of pressure. The equilibrium constant does depend on the temperature in a manner that can be predicted from the standard reaction enthalpy.

## 6B.1 The response to pressure

The equilibrium constant depends on the value of  $\Delta_r G^\ominus$ , which is defined at a single, standard pressure. The value of  $\Delta_r G^\ominus$ , and hence of  $K$ , is therefore independent of the pressure at which the equilibrium is actually established. In other words, at a given temperature  $K$  is a constant.

The conclusion that  $K$  is independent of pressure does not necessarily mean that the equilibrium composition is independent of the pressure, and the effect depends on how the pressure is applied.

The pressure within a reaction vessel can be increased by injecting an inert gas into it. However, so long as the gases are perfect, this addition of gas leaves all the partial pressures of the reacting gases unchanged: the partial pressures of a perfect gas is the pressure it would exert if it were alone in the container, so the presence of another gas has no effect. It follows that pressurization by the addition of an inert gas has no effect on the equilibrium composition of the system (provided the gases are perfect).

Alternatively, the pressure of the system may be increased by confining the gases to a smaller volume (that is, by compression). Now the individual partial pressures are changed but their ratio (as it appears in the equilibrium constant) remains the same. Consider, for instance, the perfect gas equilibrium  $A \rightleftharpoons 2 B$ , for which the equilibrium constant is

$$K = \frac{p_B^2}{p_A p^\ominus}$$

The right-hand side of this expression remains constant only if an increase in  $p_A$  cancels an increase in the *square* of  $p_B$ . This relatively steep increase of  $p_A$  compared to  $p_B$  will occur if the equilibrium composition shifts in favour of A at the expense of B. Then the number of A molecules will increase as the volume of the container is decreased and its partial pressure will rise

**Figure 6B.1** When a reaction at equilibrium is compressed (from *a* to *b*), the reaction responds by reducing the number of molecules in the gas phase (in this case by producing the dimers represented by the linked spheres).

more rapidly than can be ascribed to a simple change in volume alone (Fig. 6B.1).

The increase in the number of A molecules and the corresponding decrease in the number of B molecules in the equilibrium  $A \rightleftharpoons 2 B$  is a special case of a principle proposed by the French chemist Henri Le Chatelier, which states that:

A system at equilibrium, when subjected to a disturbance, responds in a way that tends to minimize the effect of the disturbance.

Le Chatelier's principle

The principle implies that, if a system at equilibrium is compressed, then the reaction will adjust so as to minimize the increase in pressure. This it can do by reducing the number of particles in the gas phase, which implies a shift  $A \leftarrow 2 B$ .

To treat the effect of compression quantitatively, we suppose that there is an amount  $n$  of A present initially (and no B). At equilibrium the amount of A is  $(1 - \alpha)n$  and the amount of B is  $2\alpha n$ , where  $\alpha$  is the degree of dissociation of A into 2B. It follows that the mole fractions present at equilibrium are

$$x_A = \frac{(1-\alpha)n}{(1-\alpha)n + 2\alpha n} = \frac{1-\alpha}{1+\alpha} \quad x_B = \frac{2\alpha}{1+\alpha}$$

The equilibrium constant for the reaction is

$$K = \frac{p_B^2}{p_A p^\ominus} = \frac{x_B^2 p^2}{x_A p p^\ominus} = \frac{4\alpha^2 (p/p^\ominus)}{1-\alpha^2}$$

which rearranges to

$$\alpha = \left( \frac{1}{1 + 4p/Kp^\ominus} \right)^{1/2} \quad (6B.1)$$

This formula shows that, even though  $K$  is independent of pressure, the amounts of A and B do depend on pressure (Fig. 6B.2). It also shows that as  $p$  is increased,  $\alpha$  decreases, in accord with Le Chatelier's principle.

### Brief illustration 6B.1 Le Chatelier's principle

To predict the effect of an increase in pressure on the composition of the ammonia synthesis at equilibrium, *Example 6A.1*, we note that the number of gas molecules decreases (from 4 to 2). So, Le Chatelier's principle predicts that an increase in pressure will favour the product. The equilibrium constant is

$$K = \frac{p_{\text{NH}_3}^2 p^\ominus}{p_{\text{N}_2} p_{\text{H}_2}^3} = \frac{x_{\text{NH}_3}^2 p^2 p^\ominus}{x_{\text{N}_2} x_{\text{H}_2}^3 p^4} = \frac{x_{\text{NH}_3}^2 p^\ominus}{x_{\text{N}_2} x_{\text{H}_2}^3 p^2} = K_x \times \frac{p^\ominus}{p^2}$$

where  $K_x$  is the part of the equilibrium constant expression that contains the equilibrium mole fractions of reactants and products (note that, unlike  $K$  itself,  $K_x$  is not an equilibrium constant). Therefore, doubling the pressure must increase  $K_x$  by a factor of 4 to preserve the value of  $K$ .

**Self-test 6B.1** Predict the effect of a tenfold pressure increase on the equilibrium composition of the reaction  $3 \text{N}_2(\text{g}) + \text{H}_2(\text{g}) \rightleftharpoons 2 \text{N}_3\text{H}(\text{g})$ .

Answer: 100-fold increase in  $K_x$

**Figure 6B.2** The pressure dependence of the degree of dissociation,  $\alpha$ , at equilibrium for an  $A(\text{g}) \rightleftharpoons 2 B(\text{g})$  reaction for different values of the equilibrium constant  $K$ . The value  $\alpha=0$  corresponds to pure A;  $\alpha=1$  corresponds to pure B

## 6B.2 The response to temperature

Le Chatelier's principle predicts that a system at equilibrium will tend to shift in the endothermic direction if the temperature is raised, for then energy is absorbed as heat and the rise in temperature is opposed. Conversely, an equilibrium can be expected to shift in the exothermic direction if the temperature is lowered, for then energy is released and the reduction in temperature is opposed. These conclusions can be summarized as follows:

Exothermic reactions: increased temperature favours the reactants.

Endothermic reactions: increased temperature favours the products.

We shall now justify these remarks thermodynamically and see how to express the changes quantitatively.

### (a) The van 't Hoff equation

The **van 't Hoff equation**, which is derived in the following *Justification*, is an expression for the slope of a plot of the equilibrium constant (specifically,  $\ln K$ ) as a function of temperature. It may be expressed in either of two ways:

$$\frac{d \ln K}{dT} = \frac{\Delta_r H^\ominus}{RT^2} \quad \text{van 't Hoff equation} \quad (6B.2a)$$

$$\frac{d \ln K}{d(1/T)} = -\frac{\Delta_r H^\ominus}{R} \quad \text{Alternative version} \quad \text{van 't Hoff equation} \quad (6B.2b)$$

#### Justification 6B.1 The van 't Hoff equation

From eqn 6A.14, we know that

$$\ln K = -\frac{\Delta_r G^\ominus}{RT}$$

Differentiation of  $\ln K$  with respect to temperature then gives

$$\frac{d \ln K}{dT} = -\frac{1}{R} \frac{d(\Delta_r G^\ominus/T)}{dT}$$

The differentials are complete (that is, they are not partial derivatives) because  $K$  and  $\Delta_r G^\ominus$  depend only on temperature, not on pressure. To develop this equation we use the Gibbs–Helmholtz equation (eqn 3D.10,  $d(\Delta G/T) = -\Delta H/T^2$ ) in the form

$$\frac{d(\Delta_r G^\ominus/T)}{dT} = -\frac{\Delta_r H^\ominus}{R}$$

where  $\Delta_r H^\ominus$  is the standard reaction enthalpy at the temperature  $T$ . Combining the two equations gives the van 't Hoff equation, eqn 6B.2a. The second form of the equation is obtained by noting that

$$\frac{d(1/T)}{dT} = -\frac{1}{T^2}, \quad \text{so } dT = -T^2 d(1/T)$$

It follows that eqn 6B.2a can be rewritten as

$$-\frac{d \ln K}{T^2 d(1/T)} = \frac{\Delta_r H^\ominus}{RT^2}$$

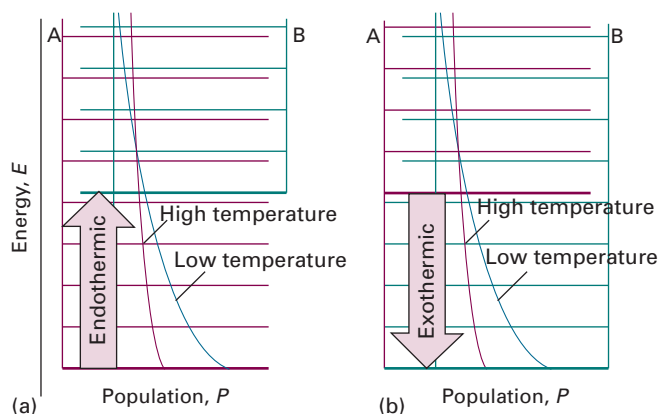

which simplifies into eqn 6B.2b.

Equation 6B.2a shows that  $d \ln K/dT < 0$  (and therefore that  $dK/dT < 0$ ) for a reaction that is exothermic under standard

conditions ( $\Delta_r H^\ominus < 0$ ). A negative slope means that  $\ln K$ , and therefore  $K$  itself, decreases as the temperature rises. Therefore, as asserted above, in the case of an exothermic reaction the equilibrium shifts away from products. The opposite occurs in the case of endothermic reactions.

Insight into the thermodynamic basis of this behaviour comes from the expression  $\Delta_r G^\ominus = \Delta_r H^\ominus - T\Delta_r S^\ominus$  written in the form  $-\Delta_r G^\ominus/T = -\Delta_r H^\ominus/T + \Delta_r S^\ominus$ . When the reaction is exothermic,  $-\Delta_r H^\ominus/T$  corresponds to a positive change of entropy of the surroundings and favours the formation of products. When the temperature is raised,  $-\Delta_r H^\ominus/T$  decreases and the increasing entropy of the surroundings has a less important role. As a result, the equilibrium lies less to the right. When the reaction is endothermic, the principal factor is the increasing entropy of the reaction system. The importance of the unfavourable change of entropy of the surroundings is reduced if the temperature is raised (because then  $\Delta_r H^\ominus/T$  is smaller), and the reaction is able to shift towards products.

These remarks have a molecular basis that stems from the Boltzmann distribution of molecules over the available energy levels (*Foundations B*, and in more detail in Topic 15F). The typical arrangement of energy levels for an endothermic reaction is shown in Fig. 6B.3a. When the temperature is increased, the Boltzmann distribution adjusts and the populations change as shown. The change corresponds to an increased population of the higher energy states at the expense of the population of the lower energy states. We see that the states that arise from the B molecules become more populated at the expense of the A molecules. Therefore, the total population of B states increases, and B becomes more abundant in the equilibrium mixture. Conversely, if the reaction is exothermic (Fig. 6B.3b),

**Figure 6B.3** The effect of temperature on a chemical equilibrium can be interpreted in terms of the change in the Boltzmann distribution with temperature and the effect of that change in the population of the species. (a) In an endothermic reaction, the population of B increases at the expense of A as the temperature is raised. (b) In an exothermic reaction, the opposite happens.

then an increase in temperature increases the population of the A states (which start at higher energy) at the expense of the B states, so the reactants become more abundant.

The temperature dependence of the equilibrium constant provides a non-calorimetric method of determining  $\Delta_r H^\ominus$ . A drawback is that the reaction enthalpy is actually temperature-dependent, so the plot is not expected to be perfectly linear. However, the temperature dependence is weak in many cases, so the plot is reasonably straight. In practice, the method is not very accurate, but it is often the only method available.

### Example 6B.1 Measuring a reaction enthalpy

The data below show the temperature variation of the equilibrium constant of the reaction  $\text{Ag}_2\text{CO}_3(\text{s}) \rightleftharpoons \text{Ag}_2\text{O}(\text{s}) + \text{CO}_2(\text{g})$ . Calculate the standard reaction enthalpy of the decomposition.

$T/\text{K}$	350	400	450	500
$K$	$3.98 \times 10^{-4}$	$1.41 \times 10^{-2}$	$1.86 \times 10^{-1}$	1.48

**Method** It follows from eqn 6B.2b that, provided the reaction enthalpy can be assumed to be independent of temperature, a plot of  $-\ln K$  against  $1/T$  should be a straight line of slope  $\Delta_r H^\ominus/R$ .

**Answer** We draw up the following table:

$T/\text{K}$	350	400	450	500
$(10^3 \text{ K})/T$	2.86	2.50	2.22	2.00
$-\ln K$	6.83	4.26	1.68	-0.39

**Figure 6B.4** When  $-\ln K$  is plotted against  $1/T$ , a straight line is expected with slope equal to  $\Delta_r H^\ominus/R$  if the standard reaction enthalpy does not vary appreciably with temperature. This is a non-calorimetric method for the measurement of reaction enthalpies.

These points are plotted in Fig. 6B.4. The slope of the graph is  $+9.6 \times 10^3$ , so

$$\Delta_r H^\ominus = (+9.6 \times 10^3 \text{ K}) \times R = +80 \text{ kJ mol}^{-1}$$

**Self-test 6B.2** The equilibrium constant of the reaction  $2 \text{SO}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2 \text{SO}_3(\text{g})$  is  $4.0 \times 10^{24}$  at 300 K,  $2.5 \times 10^{10}$  at 500 K, and  $3.0 \times 10^4$  at 700 K. Estimate the reaction enthalpy at 500 K.

Answer:  $-200 \text{ kJ mol}^{-1}$

### (b) The value of $K$ at different temperatures

To find the value of the equilibrium constant at a temperature  $T_2$  in terms of its value  $K_1$  at another temperature  $T_1$ , we integrate eqn 6B.2b between these two temperatures:

$$\ln K_2 - \ln K_1 = -\frac{1}{R} \int_{1/T_1}^{1/T_2} \Delta_r H^\ominus d(1/T) \quad (6B.4)$$

If we suppose that  $\Delta_r H^\ominus$  varies only slightly with temperature over the temperature range of interest, then we may take it outside the integral. It follows that

$$\ln K_2 - \ln K_1 = -\frac{\Delta_r H^\ominus}{R} \left( \frac{1}{T_2} - \frac{1}{T_1} \right) \quad \text{Temperature dependence of } K \quad (6B.5)$$

### Brief illustration 6B.2 The temperature dependence of $K$

To estimate the equilibrium constant or the synthesis of ammonia at 500 K from its value at 298 K ( $6.1 \times 10^5$  for the reaction written as  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightleftharpoons 2 \text{NH}_3(\text{g})$ ) we use the standard reaction enthalpy, which can be obtained from Table 2C.2 in the *Resource section* by using  $\Delta_r H^\ominus = 2\Delta_f H^\ominus(\text{NH}_3, \text{g})$  and assume that its value is constant over the range of temperatures. Then, with  $\Delta_r H^\ominus = -92.2 \text{ kJ mol}^{-1}$ , from eqn 6B.3 we find

$$\begin{aligned} \ln K_2 &= \ln(6.1 \times 10^5) - \left( \frac{-9.22 \times 10^4 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \right) \times \left( \frac{1}{500 \text{ K}} - \frac{1}{298 \text{ K}} \right) \\ &= -1.7 \dots \end{aligned}$$

It follows that  $K_2 = 0.18$ , a lower value than at 298 K, as expected for this exothermic reaction.

**Self-test 6B.3** The equilibrium constant for  $\text{N}_2\text{O}_4(\text{g}) \rightleftharpoons 2 \text{NO}_2(\text{g})$  was calculated in *Self-test 6A.6*. Estimate its value at  $100^\circ\text{C}$ .

Answer: 15

## Checklist of concepts

- 1. The thermodynamic equilibrium constant is independent of pressure.
- 3. The dependence of the equilibrium constant on the temperature is expressed by the **van 't Hoff equation** and can be explained in terms of the distribution of molecules over the available states.
- 2. The response of composition to changes in the conditions is summarized by **Le Chatelier's principle**.

## Checklist of equations

Property	Equation	Comment	Equation number
van 't Hoff equation	$d \ln K/dT = \Delta_r H^\ominus / RT^2$		6B.2a
	$d \ln K/d(1/T) = -\Delta_r H^\ominus / R$	Alternative version	6B.2b
Temperature dependence of equilibrium constant	$\ln K_2 - \ln K_1 = -(\Delta_r H^\ominus / R)(1/T_2 - 1/T_1)$	$\Delta_r H^\ominus$ assumed constant	6B.5

of how to calculate the work of moving a charge through an electrical potential difference (Topic 2A). The equations make use of the definition of the reaction quotient  $Q$  and the equilibrium constant  $K$  (Topic 6A).

An **electrochemical cell** consists of two **electrodes**, or metallic conductors, in contact with an **electrolyte**, an ionic conductor (which may be a solution, a liquid, or a solid). An electrode and its electrolyte comprise an **electrode compartment**. The two electrodes may share the same compartment. The various kinds of electrode are summarized in Table 6C.1. Any ‘inert metal’ shown as part of the specification is present to act as a source or sink of electrons, but takes no other part in the reaction other than acting as a catalyst for it. If the electrolytes are different, the two compartments may be joined by a **salt bridge**, which is a tube containing a concentrated electrolyte solution (for instance, potassium chloride in agar jelly) that completes the electrical circuit and enables the cell to function. A **galvanic cell** is an electrochemical cell that produces electricity as a result of the spontaneous reaction occurring inside it. An **electrolytic cell** is an electrochemical cell in which a non-spontaneous reaction is driven by an external source of current.

### ► Why do you need to know this material?

One very special case of the material treated in Topic 6B that has enormous fundamental, technological, and economic significance concerns reactions that take place in electrochemical cells. Moreover, the ability to make very precise measurements of potential differences (‘voltages’) means that electrochemical methods can be used to determine thermodynamic properties of reactions that may be inaccessible by other methods.

### ► What is the key idea?

The electrical work that a reaction can perform at constant pressure and temperature is equal to the reaction Gibbs energy.

### ► What do you need to know already?

This Topic develops the relation between the Gibbs energy and non-expansion work (Topic 3C). You need to be aware

## 6C.1 Half-reactions and electrodes

It will be familiar from introductory chemistry courses that **oxidation** is the removal of electrons from a species, a **reduction** is the addition of electrons to a species, and a **redox reaction** is a

Table 6C.1 Varieties of electrode

Electrode type	Designation	Redox couple	Half-reaction
Metal/ metal ion	$M(s) M^+(aq)$	$M^+/M$	$M^+(aq) + e^- \rightarrow M(s)$
Gas	$Pt(s) X_2(g) X^+(aq)$	$X^+/X_2$	$X^+(aq) + e^- \rightarrow \frac{1}{2} X_2(g)$
	$Pt(s) X_2(g) X^-(aq)$	$X_2/X^-$	$\frac{1}{2} X_2(g) + e^- \rightarrow X^-(aq)$
Metal/ insoluble salt	$M(s) MX(s) X^-(aq)$	$MX/M, X^-$	$MX(s) + e^- \rightarrow M(s) + X^-(aq)$
Redox	$Pt(s) M^+(aq), M^{2+}(aq)$	$M^{2+}/M^+$	$M^{2+}(aq) + e^- \rightarrow M^+(aq)$

reaction in which there is a transfer of electrons from one species to another. The electron transfer may be accompanied by other events, such as atom or ion transfer, but the net effect is electron transfer and hence a change in oxidation number of an element. The **reducing agent** (or *reductant*) is the electron donor; the **oxidizing agent** (or *oxidant*) is the electron acceptor. It should also be familiar that any redox reaction may be expressed as the difference of two reduction **half-reactions**, which are conceptual reactions showing the gain of electrons. Even reactions that are not redox reactions may often be expressed as the difference of two reduction half-reactions. The reduced and oxidized species in a half-reaction form a **redox couple**. In general we write a couple as Ox/Red and the corresponding reduction half-reaction as

### Brief illustration 6C.1 Redox couples

The dissolution of silver chloride in water  $\text{AgCl}(s) \rightarrow \text{Ag}^+(aq) + \text{Cl}^-(aq)$ , which is not a redox reaction, can be expressed as the difference of the following two reduction half-reactions:

The redox couples are  $\text{AgCl}/\text{Ag}, \text{Cl}^-$  and  $\text{Ag}^+/\text{Ag}$ , respectively.

**Self-test 6C.1** Express the formation of  $\text{H}_2\text{O}$  from  $\text{H}_2$  and  $\text{O}_2$  in acidic solution (a redox reaction) as the difference of two reduction half-reactions.

We shall often find it useful to express the composition of an electrode compartment in terms of the reaction quotient,  $Q$ , for the half-reaction. This quotient is defined like the reaction quotient for the overall reaction (Topic 6A,  $Q = \prod a_j^{\nu_j}$ ), but the electrons are ignored because they are stateless.

### Brief illustration 6C.2 The reaction quotient

The reaction quotient for the reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$  in acid solution,  $\text{O}_2(g) + 4 \text{H}^+(aq) + 4 e^- \rightarrow 2 \text{H}_2\text{O}(l)$ , is

$$Q = \frac{a_{\text{H}_2\text{O}}^2}{a_{\text{H}^+}^4 a_{\text{O}_2}} \approx \frac{p^\ominus}{a_{\text{H}^+}^4 p_{\text{O}_2}}$$

The approximations used in the second step are that the activity of water is 1 (because the solution is dilute) and the oxygen behaves as a perfect gas, so  $a_{\text{O}_2} \approx p_{\text{O}_2}/p^\ominus$ .

**Self-test 6C.2** Write the half-reaction and the reaction quotient for a chlorine gas electrode.

The reduction and oxidation processes responsible for the overall reaction in a cell are separated in space: oxidation takes place at one electrode and reduction takes place at the other. As the reaction proceeds, the electrons released in the oxidation  $\text{Red}_1 \rightarrow \text{Ox}_1 + \nu e^-$  at one electrode travel through the external circuit and re-enter the cell through the other electrode. There they bring about reduction  $\text{Ox}_2 + \nu e^- \rightarrow \text{Red}_2$ . The electrode at which oxidation occurs is called the **anode**; the electrode at which reduction occurs is called the **cathode**. In a galvanic cell, the cathode has a higher potential than the anode: the species undergoing reduction,  $\text{Ox}_2$ , withdraws electrons from its electrode (the cathode, Fig. 6C.1), so leaving a relative positive charge on it (corresponding to a high potential). At the anode, oxidation results in the transfer of electrons to the electrode, so giving it a relative negative charge (corresponding to a low potential).

## 6C.2 Varieties of cells

The simplest type of cell has a single electrolyte common to both electrodes (as in Fig. 6C.1). In some cases it is necessary to immerse the electrodes in different electrolytes, as in the ‘Daniell cell’ in which the redox couple at one electrode is  $\text{Cu}^{2+}/\text{Cu}$  and at the other is  $\text{Zn}^{2+}/\text{Zn}$  (Fig. 6C.2). In an **electrolyte concentration cell**, the electrode compartments are identical except for the concentrations of the electrolytes. In an **electrode concentration cell** the electrodes themselves have different concentrations, either because they are gas electrodes operating at different pressures or because they are amalgams (solutions in mercury) with different concentrations.

**Figure 6C.1** When a spontaneous reaction takes place in a galvanic cell, electrons are deposited in one electrode (the site of oxidation, the anode) and collected from another (the site of reduction, the cathode), and so there is a net flow of current which can be used to do work. Note that the + sign of the cathode can be interpreted as indicating the electrode at which electrons enter the cell, and the - sign of the anode is where the electrons leave the cell.

**Figure 6C.2** One version of the Daniell cell. The copper electrode is the cathode and the zinc electrode is the anode. Electrons leave the cell from the zinc electrode and enter it again through the copper electrode.

### (a) Liquid junction potentials

In a cell with two different electrolyte solutions in contact, as in the Daniell cell, there is an additional source of potential difference across the interface of the two electrolytes. This potential is called the **liquid junction potential**,  $E_{lj}$ . Another example of a junction potential is that between different concentrations of hydrochloric acid. At the junction, the mobile  $H^+$  ions diffuse into the more dilute solution. The bulkier  $Cl^-$  ions follow, but initially do so more slowly, which results in a potential difference at the junction. The potential then settles down to a value such that, after that brief initial period, the ions diffuse at the same rates. Electrolyte concentration cells always have a liquid junction; electrode concentration cells do not.

The contribution of the liquid junction to the potential can be reduced (to about 1 to 2 mV) by joining the electrolyte compartments through a salt bridge (Fig. 6C.3). The reason for the success of the salt bridge is that provided the ions dissolved in the jelly have similar mobilities, then the liquid junction potentials at either end are largely independent of the concentrations of the two dilute solutions, and so nearly cancel.

**Figure 6C.3** The salt bridge, essentially an inverted U-tube full of concentrated salt solution in a jelly, has two opposing liquid junction potentials that almost cancel.

### (b) Notation

We use the following notation for cells:

	A phase boundary
:	A liquid junction
	An interface for which it is assumed that the junction potential has been eliminated

#### Brief illustration 6C.3 Cell notation

A cell in which two electrodes share the same electrolyte is

The cell in Fig. 6C.2 is denoted

The cell in Fig. 6C.3 is denoted

An example of an electrolyte concentration cell in which the liquid junction potential is assumed to be eliminated is

**Self-test 6C.3** Write the symbolism for a cell in which the half-reactions are  $4 H^+(aq) + 4 e^- \rightarrow 2 H_2(g)$  and  $O_2(g) + 4 H^+(aq) + 4 e^- \rightarrow 2 H_2O(l)$ , (a) with a common electrolyte, (b) with separate compartments joined by a salt bridge.

Answer: (a)  $Pt(s)|H_2(g)|HCl(aq, b)|O_2(g)|Pt(s)$ ;  
(b)  $Pt(s)|H_2(g)|HCl(aq, b_1)||HCl(aq, b_2)|O_2(g)|Pt(s)$

## 6C.3 The cell potential

The current produced by a galvanic cell arises from the spontaneous chemical reaction taking place inside it. The **cell reaction** is the reaction in the cell written on the assumption that the right-hand electrode is the cathode, and hence that the spontaneous reaction is one in which reduction is taking place in the right-hand compartment. Later we see how to predict if the right-hand electrode is in fact the cathode; if it is, then the cell reaction is spontaneous as written. If the left-hand electrode turns out to be the cathode, then the reverse of the corresponding cell reaction is spontaneous.

To write the cell reaction corresponding to a cell diagram, we first write the right-hand half-reaction as a reduction (because we have assumed that to be spontaneous). Then we subtract from it the left-hand reduction half-reaction (for, by implication, that electrode is the site of oxidation).

**Brief illustration 6C.4** The cell reaction

For the cell  $\text{Zn(s)}|\text{ZnSO}_4(\text{aq})||\text{CuSO}_4(\text{aq})|\text{Cu(s)}$  the two electrodes and their reduction half-reactions are

Hence, the overall cell reaction is the difference Right – Left:

which, after cancellation of the  $2\text{e}^-$ , rearranges to

**Self-test 6C.4** Construct the overall cell reaction for the cells:

**(a) The Nernst equation**

A cell in which the overall cell reaction has not reached chemical equilibrium can do electrical work as the reaction drives electrons through an external circuit. The work that a given transfer of electrons can accomplish depends on the potential difference between the two electrodes. When the potential difference is large, a given number of electrons travelling between the electrodes can do a large amount of electrical work. When the potential difference is small, the same number of electrons can do only a small amount of work. A cell in which the overall reaction is at equilibrium can do no work, and then the potential difference is zero.

According to the discussion in Topic 3C, we know that the maximum non-expansion work a system can do at constant temperature and pressure is given by eqn 3C.16b ( $w_{\text{e,max}} = \Delta G$ ). In electrochemistry, the non-expansion work is identified with electrical work, the system is the cell, and  $\Delta G$  is the Gibbs energy of the cell reaction,  $\Delta_r G$ . Maximum work is produced when a change occurs reversibly. It follows that, to draw thermodynamic conclusions from measurements of the work that a cell can do, we must ensure that the cell is operating reversibly. Moreover, it is established in Topic 6A that the reaction Gibbs energy is actually a property related, through  $RT \ln Q$ , to a specified composition of the reaction mixture. Therefore, to make use of  $\Delta_r G$  we must ensure that the cell is operating reversibly at a specific, constant composition. Both these conditions are achieved by measuring the cell potential when it is balanced by an exactly opposing source of potential so that the cell reaction occurs reversibly, the composition is constant, and no current flows: in effect, the cell reaction is poised for change, but not actually changing. The

resulting potential difference is called the **cell potential**,  $E_{\text{cell}}$ , of the cell.

*A note on good practice* The cell potential was formerly, and is still widely, called the *electromotive force* (emf) of the cell. IUPAC prefers the term ‘cell potential’ because a potential difference is not a force.

As we show in the following *Justification*, the relation between the reaction Gibbs energy and the cell potential is

$$-\nu F E_{\text{cell}} = \Delta_r G \quad \text{The cell potential} \quad (6C.2)$$

where  $F$  is Faraday’s constant,  $F = eN_A$ , and  $\nu$  is the stoichiometric coefficient of the electrons in the half-reactions into which the cell reaction can be divided. This equation is the key connection between electrical measurements on the one hand and thermodynamic properties on the other. It will be the basis of all that follows.

**Justification 6C.1** The relation between the cell potential and the reaction Gibbs energy

We consider the change in  $G$  when the cell reaction advances by an infinitesimal amount  $d\xi$  at some composition. From *Justification 6A.1*, specifically the equation  $\Delta_r G = (\partial G / \partial \xi)_{T,p}$ , we can write (at constant temperature and pressure)

$$dG = \Delta_r G d\xi$$

The maximum non-expansion (electrical) work that the reaction can do as it advances by  $d\xi$  at constant temperature and pressure is therefore

$$dw_{\text{e}} = \Delta_r G d\xi$$

This work is infinitesimal, and the composition of the system is virtually constant when it occurs.

Suppose that the reaction advances by  $d\xi$ , then  $\nu d\xi$  electrons must travel from the anode to the cathode. The total charge transported between the electrodes when this change occurs is  $-\nu e N_A d\xi$  (because  $\nu d\xi$  is the amount of electrons in moles and the charge per mole of electrons is  $-e N_A$ ). Hence, the total charge transported is  $-\nu F d\xi$  because  $e N_A = F$ . The work done when an infinitesimal charge  $-\nu F d\xi$  travels from the anode to the cathode is equal to the product of the charge and the potential difference  $E_{\text{cell}}$  (see Table 2A.1, the entry  $dw = Q d\phi$ ):

$$dw_{\text{e}} = -\nu F E_{\text{cell}} d\xi$$

When this relation is equated to the one above ( $dw_{\text{e}} = \Delta_r G d\xi$ ), the advancement  $d\xi$  cancels, and we obtain eqn 6C.2.

It follows from eqn 6C.2 that, by knowing the reaction Gibbs energy at a specified composition, we can state the cell

**Figure 6C.4** A spontaneous reaction occurs in the direction of decreasing Gibbs energy. When expressed in terms of a cell potential, the spontaneous direction of change can be expressed in terms of the cell potential,  $E_{\text{cell}}$ . The reaction is spontaneous as written (from left to right on the illustration) when  $E_{\text{cell}} > 0$ . The reverse reaction is spontaneous when  $E_{\text{cell}} < 0$ . When the cell reaction is at equilibrium, the cell potential is zero.

potential at that composition. Note that a negative reaction Gibbs energy, corresponding to a spontaneous cell reaction, corresponds to a positive cell potential. Another way of looking at the content of eqn 6C.2 is that it shows that the driving power of a cell (that is, its potential) is proportional to the slope of the Gibbs energy with respect to the extent of reaction. It is plausible that a reaction that is far from equilibrium (when the slope is steep) has a strong tendency to drive electrons through an external circuit (Fig. 6C.4). When the slope is close to zero (when the cell reaction is close to equilibrium), the cell potential is small.

#### Brief illustration 6C.5 The reaction Gibbs energy

Equation 6C.2 provides an electrical method for measuring a reaction Gibbs energy at any composition of the reaction mixture: we simply measure the cell potential and convert it to  $\Delta_r G$ . Conversely, if we know the value of  $\Delta_r G$  at a particular composition, then we can predict the cell potential. For example, if  $\Delta_r G = -1 \times 10^5 \text{ kJ mol}^{-1}$  and  $\nu = 1$ , then

$$E_{\text{cell}} = -\frac{\Delta_r G}{\nu F} = -\frac{(-1 \times 10^5 \text{ J mol}^{-1})}{1 \times (9.6485 \times 10^4 \text{ C mol}^{-1})} = 1 \text{ V}$$

where we have used  $1 \text{ J} = 1 \text{ C V}$ .

**Self-test 6C.5** Estimate the potential of a fuel cell in which the reaction is  $\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})$ .

Answer: 1.2 V

We can go on to relate the cell potential to the activities of the participants in the cell reaction. We know that the

reaction Gibbs energy is related to the composition of the reaction mixture by eqn 6A.10 ( $\Delta_r G = \Delta_r G^\ominus + RT \ln Q$ ); it follows, on division of both sides by  $-\nu F$  and recognizing that  $\Delta_r G / (-\nu F) = E_{\text{cell}}$ , that

$$E_{\text{cell}} = -\frac{\Delta_r G^\ominus}{\nu F} - \frac{RT}{\nu F} \ln Q$$

The first term on the right is written

$$E_{\text{cell}}^\ominus = -\frac{\Delta_r G^\ominus}{\nu F} \quad \text{Definition} \quad \text{Standard cell potential} \quad (6C.3)$$

and called the **standard cell potential**. That is, the standard cell potential is the standard reaction Gibbs energy expressed as a potential difference (in volts). It follows that

$$E_{\text{cell}} = E_{\text{cell}}^\ominus - \frac{RT}{\nu F} \ln Q \quad \text{Nernst equation} \quad (6C.4)$$

This equation for the cell potential in terms of the composition is called the **Nernst equation**; the dependence that it predicts is summarized in Fig. 6C.5. One important application of the Nernst equation is to the determination of the pH of a solution and, with a suitable choice of electrodes, of the concentration of other ions (Topic 6D).

We see from eqn 6C.4 that the standard cell potential can be interpreted as the cell potential when all the reactants and products in the cell reaction are in their standard states, for then all activities are 1, so  $Q = 1$  and  $\ln Q = 0$ . However, the fact that the standard cell potential is merely a disguised form of the standard reaction Gibbs energy (eqn 6C.3) should always be kept in mind and underlies all its applications.

**Figure 6C.5** The variation of cell potential with the value of the reaction quotient for the cell reaction for different values of  $\nu$  (the number of electrons transferred). At 298 K,  $RT/F = 25.69 \text{ mV}$ , so the vertical scale refers to multiples of this value.

**Brief illustration 6C.6** The Nernst equation

Because  $RT/F = 25.7$  mV at  $25^\circ\text{C}$ , a practical form of the Nernst equation is

$$E_{\text{cell}} = E_{\text{cell}}^\ominus - \frac{25.7 \text{ mV}}{\nu} \ln Q$$

It then follows that, for a reaction in which  $\nu = 1$ , if  $Q$  is increased by a factor of 10, then the cell potential decreases by 59.2 mV.

**Self-test 6C.6** By how much does the cell potential change when  $Q$  is decreased by a factor of 10 for a reaction in which  $\nu = 2$ ?

Answer:  $-29.6$  V

An important feature of a standard cell potential is that it is unchanged if the chemical equation for the cell reaction is multiplied by a numerical factor. A numerical factor increases the value of the standard Gibbs energy for the reaction. However, it also increases the number of electrons transferred by the same factor, and by eqn 6D.2 the value of  $E_{\text{cell}}^\ominus$  remains unchanged. A practical consequence is that a cell potential is independent of the physical size of the cell. In other words, the cell potential is an intensive property.

**(b) Cells at equilibrium**

A special case of the Nernst equation has great importance in electrochemistry and provides a link to the discussion of equilibrium in Topic 6A. Suppose the reaction has reached equilibrium; then  $Q = K$ , where  $K$  is the equilibrium constant of the cell reaction. However, a chemical reaction at equilibrium cannot do work, and hence it generates zero potential difference between the electrodes of a galvanic cell. Therefore, setting  $E_{\text{cell}} = 0$  and  $Q = K$  in the Nernst equation gives

$$E_{\text{cell}}^\ominus = \frac{RT}{\nu F} \ln K \quad \text{Equilibrium constant and standard cell potential} \quad (6C.5)$$

This very important equation (which could also have been obtained more directly by substituting eqn 6A.14,  $\Delta_r G^\ominus = -RT \ln K$ , into eqn 6C.3) lets us predict equilibrium constants from measured standard cell potentials. However, before we use it extensively, we need to establish a further result.

**Brief illustration 6C.7** Equilibrium constants

Because the standard potential of the Daniell cell is  $+1.10$  V, the equilibrium constant for the cell reaction  $\text{Cu}^{2+}(\text{aq}) + \text{Zn}(\text{s}) \rightarrow \text{Cu}(\text{s}) + \text{Zn}^{2+}(\text{aq})$ , for which  $\nu = 2$ , is  $K = 1.5 \times 10^{37}$  at  $298$  K. We conclude that the displacement of copper by zinc goes

virtually to completion. Note that a cell potential of about 1 V is easily measurable but corresponds to an equilibrium constant that would be impossible to measure by direct chemical analysis.

**Self-test 6C.7** What would be the standard cell potential for a reaction with  $K = 1$ ?

Answer: 0

**6C.4 The determination of thermodynamic functions**

The standard potential of a cell is related to the standard reaction Gibbs energy through eqn 6C.3 (written as  $-\nu FE_{\text{cell}}^\ominus = \Delta_r G^\ominus$ ). Therefore, by measuring  $E_{\text{cell}}^\ominus$  we can obtain this important thermodynamic quantity. Its value can then be used to calculate the Gibbs energy of formation of ions by using the convention explained in Topic 3C, that  $\Delta_f G^\ominus(\text{H}^+, \text{aq}) = 0$ .

**Brief illustration 6C.8** The reaction Gibbs energy

The reaction taking place in the cell

is

Therefore, with  $\nu = 1$ , we find

$$\begin{aligned} \Delta_f G^\ominus(\text{Ag}^+, \text{aq}) &= -(FE_{\text{cell}}^\ominus) \\ &= (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (0.7996 \text{ V}) \\ &= +77.15 \text{ kJ mol}^{-1} \end{aligned}$$

which is in close agreement with the value in Table 2C.2 of the *Resource section*.

**Self-test 6C.8** Derive the value of  $\Delta_f G^\ominus(\text{H}_2\text{O}, \text{l})$  at  $298$  K from the standard potential of the cell  $\text{Pt}(\text{s}) | \text{H}_2(\text{g}) | \text{HCl}(\text{aq}) | \text{O}_2(\text{g}) | \text{Pt}$ ,  $E_{\text{cell}}^\ominus = +1.23$  V.

Answer:  $-237$  kJ mol<sup>-1</sup>

The temperature coefficient of the standard cell potential,  $dE_{\text{cell}}^\ominus/dT$ , gives the standard entropy of the cell reaction. This conclusion follows from the thermodynamic relation  $(\partial G/\partial T)_p = -S$  derived in Topic 3D and eqn 6C.3, which combine to give

$$\frac{dE_{\text{cell}}^\ominus}{dT} = \frac{\Delta_r S^\ominus}{\nu F} \quad \text{Temperature coefficient of standard cell potential} \quad (6C.6)$$

The derivative is complete (not partial) because  $E_{\text{cell}}^{\ominus}$  like  $\Delta_r G^{\ominus}$ , is independent of the pressure. Hence we have an electrochemical technique for obtaining standard reaction entropies and through them the entropies of ions in solution.

Finally, we can combine the results obtained so far and use them to obtain the standard reaction enthalpy:

$$\Delta_r H^{\ominus} = \Delta_r G^{\ominus} + T\Delta_r S^{\ominus} = -\nu F \left( E_{\text{cell}}^{\ominus} - T \frac{dE_{\text{cell}}^{\ominus}}{dT} \right) \quad (6C.7)$$

This expression provides a non-calorimetric method for measuring  $\Delta_r H^{\ominus}$  and, through the convention  $\Delta_r H^{\ominus}(\text{H}^+, \text{aq}) = 0$  the standard enthalpies of formation of ions in solution (Topic 2C).

### Example 6C.1 Using the temperature coefficient of the cell potential

The standard potential of the cell  $\text{Pt(s)}|\text{H}_2(\text{g})|\text{HBr(aq)}|\text{AgBr(s)}|\text{Ag(s)}$  was measured over a range of temperatures, and the data were found to fit the following polynomial:

$$E_{\text{cell}}^{\ominus}/\text{V} = 0.07131 - 4.99 \times 10^{-4}(T/\text{K} - 298) - 3.45 \times 10^{-6}(T/\text{K} - 298)^2$$

The cell reaction is  $\text{AgBr(s)} + \frac{1}{2}\text{H}_2(\text{g}) \rightarrow \text{Ag(s)} + \text{HBr(aq)}$ . Evaluate the standard reaction Gibbs energy, enthalpy, and entropy at 298 K.

**Method** The standard Gibbs energy of reaction is obtained by using eqn 6C.2 after evaluating  $E_{\text{cell}}^{\ominus}$  at 298 K and by using  $1 \text{ V C} = 1 \text{ J}$ . The standard entropy of reaction is obtained by using eqn 6C.6, which involves differentiating the polynomial with respect to  $T$  and then setting  $T = 298 \text{ K}$ . The reaction enthalpy is obtained by combining the values of the standard Gibbs energy and entropy.

**Answer** At  $T = 298 \text{ K}$ ,  $E_{\text{cell}}^{\ominus}/\text{V} = 0.07131 \text{ V}$ , so

$$\begin{aligned} \Delta_r G^{\ominus} &= -\nu F E_{\text{cell}}^{\ominus} = -(1) \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (0.07131 \text{ V}) \\ &= -6.880 \times 10^3 \text{ C V mol}^{-1} = -6.880 \text{ kJ mol}^{-1} \end{aligned}$$

The temperature coefficient of the cell potential is

$$\frac{dE_{\text{cell}}^{\ominus}}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1} - 2(3.45 \times 10^{-6})(T/\text{K} - 298) \text{ V K}^{-1}$$

At  $T = 298 \text{ K}$  this expression evaluates to

$$\frac{dE_{\text{cell}}^{\ominus}}{dT} = -4.99 \times 10^{-4} \text{ V K}^{-1}$$

So, from eqn 6C.6 the reaction entropy is

$$\begin{aligned} \Delta_r S^{\ominus} &= \nu F \frac{dE_{\text{cell}}^{\ominus}}{dT} = (1) \times (9.6485 \times 10^4 \text{ C mol}^{-1}) \times (-4.99 \times 10^{-4} \text{ V}) \\ &= -48.2 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

The negative value stems in part from the elimination of gas in the cell reaction. It then follows that

$$\begin{aligned} \Delta_r H^{\ominus} &= \Delta_r G^{\ominus} + T\Delta_r S^{\ominus} = -6.880 \text{ kJ mol}^{-1} \\ &\quad + (298 \text{ K}) \times (-0.0482 \text{ kJ K}^{-1} \text{ mol}^{-1}) \\ &= -21.2 \text{ kJ mol}^{-1} \end{aligned}$$

One difficulty with this procedure lies in the accurate measurement of small temperature coefficients of cell potential. Nevertheless, it is another example of the striking ability of thermodynamics to relate the apparently unrelated, in this case to relate electrical measurements to thermal properties.

**Self-test 6C.9** Predict the standard potential of the Harned cell at 303 K from tables of thermodynamic data.

Answer: +0.2222 V

## Checklist of concepts

1. A **redox reaction** is expressed as the difference of two reduction **half-reactions**; each one defines a redox couple.
2. **Galvanic cells** are classified as **electrolyte concentration** and **electrode concentration cells**.
3. A **liquid junction potential** arises at the junction of two electrolyte solutions.
4. The cell notation specifies the structure of a cell.
5. The **Nernst equation** relates the cell potential to the composition of the reaction mixture.
6. The **standard cell potential** may be used to calculate the equilibrium constant of the cell reaction.
7. The temperature coefficient of the cell potential is used to measure thermodynamic properties of electroactive species.

### ► Why do you need to know this material?

A very powerful, compact, and widely used way to report standard cell potentials is to ascribe a potential to each electrode. Electrode potentials are widely used in chemistry to assess the oxidizing and reducing power of redox couples and to infer thermodynamic properties, including equilibrium constants.

### ► What is the key idea?

Each electrode of a cell can be supposed to make a characteristic contribution to the cell potential; redox couples with low electrode potentials tend to reduce those with higher potentials.

### ► What do you need to know already?

This Topic develops the concepts in Topic 6D, so you need to understand the concept of cell potential and standard cell potential (Topic 6D); it makes use of the Nernst equation (Topic 6D). The measurement of standard potentials makes use of the Debye–Hückel limiting law (Topic 5F).

As explained in Topic 6C, a galvanic cell is a combination of two electrodes each of which can be considered to make a characteristic contribution to the overall cell potential.

Although it is not possible to measure the contribution of a single electrode, we can define the potential of one of the electrodes as zero and then assign values to others on that basis.

## 6D.1 Standard potentials

The specially selected electrode is the **standard hydrogen electrode (SHE)**:

at all temperatures. To achieve the standard conditions, the activity of the hydrogen ions must be 1 (that is, pH=0) and the pressure (more precisely, the fugacity) of the hydrogen gas must be 1 bar. The **standard potential**,  $E^\ominus(\text{X})$ , of another couple X is then assigned by constructing a cell in which it is the right-hand electrode and the standard hydrogen electrode is the left-hand electrode:

The standard potential of a cell of the form L||R, where L is the left-hand electrode of the cell as written (not as arranged on the bench) and R is the right-hand electrode, is then given by the difference of the two standard potentials:

A list of standard potentials at 298 K is given in Table 6D.1, and longer lists in numerical and alphabetical order are in the *Resource section*.

Table 6D.1\* Standard potentials at 298 K,  $E^\ominus/\text{V}$

Couple	$E^\ominus/\text{V}$
$\text{Ce}^{4+}(\text{aq}) + \text{e}^- \rightarrow \text{Ce}^{3+}(\text{aq})$	+1.61
$\text{Cu}^{2+}(\text{aq}) + 2 \text{e}^- \rightarrow \text{Cu}(\text{s})$	+0.34
$\text{H}^+(\text{aq}) + \text{e}^- \rightarrow \frac{1}{2} \text{H}_2(\text{g})$	0
$\text{AgCl}(\text{s}) + \text{e}^- \rightarrow \text{Ag}(\text{s}) + \text{Cl}^-(\text{aq})$	+0.22
$\text{Zn}^{2+}(\text{aq}) + 2 \text{e}^- \rightarrow \text{Zn}(\text{s})$	-0.76
$\text{Na}^+(\text{aq}) + \text{e}^- \rightarrow \text{Na}(\text{s})$	-2.71

\*More values are given in the *Resource section*.

**Brief illustration 6D.1** Standard electrode potentials

The cell  $\text{Ag(s)}|\text{AgCl(s)}|\text{HCl(aq)}|\text{O}_2(\text{g})|\text{Pt(s)}$  can be regarded as formed from the following two electrodes, with their standard potentials taken from the *Resource section*:

Electrode	Half-reaction	Standard potential
R: $\text{Pt(s)} \text{O}_2(\text{g}) \text{H}^+(\text{aq})$	$\text{O}_2(\text{g}) + 4 \text{H}^+(\text{aq}) + 4 \text{e}^- \rightarrow 2 \text{H}_2\text{O(l)}$	+1.23 V
L: $\text{Ag(s)} \text{AgCl(s)} \text{Cl}^-(\text{aq})$	$\text{AgCl(s)} + \text{e}^- \rightarrow \text{Ag(s)} + \text{Cl}^-(\text{aq})$	+0.22 V
		$E_{\text{cell}}^\ominus = +1.01 \text{ V}$

**Self-test 6D.1** What is the standard potential of the cell  $\text{Pt(s)}|\text{Fe}^{2+}(\text{aq}), \text{Fe}^{3+}(\text{aq})||\text{Ce}^{4+}(\text{aq}), \text{Ce}^{3+}(\text{aq})|\text{Pt(s)}$ ?

Answer: +0.84 V

**(a) The measurement procedure**

The procedure for measuring a standard potential can be illustrated by considering a specific case, the silver chloride electrode. The measurement is made on the ‘Harned cell’:

for which the Nernst equation is

$$E_{\text{cell}} = E^\ominus(\text{AgCl/Ag, Cl}^-) - \frac{RT}{F} \ln \frac{a_{\text{H}^+} a_{\text{Cl}^-}}{a_{\text{H}_2}^{1/2}}$$

We shall set  $a_{\text{H}_2} = 1$  from now on, and for simplicity write the standard potential of the  $\text{AgCl/Ag, Cl}^-$  electrode as  $E^\ominus$ ; then

$$E_{\text{cell}} = E^\ominus - \frac{RT}{F} \ln a_{\text{H}^+} a_{\text{Cl}^-}$$

We show in the following *Justification* that as the molality  $b \rightarrow 0$ ,

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = \overbrace{\frac{2RT}{F} \ln b}^y = \overbrace{E^\ominus}^{\text{intercept}} + \overbrace{C \times b^{1/2}}^{\text{slope} \times x} \quad (6D.4)$$

where  $C$  is a constant. To use this equation, which has the form  $y = \text{intercept} + \text{slope} \times x$  with  $x = b^{1/2}$ , the expression on the left is evaluated at a range of molalities, plotted against  $b^{1/2}$ , and extrapolated to  $b = 0$ . The intercept at  $b^{1/2} = 0$  is the value of  $E^\ominus$  for the silver/silver chloride electrode. In precise work, the  $b^{1/2}$  term is brought to the left, and a higher-order correction term from extended versions of the Debye–Hückel law is used on the right.

**Justification 6D.1** The Harned cell potential

The activities in the expression for  $E_{\text{cell}}$  can be expressed in terms of the molality  $b$  of  $\text{HCl(aq)}$  through  $a_{\text{H}^+} = \gamma_{\pm} b / b^\ominus$  and  $a_{\text{Cl}^-} = \gamma_{\pm} b / b^\ominus$  as established in Topic 5E, so, with  $b/b^\ominus$  replaced by  $b$

$$E_{\text{cell}} = E^\ominus - \frac{RT}{F} \ln b^2 - \frac{RT}{F} \ln \gamma_{\pm}^2$$

$$= E^\ominus - \frac{2RT}{F} \ln b - \frac{2RT}{F} \ln \gamma_{\pm}$$

and therefore

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = E^\ominus - \frac{2RT}{F} \ln \gamma_{\pm}$$

From the Debye–Hückel limiting law for a 1,1-electrolyte (eqn 5F.8,  $\log \gamma_{\pm} = -A|z_+ z_-| I^{1/2}$ ), as  $b \rightarrow 0$

$$\log \gamma_{\pm} = -A|z_+ z_-| I^{1/2} = -A(b/b^\ominus)^{1/2}$$

Therefore, because  $\ln x = \ln 10 \log x$ ,

$$\ln \gamma_{\pm} = \ln 10 \log \gamma_{\pm} = -A \ln 10 (b/b^\ominus)^{1/2}$$

and the equation for  $E_{\text{cell}}$  becomes

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = E^\ominus + \frac{2A \ln 10}{F(b^\ominus)^{1/2}} b^{1/2} \quad \text{as } b \rightarrow 0$$

With the term in blue denoted  $C$ , this equation becomes eqn 6D.4.

**Example 6D.1** Evaluating a standard electrode potential

The potential of the Harned cell at 25 °C has the following values:

$b/(10^{-3} b^\ominus)$	3.215	5.619	9.138	25.63
$E_{\text{cell}}/\text{V}$	0.520 53	0.492 57	0.468 60	0.418 24

Determine the standard potential of the silver–silver chloride electrode.

**Method** As explained in the text, evaluate  $y = E_{\text{cell}} + (2RT/F) \ln b$  and plot it against  $b^{1/2}$ ; then extrapolate to  $b = 0$ . Use  $2RT/F = 0.051 39 \text{ V}$ .

**Answer** To determine the standard potential of the cell we draw up the following table:

$b/(10^{-3} b^\ominus)$	3.215	5.619	9.138	25.63
$\{b/(10^{-3} b^\ominus)\}^{1/2}$	1.793	2.370	3.023	5.063
$E_{\text{cell}}/\text{V}$	0.520 53	0.492 57	0.468 60	0.418 24
$y/\text{V}$	0.2256	0.2263	0.2273	0.2299

The data are plotted in Fig. 6D.1; as can be seen, they extrapolate to  $E^\ominus = +0.2232 \text{ V}$  (the value obtained, to preserve the precision of the data, by linear regression).

**Figure 6D.1** The plot and the extrapolation used for the experimental measurement of a standard cell potential. The intercept at  $b^{1/2}=0$  is  $E_{\text{cell}}^{\ominus}$ .

**Self-test 6D.2** The data below are for the cell  $\text{Pt(s)}|\text{H}_2(\text{g})|\text{HBr}(\text{aq}, b)|\text{AgBr(s)}|\text{Ag(s)}$  at  $25^\circ\text{C}$ . Determine the standard cell potential.

$b/(10^{-4}b^{\ominus})$	4.042	8.444	37.19
$E_{\text{cell}}/\text{V}$	0.47381	0.43636	0.36173

Answer: +0.071 V

## (b) Combining measured values

The standard potentials in Table 6D.1 may be combined to give values for couples that are not listed there. However, to do so, we must take into account the fact that different couples may correspond to the transfer of different numbers of electrons. The procedure is illustrated in the following *Example*.

### Example 6D.2 Evaluating a standard potential from two others

Given that the standard potentials of the  $\text{Cu}^{2+}/\text{Cu}$  and  $\text{Cu}^+/\text{Cu}$  couples are +0.340 V and +0.522 V, respectively, evaluate  $E^{\ominus}(\text{Cu}^{2+}, \text{Cu}^+)$ .

**Method** First, we note that reaction Gibbs energies may be added (as in a Hess's law analysis of reaction enthalpies). Therefore, we should convert the  $E^{\ominus}$  values to  $\Delta_r G^{\ominus}$  values by using eqn 6C.2 ( $-\nu F E^{\ominus} = \Delta_r G^{\ominus}$ ), add them appropriately, and then convert the overall  $\Delta_r G^{\ominus}$  to the required  $E^{\ominus}$  by using eqn 6D.2 again. This roundabout procedure is necessary because, as we shall see, although the factor  $F$  cancels, the factor  $\nu$  in general does not.

**Answer** The electrode half-reactions are as follows:

- (a)  $\text{Cu}^{2+}(\text{aq}) + 2 e^- \rightarrow \text{Cu(s)}$   $E^{\ominus}(\text{a}) = +0.340 \text{ V}$ ,  
so  $\Delta_r G^{\ominus}(\text{a}) = -2(0.340 \text{ V})F$
- (b)  $\text{Cu}^+(\text{aq}) + e^- \rightarrow \text{Cu(s)}$   $E^{\ominus}(\text{b}) = +0.522 \text{ V}$ ,  
so  $\Delta_r G^{\ominus}(\text{b}) = -(0.522 \text{ V})F$

The required reaction is

Because  $(c) = (a) - (b)$ , the standard Gibbs energy of reaction (c) is

$$-\Delta_r G^{\ominus}(\text{c}) = \Delta_r G^{\ominus}(\text{a}) - \Delta_r G^{\ominus}(\text{b}) = -(0.680 \text{ V})F - (-0.522 \text{ V})F = (+0.158 \text{ V})F$$

Therefore,  $E^{\ominus}(\text{c}) = +0.158 \text{ V}$ .

**Self-test 6D.3** Evaluate  $E^{\ominus}(\text{Fe}^{3+}, \text{Fe}^{2+})$  from  $E^{\ominus}(\text{Fe}^{3+}, \text{Fe})$  and  $E^{\ominus}(\text{Fe}^{2+}, \text{Fe})$ .

Answer: +0.76 V

The generalization of the calculation in *Example 6D.2* is

$$\nu_c E^{\ominus}(\text{c}) = \nu_a E^{\ominus}(\text{a}) - \nu_b E^{\ominus}(\text{b}) \quad \text{Combination of standard potentials} \quad (6D.5)$$

with the  $\nu_r$  the stoichiometric coefficients of the electrons in each half-reaction

## 6D.2 Applications of standard potentials

Cell potentials are a convenient source of data on equilibrium constants and the Gibbs energies, enthalpies, and entropies of reactions. In practice the standard values of these quantities are the ones normally determined.

### (a) The electrochemical series

We have seen that for two redox couples,  $\text{Ox}_L/\text{Red}_L$  and  $\text{Ox}_R/\text{Red}_R$ , and the cell

that the cell reaction

has  $K > 1$  as written if  $E_{\text{cell}}^{\ominus} > 0$ , and therefore if  $E^{\ominus}(\text{L}) < E^{\ominus}(\text{R})$ . Because in the cell reaction  $\text{Red}_L$  reduces  $\text{Ox}_R$ , we can conclude that:

$\text{Red}_L$  has a thermodynamic tendency (in the sense  $K > 1$ ) to reduce  $\text{Ox}_R$  if  $E^{\ominus}(\text{L}) < E^{\ominus}(\text{R})$

More briefly: low reduces high.

**Table 6D.2\*** The electrochemical series of the metals*Least strongly reducing*

Gold  
Platinum  
Silver  
Mercury  
Copper  
(Hydrogen)  
Lead  
Tin  
Nickel  
Iron  
Zinc  
Chromium  
Aluminium  
Magnesium  
Sodium  
Calcium  
Potassium

*Most strongly reducing*\*The complete series can be inferred from Table 6D.1 in the *Resource section*.

Table 6D.2 shows a part of the **electrochemical series**, the metallic elements (and hydrogen) arranged in the order of their reducing power as measured by their standard potentials in aqueous solution. A metal low in the series (with a lower standard potential) can reduce the ions of metals with higher standard potentials. This conclusion is qualitative. The quantitative value of  $K$  is obtained by doing the calculations we have described previously and review below.

**Brief illustration 6D.2** The electrochemical series

Zinc lies above magnesium in the electrochemical series, so zinc cannot reduce magnesium ions in aqueous solution. Zinc can reduce hydrogen ions, because hydrogen lies higher in the series. However, even for reactions that are thermodynamically favourable, there may be kinetic factors that result in very slow rates of reaction.

**Self-test 6D.4** Can nickel reduce hydrogen ions to hydrogen gas?

Answer: Yes

**(b) The determination of activity coefficients**

Once the standard potential of an electrode in a cell is known, we can use it to determine mean activity coefficients by measuring the cell potential with the ions at the concentration of interest. For example, the mean activity coefficient of the ions in hydrochloric acid of molality  $b$  is obtained from the relation

$$E_{\text{cell}} + \frac{2RT}{F} \ln b = E^{\ominus} - \frac{2RT}{F} \ln \gamma_{\pm}$$

in *Justification 6D.1* in the form

$$\ln \gamma_{\pm} = \frac{E_{\text{cell}}^{\ominus} - E_{\text{cell}}}{2RT/F} - \ln b \quad (6D.7)$$

**Brief illustration 6D.3** Activity coefficients

The data in *Example 6D.1* include the fact that  $E_{\text{cell}} = 0.46860 \text{ V}$  when  $b = 9.138 \times 10^{-3} b^{\ominus}$ . Because  $2RT/F = 0.05139 \text{ V}$ , and in the *Example* it is established that  $E_{\text{cell}}^{\ominus} = 0.2232 \text{ V}$ , the mean activity coefficient at this molality is

$$\ln \gamma_{\pm} = \frac{0.2232 \text{ V} - 0.46860 \text{ V}}{0.05139 \text{ V}} - \ln(9.138 \times 10^{-3}) = -0.0788 \dots$$

Therefore,  $\gamma_{\pm} = 0.9242$ .

**Self-test 6D.5** Evaluate the mean activity coefficient when  $b = 5.619 \times 10^{-3} b^{\ominus}$ .

Answer: 0.9417

**(c) The determination of equilibrium constants**

The principal use for standard potentials is to calculate the standard potential of a cell formed from any two electrodes. To do so, we construct  $E_{\text{cell}}^{\ominus} = E^{\ominus}(\text{R}) - E^{\ominus}(\text{L})$  and use eqn 6C.5 of Topic 6C ( $E_{\text{cell}}^{\ominus} = (RT/\nu F) \ln K$ , arranged into  $\ln K = \nu F E_{\text{cell}}^{\ominus} / RT$ ).

**Brief illustration 6D.4** Equilibrium constants

A disproportionation reaction is a reaction in which a species is both oxidized and reduced. To study the disproportionation  $2 \text{Cu}^+(\text{aq}) \rightarrow \text{Cu}(\text{s}) + \text{Cu}^{2+}(\text{aq})$  at 298 K we combine the following electrodes:

The standard potential of the cell is therefore

$$E_{\text{cell}}^{\ominus} = 0.52 \text{ V} - 0.16 \text{ V} = +0.36 \text{ V}$$

We can now calculate the equilibrium constant of the cell reaction. Because  $\nu = 1$ , from eqn 6C.5 with  $RT/F = 0.025693 \text{ V}$ ,

$$\ln K = \frac{0.36 \text{ V}}{0.025693 \text{ V}} = 14.0 \dots$$

Hence,  $K = 1.2 \times 10^6$ .

**Self-test 6D.6** Evaluate the equilibrium constant for the reaction  $\text{Sn}(\text{s}) + \text{Sn}^{4+}(\text{aq}) \rightleftharpoons 2 \text{Sn}^{2+}(\text{aq})$ .

Answer:  $6.5 \times 10^9$

## Checklist of concepts

- 1. The **standard potential** of a couple is the cell potential in which it forms the right-hand electrode and the left-hand electrode is a **standard hydrogen electrode**.
- 2. The **electrochemical series** lists the metallic elements in the order of their reducing power as measured by their standard potentials in aqueous solution: low reduces high.
- 3. The cell potential is used to measure the activity coefficient of electroactive ions.
- 4. The standard cell potential is used to infer the equilibrium constant of the cell reaction.

## Checklist of equations

Property	Equation	Comment	Equation number
Standard cell potential	$E_{\text{cell}}^{\ominus} = E^{\ominus}(\text{R}) - E^{\ominus}(\text{L})$	Cell: L  R	6D.3
Combined potentials	$\nu_c E^{\ominus}(\text{c}) = \nu_a E^{\ominus}(\text{a}) - \nu_b E^{\ominus}(\text{b})$		6D.5

# CHAPTER 6 Chemical equilibrium

## TOPIC 6A The equilibrium constant

### Discussion questions

**6A.1** Explain how the mixing of reactants and products affects the position of chemical equilibrium.

**6A.2** What is the justification for not including a pure liquid or solid in the expression for an equilibrium constant?

### Exercises

**6A.1(a)** Consider the reaction  $A \rightarrow 2B$ . Initially, 1.50 mol A is present and no B. What are the amounts of A and B when the extent of reaction is 0.60 mol?

**6A.1(b)** Consider the reaction  $2A \rightarrow B$ . Initially, 1.75 mol A and 0.12 mol B are present. What are the amounts of A and B when the extent of reaction is 0.30 mol?

**6A.2(a)** When the reaction  $A \rightarrow 2B$  advances by 0.10 mol (that is,  $\Delta\xi = +0.10$  mol) the Gibbs energy of the system changes by  $-6.4$  kJ mol<sup>-1</sup>. What is the Gibbs energy of reaction at this stage of the reaction?

**6A.2(b)** When the reaction  $2A \rightarrow B$  advances by 0.051 mol (that is,  $\Delta\xi = +0.051$  mol) the Gibbs energy of the system changes by  $-2.41$  kJ mol<sup>-1</sup>. What is the Gibbs energy of reaction at this stage of the reaction?

**6A.3(a)** The standard Gibbs energy of the reaction  $N_2(g) + 3H_2(g) \rightarrow 2NH_3(g)$  is  $-32.9$  kJ mol<sup>-1</sup> at 298 K. What is the value of  $\Delta_r G$  when  $Q =$  (i) 0.010, (ii) 1.0, (iii) 10.0, (iv) 100 000, (v) 1 000 000? Estimate (by interpolation) the value of  $K$  from the values you calculate. What is the actual value of  $K$ ?

**6A.3(b)** The standard Gibbs energy of the reaction  $2NO_2(g) \rightarrow N_2O_4(g)$  is  $-4.73$  kJ mol<sup>-1</sup> at 298 K. What is the value of  $\Delta_r G$  when  $Q =$  (i) 0.10, (ii) 1.0, (iii) 10, (iv) 100? Estimate (by interpolation) the value of  $K$  from the values you calculate. What is the actual value of  $K$ ?

**6A.4(a)** At 2257 K and 1.00 bar total pressure, water is 1.77 per cent dissociated at equilibrium by way of the reaction  $2H_2O(g) \rightleftharpoons 2H_2(g) + O_2(g)$ . Calculate  $K$ .

**6A.4(b)** For the equilibrium,  $N_2O_4(g) \rightleftharpoons 2NO_2(g)$ , the degree of dissociation,  $\alpha$ , at 298 K is 0.201 at 1.00 bar total pressure. Calculate  $K$ .

**6A.5(a)** Dinitrogen tetroxide is 18.46 per cent dissociated at 25 °C and 1.00 bar in the equilibrium  $N_2O_4(g) \rightleftharpoons 2NO_2(g)$ . Calculate  $K$  at (i) 25 °C, (ii) 100 °C given that  $\Delta_r H^\ominus = +56.2$  kJ mol<sup>-1</sup> over the temperature range.

**6A.5(b)** Molecular bromine is 24 per cent dissociated at 1600 K and 1.00 bar in the equilibrium  $Br_2(g) \rightleftharpoons 2Br(g)$ . Calculate  $K$  at (i) 1600 °C, (ii) 2000 °C given that  $\Delta_r H^\ominus = +112$  kJ mol<sup>-1</sup> over the temperature range.

**6A.6(a)** From information in the *Resource section*, calculate the standard Gibbs energy and the equilibrium constant at (i) 298 K and (ii) 400 K for the reaction  $PbO(s) + CO(g) \rightleftharpoons Pb(s) + CO_2(g)$ . Assume that the reaction enthalpy is independent of temperature.

**6A.6(b)** From information in the *Resource section*, calculate the standard Gibbs energy and the equilibrium constant at (i) 25 °C and (ii) 50 °C for the reaction  $CH_4(g) + 3Cl_2(g) \rightleftharpoons CHCl_3(l) + 3HCl(g)$ . Assume that the reaction enthalpy is independent of temperature.

**6A.7(a)** Establish the relation between  $K$  and  $K_c$  for the reaction  $H_2CO(g) \rightleftharpoons CO(g) + H_2(g)$ .

**6A.7(b)** Establish the relation between  $K$  and  $K_c$  for the reaction  $3N_2(g) + H_2(g) \rightleftharpoons 2HN_3(g)$ .

**6A.8(a)** In the gas-phase reaction  $2A + B \rightleftharpoons 3C + 2D$ , it was found that, when 1.00 mol A, 2.00 mol B, and 1.00 mol D were mixed and allowed to come to equilibrium at 25 °C, the resulting mixture contained 0.90 mol C at a total pressure of 1.00 bar. Calculate (i) the mole fractions of each species at equilibrium, (ii)  $K_x$ , (iii)  $K$ , and (iv)  $\Delta_r G^\ominus$ .

**6A.8(b)** In the gas-phase reaction  $A + B \rightleftharpoons C + 2D$ , it was found that, when 2.00 mol A, 1.00 mol B, and 3.00 mol D were mixed and allowed to come to equilibrium at 25 °C, the resulting mixture contained 0.79 mol C at a total pressure of 1.00 bar. Calculate (i) the mole fractions of each species at equilibrium, (ii)  $K_x$ , (iii)  $K$ , and (iv)  $\Delta_r G^\ominus$ .

**6A.9(a)** The standard reaction Gibbs energy of the isomerization of borneol ( $C_{10}H_{17}OH$ ) to isoborneol in the gas phase at 503 K is  $+9.4$  kJ mol<sup>-1</sup>. Calculate the reaction Gibbs energy in a mixture consisting of 0.15 mol of borneol and 0.30 mol of isoborneol when the total pressure is 600 Torr.

**6A.9(b)** The equilibrium pressure of  $H_2$  over solid uranium and uranium hydride,  $UH_3$ , at 500 K is 139 Pa. Calculate the standard Gibbs energy of formation of  $UH_3(s)$  at 500 K.

**6A.10(a)** The standard Gibbs energy of formation of  $NH_3(g)$  is  $-16.5$  kJ mol<sup>-1</sup> at 298 K. What is the reaction Gibbs energy when the partial pressures of the  $N_2$ ,  $H_2$ , and  $NH_3$  (treated as perfect gases) are 3.0 bar, 1.0 bar, and 4.0 bar, respectively? What is the spontaneous direction of the reaction in this case?

**6A.10(b)** The standard Gibbs energy of formation of  $PH_3(g)$  is  $+13.4$  kJ mol<sup>-1</sup> at 298 K. What is the reaction Gibbs energy when the partial pressures of the  $H_2$  and  $PH_3$  (treated as perfect gases) are 1.0 bar and 0.60 bar, respectively? What is the spontaneous direction of the reaction in this case?

**6A.11(a)** For  $CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2F^-(aq)$ ,  $K = 3.9 \times 10^{-11}$  at 25 °C and the standard Gibbs energy of formation of  $CaF_2(s)$  is  $-1167$  kJ mol<sup>-1</sup>. Calculate the standard Gibbs energy of formation of  $CaF_2(aq)$ .

**6A.11(b)** For  $PbI_2(s) \rightleftharpoons Pb^{2+}(aq) + 2I^-(aq)$ ,  $K = 1.4 \times 10^{-8}$  at 25 °C and the standard Gibbs energy of formation of  $PbI_2(s)$  is  $-173.64$  kJ mol<sup>-1</sup>. Calculate the standard Gibbs energy of formation of  $PbI_2(aq)$ .

### Problems

**6A.1** The equilibrium constant for the reaction  $I_2(s) + Br_2(g) \rightleftharpoons 2IBr(g)$  is 0.164 at 25 °C. (a) Calculate  $\Delta_r G^\ominus$  for this reaction. (b) Bromine gas is introduced into a container with excess solid iodine. The pressure and temperature are held at 0.164 atm and 25 °C, respectively. Find the partial pressure of  $IBr(g)$  at equilibrium. Assume that all the bromine is in the liquid form and that the vapour pressure of iodine is negligible. (c) In fact,

solid iodine has a measurable vapour pressure at 25 °C. In this case, how would the calculation have to be modified?

**6A.2** Calculate the equilibrium constant of the reaction  $CO(g) + H_2(g) \rightleftharpoons H_2CO(g)$  given that, for the production of liquid formaldehyde,  $\Delta_r G^\ominus = +28.95$  kJ mol<sup>-1</sup> at 298 K and that the vapour pressure of formaldehyde is 1500 Torr at that temperature.

**6A.3** A sealed container was filled with 0.300 mol  $\text{H}_2(\text{g})$ , 0.400 mol  $\text{I}_2(\text{g})$ , and 0.200 mol  $\text{HI}(\text{g})$  at 870 K and total pressure 1.00 bar. Calculate the amounts of the components in the mixture at equilibrium given that  $K=870$  for the reaction  $\text{H}_2(\text{g})+\text{I}_2(\text{g})\rightleftharpoons 2\text{HI}(\text{g})$ .

**6A.4\*** Nitric acid hydrates have received much attention as possible catalysts for heterogeneous reactions that bring about the Antarctic ozone hole. Standard reaction Gibbs energies are as follows:

Which solid is thermodynamically most stable at 190 K if  $p_{\text{H}_2\text{O}}=0.13 \mu\text{bar}$  and  $p_{\text{HNO}_3}=0.41 \text{ nbar}$  *Hint*: Try computing  $\Delta_r G$  for each reaction under the prevailing conditions; if more than one solid form spontaneously, examine  $\Delta_r G$  for the conversion of one solid to another.

**6A.5** Express the equilibrium constant of a gas-phase reaction  $\text{A} + 3\text{B} \rightleftharpoons 2\text{C}$  in terms of the equilibrium value of the extent of reaction,  $\xi$ , given that initially A and B were present in stoichiometric proportions. Find an expression for  $\xi$  as a function of the total pressure,  $p$ , of the reaction mixture and sketch a graph of the expression obtained.

## TOPIC 6B The response to equilibria to the conditions

### Discussion questions

**6B.1** Suggest how the thermodynamic equilibrium constant may respond differently to changes in pressure and temperature from the equilibrium constant expressed in terms of partial pressures.

**6B.2** Account for Le Chatelier's principle in terms of thermodynamic quantities.

**6B.3** Explain the molecular basis of the van 't Hoff equation for the temperature dependence of  $K$ .

### Exercises

**6B.1(a)** The standard reaction enthalpy of  $\text{Zn}(\text{s}) + \text{H}_2\text{O}(\text{g}) \rightarrow \text{ZnO}(\text{s}) + \text{H}_2(\text{g})$  is approximately constant at  $+224 \text{ kJ mol}^{-1}$  from 920 K up to 1280 K. The standard reaction Gibbs energy is  $+33 \text{ kJ mol}^{-1}$  at 1280 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.

**6B.1(b)** The standard enthalpy of a certain reaction is approximately constant at  $+125 \text{ kJ mol}^{-1}$  from 800 K up to 1500 K. The standard reaction Gibbs energy is  $+22 \text{ kJ mol}^{-1}$  at 1120 K. Estimate the temperature at which the equilibrium constant becomes greater than 1.

**6B.2(a)** The equilibrium constant of the reaction  $2\text{C}_2\text{H}_6(\text{g}) \rightleftharpoons \text{C}_2\text{H}_4(\text{g}) + \text{C}_4\text{H}_8(\text{g})$  is found to fit the expression  $\ln K = A + B/T + C/T^2$  between 300 K and 600 K, with  $A = -1.04$ ,  $B = -1088 \text{ K}$ , and  $C = 1.51 \times 10^5 \text{ K}^2$ . Calculate the standard reaction enthalpy and standard reaction entropy at 400 K.

**6B.2(b)** The equilibrium constant of a reaction is found to fit the expression  $\ln K = A + B/T + C/T^3$  between 400 K and 500 K with  $A = -2.04$ ,  $B = -1176 \text{ K}$ , and  $C = 2.1 \times 10^7 \text{ K}^3$ . Calculate the standard reaction enthalpy and standard reaction entropy at 450 K.

**6B.3(a)** Calculate the percentage change in  $K_x$  for the reaction  $\text{H}_2\text{CO}(\text{g}) \rightleftharpoons \text{CO}(\text{g}) + \text{H}_2(\text{g})$  when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

**6B.3(b)** Calculate the percentage change in  $K_x$  for the reaction  $\text{CH}_3\text{OH}(\text{g}) + \text{NOCl}(\text{g}) \rightleftharpoons \text{HCl}(\text{g}) + \text{CH}_3\text{NO}_2(\text{g})$  when the total pressure is increased from 1.0 bar to 2.0 bar at constant temperature.

**6B.4(a)** The equilibrium constant for the gas-phase isomerization of borneol ( $\text{C}_{10}\text{H}_{17}\text{OH}$ ) to isoborneol at 503 K is 0.106. A mixture consisting of 7.50 g of borneol and 14.0 g of isoborneol in a container of volume 5.0  $\text{dm}^3$  is heated to 503 K and allowed to come to equilibrium. Calculate the mole fractions of the two substances at equilibrium.

### Problems

**6B.1** Consider the dissociation of methane,  $\text{CH}_4(\text{g})$ , into the elements  $\text{H}_2(\text{g})$  and C(s, graphite). (a) Given that  $\Delta_r H^\ominus(\text{CH}_4, \text{g}) = -74.85 \text{ kJ mol}^{-1}$  and that

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**6B.4(b)** The equilibrium constant for the reaction  $\text{N}_2(\text{g}) + \text{O}_2(\text{g}) \rightleftharpoons 2\text{NO}(\text{g})$  is  $1.69 \times 10^{-3}$  at 2300 K. A mixture consisting of 5.0 g of nitrogen and 2.0 g of oxygen in a container of volume 1.0  $\text{dm}^3$  is heated to 2300 K and allowed to come to equilibrium. Calculate the mole fraction of NO at equilibrium.

**6B.5(a)** What is the standard enthalpy of a reaction for which the equilibrium constant is (i) doubled, (ii) halved when the temperature is increased by 10 K at 298 K?

**6B.5(b)** What is the standard enthalpy of a reaction for which the equilibrium constant is (i) doubled, (ii) halved when the temperature is increased by 15 K at 310 K?

**6B.6(a)** Estimate the temperature at which  $\text{CaCO}_3$  (calcite) decomposes.

**6B.6(b)** Estimate the temperature at which  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  undergoes dehydration.

**6B.7(a)** The dissociation vapour pressure of a salt  $\text{A}_2\text{B}(\text{s}) \rightleftharpoons \text{A}_2(\text{g}) + \text{B}(\text{g})$  at 367 °C is 208 kPa but at 477 °C it has risen to 547 kPa. Calculate (i) the equilibrium constant, (ii) the standard reaction Gibbs energy, (iii) the standard enthalpy, (iv) the standard entropy of dissociation, all at 422 °C. Assume that the vapour behaves as a perfect gas and that  $\Delta_r H^\ominus$  and  $\Delta_r S^\ominus$  are independent of temperature in the range given.

**6B.7(b)** The dissociation vapour pressure of  $\text{NH}_4\text{Cl}$  at 427 °C is 608 kPa but at 459 °C it has risen to 1115 kPa. Calculate (i) the equilibrium constant, (ii) the standard reaction Gibbs energy, (iii) the standard enthalpy, (iv) the standard entropy of dissociation, all at 427 °C. Assume that the vapour behaves as a perfect gas and that  $\Delta_r H^\ominus$  and  $\Delta_r S^\ominus$  are independent of temperature in the range given.

$\Delta_r S^\ominus = -80.67 \text{ J K}^{-1} \text{ mol}^{-1}$  at 298 K, calculate the value of the equilibrium constant at 298 K. (b) Assuming that  $\Delta_r H^\ominus$  is independent of temperature, calculate  $K$  at 50 °C. (c) Calculate the degree of dissociation,  $\alpha$ , of methane

at 25 °C and a total pressure of 0.010 bar. (d) Without doing any numerical calculations, explain how the degree of dissociation for this reaction will change as the pressure and temperature are varied.

**6B.2** The equilibrium pressure of  $\text{H}_2$  over  $\text{U}(\text{s})$  and  $\text{UH}_3(\text{s})$  between 450 K and 715 K fits the expression  $\ln(p/\text{Pa}) = A + B/T + C \ln(T/\text{K})$ , with  $A = 69.32$ ,  $B = -1.464 \times 10^4 \text{ K}$ , and  $C = -5.65$ . Find an expression for the standard enthalpy of formation of  $\text{UH}_3(\text{s})$  and from it calculate  $\Delta_f C_p^\ominus$ .

**6B.3** The degree of dissociation,  $\alpha$ , of  $\text{CO}_2(\text{g})$  into  $\text{CO}(\text{g})$  and  $\text{O}_2(\text{g})$  at high temperatures was found to vary with temperature as follows:

$T/\text{K}$	1395	1443	1498
$\alpha/10^{-4}$	1.44	2.50	4.71

Assuming  $\Delta_f H^\ominus$  to be constant over this temperature range, calculate  $K$ ,  $\Delta_r G^\ominus$ ,  $\Delta_r H^\ominus$ , and  $\Delta_r S^\ominus$ . Make any justifiable approximations.

**6B.4** The standard reaction enthalpy for the decomposition of  $\text{CaCl}_2 \cdot \text{NH}_3(\text{s})$  into  $\text{CaCl}_2(\text{s})$  and  $\text{NH}_3(\text{g})$  is nearly constant at  $+78 \text{ kJ mol}^{-1}$  between 350 K and 470 K. The equilibrium pressure of  $\text{NH}_3$  in the presence of  $\text{CaCl}_2 \cdot \text{NH}_3$  is 1.71 kPa at 400 K. Find an expression for the temperature dependence of  $\Delta_r G^\ominus$  in the same range.

**6B.5** Acetic acid was evaporated in a container of volume  $21.45 \text{ cm}^3$  at 437 K and at an external pressure of 101.9 kPa, and the container was then sealed. The mass of acid present in the sealed container was 0.0519 g. The experiment was repeated with the same container but at 471 K, and it was found that

0.0380 g of acetic acid was present. Calculate the equilibrium constant for the dimerization of the acid in the vapour and the enthalpy of vaporization.

**6B.6** The dissociation of  $\text{I}_2$  can be monitored by measuring the total pressure, and three sets of results are as follows:

$T/\text{K}$	973	1073	1173
$100p/\text{atm}$	6.244	6.500	9.181
$10^4 n_1$	2.4709	2.4555	2.4366

where  $n_1$  is the amount of I atoms per mole of  $\text{I}_2$  molecules in the mixture, which occupied  $342.68 \text{ cm}^3$ . Calculate the equilibrium constants of the dissociation and the standard enthalpy of dissociation at the mean temperature.

**6B.7\*** The 1980s saw reports of  $\Delta_f G^\ominus(\text{SiH}_2)$  ranging from 243 to 289  $\text{kJ mol}^{-1}$ . If the standard enthalpy of formation is uncertain by this amount, by what factor is the equilibrium constant for the formation of  $\text{SiH}_2$  from its elements uncertain at (a) 298 K, (b) 700 K?

**6B.8** Find an expression for the standard reaction Gibbs energy at a temperature  $T'$  in terms of its value at another temperature  $T$  and the coefficients  $a$ ,  $b$ , and  $c$  in the expression for the molar heat capacity listed in Table 2B.1. Evaluate the standard Gibbs energy of formation of  $\text{H}_2\text{O}(\text{l})$  at 372 K from its value at 298 K.

**6B.9** Derive an expression for the temperature dependence of  $K_c$  for a gas-phase reaction.

## TOPIC 6C Electrochemical cells

### Discussion questions

**6C.1** Explain why reactions that are not redox reactions may be used to generate an electric current.

**6C.2** Explain the role of a salt bridge.

**6C.3** Why is it necessary to measure the cell potential under zero-current conditions?

**6C.4** Can you identify other contributions to the cell potential when a current is being drawn from the cell?

### Exercises

**6C.1(a)** Write the cell reaction and electrode half-reactions and calculate the standard potential of each of the following cells:

- $\text{Zn}|\text{ZnSO}_4(\text{aq})||\text{AgNO}_3(\text{aq})|\text{Ag}$
- $\text{Cd}|\text{CdCl}_2(\text{aq})||\text{HNO}_3(\text{aq})|\text{H}_2(\text{g})|\text{Pt}$
- $\text{Pt}|\text{K}_3[\text{Fe}(\text{CN})_6](\text{aq}), \text{K}_4[\text{Fe}(\text{CN})_6](\text{aq})||\text{CrCl}_3(\text{aq})|\text{Cr}$

**6C.1(b)** Write the cell reaction and electrode half-reactions and calculate the standard potential of each the following cells:

- $\text{Pt}|\text{Cl}_2(\text{g})|\text{HCl}(\text{aq})||\text{K}_2\text{CrO}_4(\text{aq})|\text{Ag}_2\text{CrO}_4(\text{s})|\text{Ag}$
- $\text{Pt}|\text{Fe}^{3+}(\text{aq}), \text{Fe}^{2+}(\text{aq})||\text{Sn}^{4+}(\text{aq}), \text{Sn}^{2+}(\text{aq})|\text{Pt}$
- $\text{Cu}|\text{Cu}^{2+}(\text{aq})||\text{Mn}^{2+}(\text{aq}), \text{H}^+(\text{aq})|\text{MnO}_2(\text{s})|\text{Pt}$

**6C.2(a)** Devise cells in which the following are the reactions and calculate the standard cell potential in each case:

- $\text{Zn}(\text{s}) + \text{CuSO}_4(\text{aq}) \rightarrow \text{ZnSO}_4(\text{aq}) + \text{Cu}(\text{s})$
- $2 \text{AgCl}(\text{s}) + \text{H}_2(\text{g}) \rightarrow 2 \text{HCl}(\text{aq}) + 2 \text{Ag}(\text{s})$
- $2 \text{H}_2(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{H}_2\text{O}(\text{l})$

**6C.2(b)** Devise cells in which the following are the reactions and calculate the standard cell potential in each case:

- $2 \text{Na}(\text{s}) + 2 \text{H}_2\text{O}(\text{l}) \rightarrow 2 \text{NaOH}(\text{aq}) + \text{H}_2(\text{g})$
- $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI}(\text{aq})$
- $\text{H}_3\text{O}^+(\text{aq}) + \text{OH}^-(\text{aq}) \rightarrow 2 \text{H}_2\text{O}(\text{l})$

**6C.3(a)** Use the Debye–Hückel limiting law and the Nernst equation to estimate the potential of the cell  $\text{Ag}|\text{AgBr}(\text{s})|\text{KBr}(\text{aq}, 0.050 \text{ mol kg}^{-1})||\text{Cd}(\text{NO}_3)_2(\text{aq}, 0.010 \text{ mol kg}^{-1})|\text{Cd}$  at 25 °C.

**6C.3(b)** Consider the cell  $\text{Pt}|\text{H}_2(\text{g}, p^\ominus)|\text{HCl}(\text{aq})|\text{AgCl}(\text{s})|\text{Ag}$ , for which the cell reaction is  $2 \text{AgCl}(\text{s}) + \text{H}_2(\text{g}) \rightarrow 2 \text{Ag}(\text{s}) + 2 \text{HCl}(\text{aq})$ . At 25 °C and a molality of  $\text{HCl}$  of  $0.010 \text{ mol kg}^{-1}$ ,  $E_{\text{cell}} = +0.4658 \text{ V}$ . (i) Write the Nernst equation for the cell reaction. (ii) Calculate  $\Delta_r G$  for the cell reaction. (iii) Assuming that the Debye–Hückel limiting law holds at this concentration, calculate  $E^\ominus(\text{Cl}^-, \text{AgCl}, \text{Ag})$ .

## Problems

**6C.1** A fuel cell develops an electric potential from the chemical reaction between reagents supplied from an outside source. What is the cell potential of a cell fuelled by (a) hydrogen and oxygen, (b) the combustion of butane at 1.0 bar and 298 K?

**6C.2** Although the hydrogen electrode may be conceptually the simplest electrode and is the basis for our reference state of electrical potential in electrochemical systems, it is cumbersome to use. Therefore, several substitutes for it have been devised. One of these alternatives is the quinhydrone electrode (quinhydrone,  $Q \cdot QH_2$ , is a complex of quinone,  $C_6H_4O_2=Q$ , and hydroquinone,  $C_6H_4O_2H_2=QH_2$ ). The electrode half-reaction is  $Q(aq) + 2 H^+(aq) + 2 e^- \rightarrow QH_2(aq)$ ,  $E^\ominus = +0.6994 V$ . If the cell  $Hg|Hg_2Cl_2(s)|HCl(aq)||Q \cdot QH_2|Au$  is prepared, and the measured cell potential

is  $+0.190 V$ , what is the pH of the HCl solution? Assume that the Debye–Hückel limiting law is applicable.

**6C.3** Fuel cells provide electrical power for spacecraft (as in the NASA space shuttles) and also show promise as power sources for automobiles. Hydrogen and carbon monoxide have been investigated for use in fuel cells, so their solubilities in molten salts are of interest. Their solubilities in a molten  $NaNO_3/KNO_3$  mixture were found to fit the following expressions:

$$\log s_{H_2} = -5.39 - \frac{980}{T/K} \quad \log s_{CO} = -5.98 - \frac{980}{T/K}$$

where  $s$  is the solubility in  $\text{mol cm}^{-3} \text{bar}^{-1}$ . Calculate the standard molar enthalpies of solution of the two gases at 570 K.

## TOPIC 6D Electrode potentials

### Discussion questions

**6D.1** Describe a method for the determination of the standard potential of a redox couple.

**6D.2** Devise a method for the determination of the pH of an aqueous solution.

### Exercises

**6D.1(a)** Calculate the equilibrium constants of the following reactions at 25 °C from standard potential data:

- (i)  $\text{Sn}(s) + \text{Sn}^{4+}(aq) \rightleftharpoons 2 \text{Sn}^{2+}(aq)$   
 (ii)  $\text{Sn}(s) + 2 \text{AgCl}(s) \rightleftharpoons \text{SnCl}_2(aq) + 2 \text{Ag}(s)$

**6D.1(b)** Calculate the equilibrium constants of the following reactions at 25 °C from standard potential data:

- (i)  $\text{Sn}(s) + \text{CuSO}_4(aq) \rightleftharpoons \text{Cu}(s) + \text{SnSO}_4(aq)$   
 (ii)  $\text{Cu}^{2+}(aq) + \text{Cu}(s) \rightleftharpoons 2 \text{Cu}^+(aq)$

**6D.2(a)** The potential of the cell  $\text{Ag}|\text{AgI}(s)|\text{AgI}(aq)|\text{Ag}$  is  $+0.9509 V$  at 25 °C. Calculate (i) the solubility product of AgI and (ii) its solubility.

**6D.2(b)** The potential of the cell  $\text{Bi}|\text{Bi}_2\text{S}_3(s)|\text{Bi}_2\text{S}_3(aq)|\text{Bi}$  is  $-0.96 V$  at 25 °C. Calculate (i) the solubility product of  $\text{Bi}_2\text{S}_3$  and (ii) its solubility.

## Problems

**6D.1** The potential of the cell  $\text{Pt}|\text{H}_2(g, p^\ominus)|\text{HCl}(aq, b)|\text{Hg}_2\text{Cl}_2(s)|\text{Hg}(l)$  has been measured with high precision with the following results at 25 °C:

$b/(\text{mmol kg}^{-1})$	1.6077	3.0769	5.0403	7.6938	10.9474
$E/V$	0.60080	0.56825	0.54366	0.52267	0.50532

Determine the standard cell potential and the mean activity coefficient of HCl at these molalities. (Make a least-squares fit of the data to the best straight line.)

**6D.2** The standard potential of the  $\text{AgCl}/\text{Ag}, \text{Cl}^-$  couple fits the expression

$$E^\ominus/V = 0.23659 - 4.8564 \times 10^{-4} (\theta/^\circ\text{C}) - 3.4205 \times 10^{-6} (\theta/^\circ\text{C})^2 + 5.869 \times 10^{-9} (\theta/^\circ\text{C})^3$$

Calculate the standard Gibbs energy and enthalpy of formation of  $\text{Cl}^-(aq)$  and its entropy at 298 K.

## Integrated activities

**6.1\*** Thorn et al. (*J. Phys. Chem.* **100**, 14178 (1996)) carried out a study of  $\text{Cl}_2\text{O}(g)$  by photoelectron ionization. From their measurements, they report  $\Delta_f H^\ominus(\text{Cl}_2\text{O}) = +77.2 \text{ kJ mol}^{-1}$ . They combined this measurement with literature data on the reaction  $\text{Cl}_2\text{O}(g) + \text{H}_2\text{O}(g) \rightarrow 2 \text{HOCl}(g)$ , for which  $K = 8.2 \times 10^{-3}$  and  $\Delta_r S^\ominus = +16.38 \text{ J K}^{-1} \text{ mol}^{-1}$ , and with readily available thermodynamic data on water vapour to report a value for  $\Delta_f H^\ominus(\text{HOCl})$ . Calculate that value. All quantities refer to 298 K.

**6.2** Given that  $\Delta_r G^\ominus = -212.7 \text{ kJ mol}^{-1}$  for the reaction in the Daniell cell at 25 °C, and  $b(\text{CuSO}_4) = 1.0 \times 10^{-3} \text{ mol kg}^{-1}$  and  $b(\text{ZnSO}_4) = 3.0 \times 10^{-3} \text{ mol kg}^{-1}$ , calculate (a) the ionic strengths of the solutions, (b) the mean ionic activity coefficients in the compartments, (c) the reaction quotient, (d) the standard cell potential, and (e) the cell potential. (Take  $\gamma_+ = \gamma_- = \gamma_{\pm}$  in the respective compartments.)

**6.3** Consider the cell,  $\text{Zn(s)}|\text{ZnCl}_2(0.0050 \text{ mol kg}^{-1})|\text{Hg}_2\text{Cl}_2(\text{s})|\text{Hg(l)}$ , for which the cell reaction is  $\text{Hg}_2\text{Cl}_2(\text{s}) + \text{Zn(s)} \rightarrow 2 \text{Hg(l)} + 2 \text{Cl}^-(\text{aq}) + \text{Zn}^{2+}(\text{aq})$ . Given that  $E^\ominus(\text{Zn}^{2+}, \text{Zn}) = -0.7628 \text{ V}$ ,  $E^\ominus(\text{Hg}_2\text{Cl}_2, \text{Hg}) = +0.2676 \text{ V}$ , and that the cell potential is  $+1.2272 \text{ V}$ , (a) write the Nernst equation for the cell. Determine (b) the standard cell potential, (c)  $\Delta_r G$ ,  $\Delta_r G^\ominus$ , and  $K$  for the cell reaction, (d) the mean ionic activity and activity coefficient of  $\text{ZnCl}_2$  from the measured cell potential, and (e) the mean ionic activity coefficient of  $\text{ZnCl}_2$  from the Debye-Hückel limiting law. (f) Given that  $(\partial E_{\text{cell}}/\partial T)_p = -4.52 \times 10^{-4} \text{ V K}^{-1}$ , calculate  $\Delta_r S$  and  $\Delta_r H$ .

**6.4** Careful measurements of the potential of the cell  $\text{Pt}|\text{H}_2(\text{g}, p^\ominus)|\text{NaOH}(\text{aq}, 0.0100 \text{ mol kg}^{-1}), \text{NaCl}(\text{aq}, 0.01125 \text{ mol kg}^{-1})|\text{AgCl}(\text{s})|\text{Ag}(\text{s})$  have been reported. Among the data is the following information:

$\theta/^\circ\text{C}$	20.0	25.0	30.0
$E_{\text{cell}}/\text{V}$	1.04774	1.04864	1.04942

Calculate  $\text{p}K_w$  at these temperatures and the standard enthalpy and entropy of the autoprotolysis of water at  $25.0^\circ\text{C}$ .

**6.5** Measurements of the potential of cells of the type  $\text{Ag}|\text{AgX}(\text{s})|\text{MX}(b_1)|\text{M}_x\text{Hg}|\text{MX}(b_2)|\text{AgX}(\text{s})|\text{Ag}$ , where  $\text{M}_x\text{Hg}$  denotes an amalgam and the electrolyte is an  $\text{LiCl}$  in ethylene glycol, are given below. Estimate the activity coefficient at the concentration marked \* and then use this value to calculate activity coefficients from the measured cell potential at the other concentrations. Base your answer on the Davies equation (eqn 5F.11) with  $A = 1.461$ ,  $B = 1.70$ ,  $C = 0.20$ , and  $I = b/b^\ominus$ . For  $b_2 = 0.09141 \text{ mol kg}^{-1}$ :

$b_1/(\text{mol kg}^{-1})$	0.0555	0.09141	0.1652	0.2171	1.040	1.350*
$E/\text{V}$	-0.0220	0.0000	0.0263	0.0379	0.1156	0.1336

**6.6\*** The table below summarizes the potential of the cell  $\text{Pd}|\text{H}_2(\text{g}, 1 \text{ bar})|\text{BH}(\text{aq}, b), \text{B}(\text{aq}, b)|\text{AgCl}(\text{s})|\text{Ag}$ . Each measurement is made at equimolar concentrations of 2-aminopyridinium chloride (BH) and 2-aminopyridine (B). The data are for  $25^\circ\text{C}$  and it is found that  $E^\ominus = 0.22251 \text{ V}$ . Use the data to determine  $\text{p}K_a$  for the acid at  $25^\circ\text{C}$  and the mean activity coefficient ( $\gamma_\pm$ ) of BH as a function of molality ( $b$ ) and ionic strength ( $I$ ). Use the Davies equation (eqn 5F.11) with  $A = 0.5091$  and  $B$  and  $C$  are parameters that depend upon the ions. Draw a graph of the mean activity coefficient with  $b = 0.04 \text{ mol kg}^{-1}$  and  $0 \leq I \leq 0.1$ .

$b/(\text{mol kg}^{-1})$	0.01	0.02	0.03	0.04	0.05
$E_{\text{cell}}(25^\circ\text{C})/\text{V}$	0.74452	0.72853	0.71928	0.71314	0.70809
$b/(\text{mol kg}^{-1})$	0.06	0.07	0.08	0.09	0.10
$E_{\text{cell}}(25^\circ\text{C})/\text{V}$	0.70380	0.70059	0.69790	0.69571	0.69338

*Hint:* Use mathematical software or a spreadsheet.

**6.7** Here we investigate the molecular basis for the observation that the hydrolysis of ATP is exergonic at  $\text{pH} = 7.0$  and  $310 \text{ K}$ . (a) It is thought that the exergonicity of ATP hydrolysis is due in part to the fact that the standard entropies of hydrolysis of polyphosphates are positive. Why would an increase in entropy accompany the hydrolysis of a triphosphate group into a diphosphate and a phosphate group? (b) Under identical conditions, the Gibbs energies of hydrolysis of  $\text{H}_4\text{ATP}$  and  $\text{MgATP}^{2-}$ , a complex between the  $\text{Mg}^{2+}$  ion and  $\text{ATP}^{4-}$ , are less negative than the Gibbs energy of hydrolysis of  $\text{ATP}^{4-}$ . This observation has been used to support the hypothesis that electrostatic repulsion between adjacent phosphate groups is a factor that controls the exergonicity of ATP hydrolysis. Provide a rationale for the hypothesis and discuss how the experimental evidence supports it. Do these electrostatic effects contribute to the  $\Delta_r H$  or  $\Delta_r S$  terms that determine the exergonicity of the reaction? *Hint.* In the  $\text{MgATP}^{2-}$  complex, the  $\text{Mg}^{2+}$  ion and  $\text{ATP}^{4-}$  anion form two bonds: one that involves a negatively charged oxygen belonging to the terminal phosphate group of  $\text{ATP}^{4-}$  and another that involves a negatively charged oxygen belonging to the phosphate group adjacent to the terminal phosphate group of  $\text{ATP}^{4-}$ .

**6.8** To get a sense of the effect of cellular conditions on the ability of ATP to drive biochemical processes, compare the standard Gibbs energy of hydrolysis of ATP to ADP with the reaction Gibbs energy in an environment at  $37^\circ\text{C}$  in which  $\text{pH} = 7.0$  and the ATP, ADP, and  $\text{P}_i^-$  concentrations are all  $1.0 \text{ mmol dm}^{-3}$ .

**6.9** Under biochemical standard conditions, aerobic respiration produces approximately 38 molecules of ATP per molecule of glucose that is completely oxidized. (a) What is the percentage efficiency of aerobic respiration under biochemical standard conditions? (b) The following conditions are more likely to be observed in a living cell:  $p_{\text{CO}_2} = 5.3 \times 10^{-2} \text{ atm}$ ,  $p_{\text{O}_2} = 0.132 \text{ atm}$ ,  $[\text{glucose}] = 5.6 \text{ pmol dm}^{-3}$ ,  $[\text{ATP}] = [\text{ADP}] = [\text{P}_i] = 0.10 \text{ mmol dm}^{-3}$ ,  $\text{pH} = 7.4$ ,  $T = 310 \text{ K}$ . Assuming that activities can be replaced by the numerical values of molar concentrations, calculate the efficiency of aerobic respiration under these physiological conditions. (c) A typical diesel engine operates between  $T_c = 873 \text{ K}$  and  $T_h = 1923 \text{ K}$  with an efficiency that is approximately 75 per cent of the theoretical limit of  $1 - T_c/T_h$  (see Topic 3A). Compare the efficiency of a typical diesel engine with that of aerobic respiration under typical physiological conditions (see part b). Why is biological energy conversion more or less efficient than energy conversion in a diesel engine?

**6.10** In anaerobic bacteria, the source of carbon may be a molecule other than glucose and the final electron acceptor is some molecule other than  $\text{O}_2$ . Could a bacterium evolve to use the ethanol/nitrate pair instead of the glucose/ $\text{O}_2$  pair as a source of metabolic energy?

**6.11** The standard potentials of proteins are not commonly measured by the methods described in this chapter because proteins often lose their native structure and function when they react on the surfaces of electrodes. In an alternative method, the oxidized protein is allowed to react with an appropriate electron donor in solution. The standard potential of the protein is then determined from the Nernst equation, the equilibrium concentrations of all species in solution, and the known standard potential of the electron donor. We illustrate this method with the protein cytochrome *c*. The one-electron reaction between cytochrome *c*, *cyt*, and 2,6-dichloroindophenol, *D*, can be followed spectrophotometrically because each of the four species in solution has a distinct absorption spectrum. We write the reaction as  $\text{cyt}_{\text{ox}} + \text{D}_{\text{red}} \rightleftharpoons \text{cyt}_{\text{red}} + \text{D}_{\text{ox}}$ , where the subscripts 'ox' and 'red' refer to oxidized and reduced states, respectively. (a) Consider  $E_{\text{cyt}}^\ominus$  and  $E_{\text{D}}^\ominus$  to be the standard potentials of cytochrome *c* and *D*, respectively. Show that, at equilibrium, a plot of  $\ln([\text{D}_{\text{ox}}]_{\text{eq}}/[\text{D}_{\text{red}}]_{\text{eq}})$  versus  $\ln([\text{cyt}_{\text{ox}}]_{\text{eq}}/[\text{cyt}_{\text{red}}]_{\text{eq}})$  is linear with slope of 1 and  $y$ -intercept  $F(E_{\text{cyt}}^\ominus - E_{\text{D}}^\ominus)/RT$ , where equilibrium activities are replaced by the numerical values of equilibrium molar concentrations. (b) The following data were obtained for the reaction between oxidized cytochrome *c* and reduced *D* in a  $\text{pH} 6.5$  buffer at  $298 \text{ K}$ . The ratios  $[\text{D}_{\text{ox}}]_{\text{eq}}/[\text{D}_{\text{red}}]_{\text{eq}}$  and  $[\text{cyt}_{\text{ox}}]_{\text{eq}}/[\text{cyt}_{\text{red}}]_{\text{eq}}$  were adjusted by titrating a solution containing oxidized cytochrome *c* and reduced *D* with a solution of sodium ascorbate, which is a strong reductant. From the data and the standard potential of *D* of  $0.237 \text{ V}$ , determine the standard potential cytochrome *c* at  $\text{pH} 6.5$  and  $298 \text{ K}$ .

$[\text{D}_{\text{ox}}]_{\text{eq}}/[\text{D}_{\text{red}}]_{\text{eq}}$	0.00279	0.00843	0.0257	0.0497	0.0748	0.238	0.534
$[\text{cyt}_{\text{ox}}]_{\text{eq}}/[\text{cyt}_{\text{red}}]_{\text{eq}}$	0.0106	0.0230	0.0894	0.197	0.335	0.809	1.39

**6.12\*** The dimerization of  $\text{ClO}$  in the Antarctic winter stratosphere is believed to play an important part in that region's severe seasonal depletion of ozone. The following equilibrium constants are based on measurements on the reaction  $2 \text{ClO}(\text{g}) \rightarrow (\text{ClO})_2(\text{g})$ .

$T/\text{K}$	233	248	258	268	273	280
$K$	$4.13 \times 10^8$	$5.00 \times 10^7$	$1.45 \times 10^7$	$5.37 \times 10^6$	$3.20 \times 10^6$	$9.62 \times 10^5$
$T/\text{K}$	288	295	303			
$K$	$4.28 \times 10^5$	$1.67 \times 10^5$	$6.02 \times 10^4$			

(a) Derive the values of  $\Delta_r H^\ominus$  and  $\Delta_r S^\ominus$  for this reaction. (b) Compute the standard enthalpy of formation and the standard molar entropy of  $(\text{ClO})_2$  given  $\Delta_r H^\ominus(\text{ClO}, \text{g}) = +101.8 \text{ kJ mol}^{-1}$  and  $S_m^\ominus(\text{ClO}, \text{g}) = 266.6 \text{ J K}^{-1} \text{ mol}^{-1}$ .

6.13<sup>†</sup> Suppose that an iron catalyst at a particular manufacturing plant produces ammonia in the most cost-effective manner at 450 °C when the pressure is such that  $\Delta_r G$  for the reaction  $\frac{1}{2}\text{N}_2(\text{g}) + \frac{3}{2}\text{H}_2(\text{g}) \rightarrow \text{NH}_3(\text{g})$  is equal to  $-500 \text{ J mol}^{-1}$ . (a) What pressure is needed? (b) Now suppose that a new catalyst is developed that is most cost-effective at 400 °C when the pressure gives the same value of  $\Delta_r G$ . What pressure is needed when the new

catalyst is used? What are the advantages of the new catalyst? Assume that (i) all gases are perfect gases or that (ii) all gases are van der Waals gases. Isotherms of  $\Delta_r G(T, p)$  in the pressure range  $100 \text{ atm} \leq p \leq 400 \text{ atm}$  are needed to derive the answer. (c) Do the isotherms you plotted confirm Le Chatelier's principle concerning the response of equilibrium changes in temperature and pressure?

# PART TWO

# Structure

In Part 1, we examined the properties of bulk matter from the viewpoint of thermodynamics. In Part 2 we examine the structures and properties of individual atoms and molecules from the viewpoint of quantum mechanics and explain how their structures are determined spectroscopically. The two viewpoints, the macroscopic and the microscopic, merge in Chapter 15, where we show how structural data are used to predict and explain the bulk thermodynamic properties encountered in Part 1. The final three chapters of this Part focus on the way that intermolecular forces lead to the aggregation of molecules, how molecular properties influence the properties of the resulting liquids and solids, and how the structures of these condensed phases are determined.

# CHAPTER 7

## Introduction to quantum theory

It was once thought that the motion of atoms and subatomic particles could be expressed using ‘classical mechanics’, the laws of motion introduced in the seventeenth century by Isaac Newton, for these laws were very successful at explaining the motion of everyday objects and planets. However, a proper description of electrons, atoms, and molecules requires a different kind of mechanics, ‘quantum mechanics’, which we introduce in this chapter and then apply throughout the remainder of the text.

### 7A The origins of quantum mechanics

Experimental evidence accumulated towards the end of the nineteenth century showed that classical mechanics failed when it was applied to particles as small as electrons. More specifically, careful measurements led to the conclusion that particles may not have an arbitrary energy and that the classical concepts of particle and wave blend together. In this Topic we see how these observations set the stage for the development of the concepts and equations of quantum mechanics through the early twentieth century.

### 7B Dynamics of microscopic systems

In quantum mechanics, all the properties of a system are expressed in terms of a wavefunction which is obtained by

solving the ‘Schrödinger equation’. In this Topic we see how to interpret wavefunctions.

### 7C The principles of quantum theory

This Topic introduces some of the mathematical techniques of quantum mechanics in terms of operators. We also see that quantum theory introduces the ‘uncertainty principle’, one of the most profound departures from classical mechanics.

### What is the impact of this material?

In *Impact 17.1* we highlight an application of quantum mechanics that still requires much research before it becomes a useful technology. It is based on the speculation that through ‘quantum computing’ calculations can be carried out on many states of a system simultaneously, leading to a new generation of very fast computers.

### ► Why do you need to know this material?

You should know how experimental results motivated the development of quantum theory, which underlies all descriptions of the structure of atoms and molecules and pervades the whole of spectroscopy and chemistry in general.

### ► What is the key idea?

Experimental evidence led to the conclusions that energy cannot be continuously varied and that the classical concepts of a 'particle' and a 'wave' blend together when applied to light, atoms, and molecules.

### ► What do you need to know already?

You should be familiar with the basic principles of classical mechanics, which are reviewed in *Foundations B*. The discussion of heat capacities of solids formally makes use of material in Topic 2A but is introduced independently here.

The basic principles of classical mechanics are reviewed in *Foundations B*. In brief, they show that classical physics

(1) predicts a precise trajectory for particles, with precisely specified locations and momenta at each instant, and (2) allows the translational, rotational, and vibrational modes of motion to be excited to any energy simply by controlling the forces that are applied. These conclusions agree with everyday experience. Everyday experience, however, does not extend to individual atoms, and careful experiments have shown that classical mechanics fails when applied to the transfers of very small energies and to objects of very small mass.

We also investigate the properties of light. The classical view, discussed in *Foundations C*, is of light as an oscillating electromagnetic field that spreads as a wave through empty space with a wavelength,  $\lambda$  (lambda), a frequency,  $\nu$  (nu), and a constant speed,  $c$  (Fig. C.1). Again, a number of experimental results are not consistent with this interpretation.

This Topic describes the experiments that revealed limitations of classical physics. The remaining Topics of the Chapter show how a new picture of light and matter led to the formulation of an entirely new and hugely successful theory called **quantum mechanics**.

## 7A.1 Energy quantization

Here we outline three experiments conducted near the end of the nineteenth century and which drove scientists to the view that energy can be transferred only in discrete amounts.

### (a) Black-body radiation

A hot object emits electromagnetic radiation. At high temperatures, an appreciable proportion of the radiation is in the visible region of the spectrum and a higher proportion of short-wavelength blue light is generated as the temperature is raised. This behaviour is seen when a heated metal bar glowing red hot becomes white hot when heated further. The dependence is illustrated in Fig. 7A.1, which shows how the energy output varies with wavelength at several temperatures. The curves are those of an ideal emitter called a **black body**, which is an object capable of emitting and absorbing all wavelengths of radiation uniformly. A good approximation to a black body is a pinhole in an empty container maintained at a constant temperature: any radiation leaking out of the hole has been absorbed and re-emitted inside so many times as it reflected around inside

**Figure 7A.1** The energy distribution in a black-body cavity at several temperatures. Note how the spectral density of states increases in the region of shorter wavelength as the temperature is raised, and how the peak shifts to shorter wavelengths.

the container that it has come to thermal equilibrium with the walls (Fig. 7A.2).

The approach adopted by nineteenth-century scientists to explain black-body radiation was to calculate the **energy density**,  $d\mathcal{E}$ , the total energy in a region of the electromagnetic field divided by the volume of the region (units: joules per metre-cubed,  $\text{J m}^{-3}$ ), due to all the oscillators corresponding to wavelengths between  $\lambda$  and  $\lambda + d\lambda$ . This energy density is proportional to the width,  $d\lambda$ , of this range, and is written

$$d\mathcal{E} = \rho(\lambda, T) d\lambda \quad (7A.1)$$

where  $\rho$  (rho), the constant of proportionality between  $d\mathcal{E}$  and  $d\lambda$ , is called the **density of states** (units: joules per metre<sup>4</sup>,  $\text{J m}^{-4}$ ). A high density of states at the wavelength  $\lambda$  and temperature  $T$  simply means that there is a lot of energy associated with wavelengths lying between  $\lambda$  and  $\lambda + d\lambda$  at that temperature. The total energy density in a region is the integral over all wavelengths:

**Figure 7A.2** An experimental representation of a black body is a pinhole in an otherwise closed container. The radiation is reflected many times within the container and comes to thermal equilibrium with the walls. Radiation leaking out through the pinhole is characteristic of the radiation within the container.

$$\mathcal{E}(T) = \int_0^{\infty} \rho(\lambda, T) d\lambda \quad (7A.2)$$

It depends on the temperature: the higher the temperature, the greater the energy density. Just as the mass of an object is its mass density multiplied by its volume, the total energy within a region of volume  $V$  is this energy density multiplied by the volume:

$$E(T) = V\mathcal{E}(T) \quad (7A.3)$$

The physicist Lord Rayleigh thought of the electromagnetic field as a collection of oscillators of all possible frequencies. He regarded the presence of radiation of frequency  $\nu$  (and therefore of wavelength  $\lambda = c/\nu$ , eqn C.3) as signifying that the electromagnetic oscillator of that frequency had been excited (Fig. 7A.3). Rayleigh knew that according to the classical equipartition principle (*Foundations* B), the average energy of each oscillator, regardless of its frequency, is  $kT$ . On that basis, with minor help from James Jeans, he arrived at the **Rayleigh–Jeans law** for the density of states:

$$\rho(\lambda, T) = \frac{8\pi kT}{\lambda^4} \quad \text{Rayleigh–Jeans law} \quad (7A.4)$$

where  $k$  is Boltzmann's constant ( $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ ).

Although the Rayleigh–Jeans law is quite successful at long wavelengths (low frequencies), it fails badly at short wavelengths (high frequencies). Thus, as  $\lambda$  decreases,  $\rho$  increases without going through a maximum (Fig. 7A.4). The equation therefore predicts that oscillators of very short wavelength (corresponding to ultraviolet radiation, X-rays, and even  $\gamma$ -rays) are strongly excited even at room temperature. The total energy density in a region, the integral in eqn 7A.2, is also predicted to be infinite at all temperatures above zero. This absurd result, which implies that a large amount of energy is radiated in the high-frequency region of the electromagnetic spectrum, is called the **ultraviolet catastrophe**. According to classical

**Figure 7A.3** The electromagnetic vacuum can be regarded as able to support oscillations of the electromagnetic field. When a high-frequency, short-wavelength oscillator (a) is excited, that frequency of radiation is present. The presence of low-frequency, long-wavelength radiation (b) signifies that an oscillator of the corresponding frequency has been excited.

**Figure 7A.4** The Rayleigh–Jeans law (eqn 7A.4) predicts an infinite spectral density of states at short wavelengths. This approach to infinity is called the ultraviolet catastrophe.

physics, even cool objects should radiate in the visible and ultraviolet regions, so objects should glow in the dark; there should in fact be no darkness.

In 1900, the German physicist Max Planck found that he could account for the experimental observations by proposing that the energy of each electromagnetic oscillator is limited to discrete values and cannot be varied arbitrarily. This proposal is contrary to the viewpoint of classical physics in which all possible energies are allowed and every oscillator has a mean energy  $kT$ . The limitation of energies to discrete values is called the **quantization of energy**. In particular, Planck found that he could account for the observed distribution of energy if he supposed that the permitted energies of an electromagnetic oscillator of frequency  $\nu$  are integer multiples of  $h\nu$ :

$$E = nh\nu \quad n = 0, 1, 2, \dots \quad (7A.5)$$

where  $h$  is a fundamental constant now known as **Planck's constant**. On the basis of this assumption, Planck was able to derive what is now called the **Planck distribution**:

$$\rho(\lambda, T) = \frac{8\pi hc}{\lambda^5 (e^{hc/\lambda kT} - 1)} \quad \text{Planck distribution} \quad (7A.6)$$

This expression fits the experimental curve very well at all wavelengths (Fig. 7A.5), and the value of  $h$ , which is an undetermined parameter in the theory, may be obtained by varying its value until a best fit is obtained. The currently accepted value for  $h$  is  $6.626 \times 10^{-34}$  J s.

As usual, it is a good idea to 'read' the content of an equation:

- The Planck distribution resembles the Rayleigh–Jeans law (eqn 7A.4) apart from the all-important exponential factor in the denominator. For short wavelengths,  $hc/\lambda kT \gg 1$  and  $e^{hc/\lambda kT} \rightarrow \infty$  faster than  $\lambda^5 \rightarrow 0$ ; therefore  $\rho \rightarrow 0$  as  $\lambda \rightarrow 0$  or  $\nu \rightarrow \infty$ . Hence, the energy density approaches zero at high frequencies, in agreement with observation.

**Figure 7A.5** The Planck distribution (eqn 7A.6) accounts very well for the experimentally determined distribution of black-body radiation. Planck's quantization hypothesis essentially quenches the contributions of high frequency, short wavelength oscillators. The distribution coincides with the Rayleigh–Jeans distribution at long wavelengths.

- For long wavelengths,  $hc/\lambda kT \ll 1$ , and the denominator in the Planck distribution can be replaced by (see *Mathematical background 1*)

$$e^{hc/\lambda kT} - 1 = \left( 1 + \frac{hc}{\lambda kT} + \dots \right) - 1 \approx \frac{hc}{\lambda kT}$$

When this approximation is substituted into eqn 7A.6, we find that the Planck distribution reduces to the Rayleigh–Jeans law.

- As we should infer from the graph in Fig. 7A.5, the total energy density (the integral in eqn 7A.2 and therefore the area under the curve) is no longer infinite, and in fact

$$\begin{aligned} \mathcal{E}(T) &= \int_0^\infty \frac{8\pi hc}{\lambda^5 (e^{hc/\lambda kT} - 1)} d\lambda = aT^4 \quad \text{with} \\ a &= \frac{8\pi^5 k^4}{15(hc)^3} \end{aligned} \quad (7A.7)$$

That is, the energy density increases as the fourth power of the temperature.

### Example 7A.1 Using the Planck distribution

Compare the energy output of a black-body radiator (such as an incandescent lamp) at two different wavelengths by calculating the ratio of the energy output at 450 nm (blue light) to that at 700 nm (red light) at 298 K.

**Method** Use eqn 7A.6. At a temperature  $T$ , the ratio of the spectral density of states at a wavelength  $\lambda_1$  to that at  $\lambda_2$  is

$$\frac{\rho(\lambda_1, T)}{\rho(\lambda_2, T)} = \left( \frac{\lambda_2}{\lambda_1} \right)^5 \times \frac{(e^{hc/\lambda_2 kT} - 1)}{(e^{hc/\lambda_1 kT} - 1)}$$

Insert the data to evaluate this ratio.

**Answer** With  $\lambda_1 = 450 \text{ nm}$  and  $\lambda_2 = 700 \text{ nm}$ :

$$\frac{hc}{\lambda_1 kT} = \frac{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})}{(450 \times 10^{-9} \text{ m}) \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} = 107.2 \dots$$

$$\frac{hc}{\lambda_2 kT} = \frac{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})}{(700 \times 10^{-9} \text{ m}) \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} = 68.9 \dots$$

and therefore

$$\frac{\rho(450 \text{ nm}, 298 \text{ K})}{\rho(700 \text{ nm}, 298 \text{ K})} = \left( \frac{700 \times 10^{-9} \text{ m}}{450 \times 10^{-9} \text{ m}} \right)^5 \times \frac{(e^{68.9 \dots} - 1)}{(e^{107.2 \dots} - 1)} \\ = 9.11 \times (2.30 \times 10^{-17}) = 2.10 \times 10^{-16}$$

At room temperature, the proportion of short wavelength radiation is insignificant.

**Self-test 7A.1** Repeat the calculation for a temperature of 13.6 MK, which is close to the temperature at the core of the Sun.

Answer: 5.85

It is easy to see why Planck's approach was successful whereas Rayleigh's was not. The thermal motion of the atoms in the walls of the black body excites the oscillators of the electromagnetic field. According to classical mechanics, all the oscillators of the field share equally in the energy supplied by the walls, so even the highest frequencies are excited. The excitation of very high frequency oscillators results in the ultraviolet catastrophe. According to Planck's hypothesis, however, oscillators are excited only if they can acquire an energy of at least  $h\nu$ . This energy is too large for the walls to supply in the case of the very high frequency oscillators, so the latter remain unexcited. The effect of quantization is to reduce the contribution from the high frequency oscillators, for they cannot be significantly excited with the energy available.

## (b) Heat capacities

In the early nineteenth century, the French scientists Pierre-Louis Dulong and Alexis-Thérèse Petit determined the heat capacities,  $C_V = (\partial U / \partial T)_V$  (Topic 2A), of a number of monatomic solids. On the basis of some somewhat slender experimental evidence, they proposed that the molar heat capacities of all monatomic solids are the same and (in modern units) close to  $25 \text{ J K}^{-1} \text{ mol}^{-1}$ .

Dulong and Petit's law is easy to justify in terms of classical physics in much the same way as Rayleigh attempted to explain black-body radiation. If classical physics were valid, the equipartition principle could be used to infer that the mean energy of an atom as it oscillates about its mean position in a solid is  $kT$  for each direction of displacement. As each atom can oscillate in three dimensions, the average

energy of each atom is  $3kT$ ; for  $N$  atoms the total energy is  $3NkT$ . The contribution of this motion to the molar internal energy is therefore

$$U_m = 3N_A kT = 3RT \quad (7A.8a)$$

because  $N_A k = R$ , the gas constant. The molar constant volume heat capacity is then predicted to be

$$C_{V,m} = \left( \frac{\partial U_m}{\partial T} \right)_V = 3R \quad (7A.8b)$$

This result, with  $3R = 24.9 \text{ J K}^{-1} \text{ mol}^{-1}$ , is in striking accord with Dulong and Petit's value.

Unfortunately (for Dulong and Petit), significant deviations from their law were observed when advances in refrigeration techniques made it possible to measure heat capacities at low temperatures. It was found that the molar heat capacities of all monatomic solids are lower than  $3R$  at low temperatures, and that the values approach zero as  $T \rightarrow 0$ . To account for these observations, Einstein (in 1905) assumed that each atom oscillated about its equilibrium position with a single frequency  $\nu$ . He then invoked Planck's hypothesis to assert that the energy of oscillation is confined to discrete values, and specifically to  $n h \nu$ , where  $n$  is an integer. Einstein discarded the equipartition result, calculated the vibrational contribution of the atoms to the total molar internal energy of the solid (by a method described in Topic 15E), and obtained the expression now known as the **Einstein formula**:

$$C_{V,m}(T) = 3R f_E(T) \quad f_E(T) = \left( \frac{\theta_E}{T} \right)^2 \left( \frac{e^{\theta_E/2T}}{e^{\theta_E/T} - 1} \right)^2 \quad \text{Einstein formula} \quad (7A.9)$$

The **Einstein temperature**,  $\theta_E = h\nu/k$ , is a way of expressing the frequency of oscillation of the atoms as a temperature and allows us to be quantitative about what we mean by 'high temperature' ( $T \gg \theta_E$ ) and 'low temperature' ( $T \ll \theta_E$ ) in this context. Note that a high vibrational frequency corresponds to a high Einstein temperature.

As before, we now 'read' this expression:

- At high temperatures (when  $T \gg \theta_E$ ) the exponentials in  $f_E$  can be expanded as  $1 + \theta_E/T + \dots$  and higher terms ignored. The result is

$$f_E(T) = \left( \frac{\theta_E}{T} \right)^2 \left\{ \frac{1 + \theta_E/2T + \dots}{(1 + \theta_E/T + \dots) - 1} \right\}^2 \approx 1 \quad (7A.10a)$$

Consequently, the classical result ( $C_{V,m} = 3R$ ) is obtained at high temperatures.

- At low temperatures (when  $T \ll \theta_E$ ) and  $e^{\theta_E/T} \gg 1$ ,

$$f_E(T) \approx \left( \frac{\theta_E}{T} \right)^2 \left( \frac{e^{\theta_E/2T}}{e^{\theta_E/T}} \right)^2 = \left( \frac{\theta_E}{T} \right)^2 e^{-\theta_E/T} \quad (7A.10b)$$

The strongly decaying exponential function goes to zero more rapidly than  $1/T$  goes to infinity; so  $f_E \rightarrow 0$  as  $T \rightarrow 0$ , and the heat capacity therefore approaches zero too.

We see that Einstein's formula accounts for the decrease of heat capacity at low temperatures. The physical reason for this success is that at low temperatures only a few oscillators possess enough energy to oscillate significantly so the solid behaves as though it contains far fewer atoms than is actually the case. At higher temperatures, there is enough energy available for all the oscillators to become active: all  $3N$  oscillators contribute, many of their energy levels are accessible, and the heat capacity approaches its classical value.

Figure 7A.6 shows the temperature dependence of the heat capacity predicted by the Einstein formula. The general shape of the curve is satisfactory, but the numerical agreement is in fact quite poor. The poor fit arises from Einstein's assumption that all the atoms oscillate with the same frequency, whereas in fact they oscillate over a range of frequencies from zero up to a maximum value,  $\nu_D$ . This complication is taken into account by averaging over all the frequencies present, the final result being the **Debye formula**:

$$C_{V,m}(T) = 3Rf_D(T) \quad f_D(T) = 3 \left( \frac{T}{\theta_D} \right)^3 \int_0^{\theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx \quad \text{Debye formula} \quad (7A.11)$$

where  $\theta_D = h\nu_D/k$  is the **Debye temperature**. The integral in eqn 7A.11 has to be evaluated numerically, but that is simple with mathematical software. The details of this modification, which, as Fig. 7A.7 shows, gives improved agreement with experiment, need not distract us at this stage from the main conclusion, which is that quantization must be introduced in order to explain the thermal properties of solids.

**Figure 7A.6** Experimental low-temperature molar heat capacities and the temperature dependence predicted on the basis of Einstein's theory. His equation (eqn 7A.10) accounts for the dependence fairly well, but is everywhere too low.

**Figure 7A.7** Debye's modification of Einstein's calculation (eqn 7A.11) gives very good agreement with experiment. For copper,  $T/\theta_D = 2$  corresponds to about 170 K, so the detection of deviations from Dulong and Petit's law had to await advances in low-temperature physics.

#### Brief illustration 7A.1 The Debye formula

The Debye temperature for lead is 105 K, corresponding to a vibrational frequency of  $2.2 \times 10^{12}$  Hz. As we see from Fig. 7A.7,  $f_D \approx 1$  for  $T > \theta_D$  and the heat capacity is almost classical. For lead at 25 °C, corresponding to  $T/\theta_D = 2.8$ ,  $f_D = 0.99$  and the heat capacity has almost its classical value.

**Self-test 7A.2** Evaluate the Debye temperature for diamond ( $\nu_D = 4.6 \times 10^{13}$  Hz). What fraction of the classical value of the heat capacity does diamond reach at 25 °C?

Answer: 2230 K; 15 per cent

### (c) Atomic and molecular spectra

The most compelling and direct evidence for the quantization of energy comes from **spectroscopy**, the detection and analysis of the electromagnetic radiation absorbed, emitted, or scattered by a substance. The record of the intensity of light intensity transmitted or scattered by a molecule as a function of frequency ( $\nu$ ), wavelength ( $\lambda$ ), or wavenumber ( $\tilde{\nu} = \nu/c$ ) is called its **spectrum** (from the Latin word for appearance).

A typical atomic spectrum is shown in Fig. 7A.8, and a typical molecular spectrum is shown in Fig. 7A.9. The obvious feature of both is that radiation is emitted or absorbed at a series of discrete frequencies. This observation can be understood if the energy of the atoms or molecules is also confined to discrete values, for then energy can be discarded or absorbed only in discrete amounts (Fig. 7A.10). Then, if the energy of an atom decreases by  $\Delta E$ , the energy is carried away as radiation of frequency  $\nu$ , and an emission 'line', a sharply defined peak, appears in the spectrum. We say that a molecule undergoes a **spectroscopic transition**, a change of state, when the **Bohr frequency condition**

$$\Delta E = h\nu \quad \text{Bohr frequency condition} \quad (7A.12)$$

Figure 7A.8 A region of the spectrum of radiation emitted by excited iron atoms consists of radiation at a series of discrete wavelengths (or frequencies).

Figure 7A.9 When a molecule changes its state, it does so by absorbing radiation at definite frequencies. This spectrum is part of that due to the electronic, vibrational, and rotational excitation of sulfur dioxide ( $\text{SO}_2$ ) molecules. This observation suggests that molecules can possess only discrete energies, not an arbitrary energy.

Figure 7A.10 Spectroscopic transitions, such as those shown above, can be accounted for if we assume that a molecule emits electromagnetic radiation as it changes between discrete energy levels. Note that high-frequency radiation is emitted when the energy change is large.

is fulfilled. We develop the principles and applications of atomic spectroscopy in Topics 9A–9C and of molecular spectroscopy in Topics 12A–14D.

#### Brief illustration 7A.2 The Bohr frequency condition

Atomic sodium produces a yellow glow (as in some street lamps) resulting from the emission of radiation of 590 nm. The spectroscopic transition responsible for the emission involves electronic energy levels that have a separation given by eqn 7A.12:

$$\begin{aligned}\Delta E = h\nu &= \frac{hc}{\lambda} = \frac{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})}{590 \times 10^{-9} \text{ m}} \\ &= 3.37 \times 10^{-19} \text{ J}\end{aligned}$$

This energy difference can be expressed in a variety of ways. For instance, multiplication by Avogadro's constant results in an energy separation per mole of atoms, of  $203 \text{ kJ mol}^{-1}$ , comparable to the energy of a weak chemical bond. The calculated value of  $\Delta E$  also corresponds to  $2.10 \text{ eV}$  (*Foundations B*).

**Self-test 7A.3** Neon lamps emit red radiation of wavelength 736 nm. What is the energy separation of the levels in joules, kilojoules per mole, and electronvolts responsible for the emission?

Answer:  $2.70 \times 10^{-19} \text{ J}$ ,  $163 \text{ kJ mol}^{-1}$ ,  $1.69 \text{ eV}$

## 7A.2 Wave–particle duality

At this stage we have established that the energies of the electromagnetic field and of oscillating atoms are quantized. In this section we see the experimental evidence that led to the revision of two other basic concepts concerning natural phenomena. One experiment shows that electromagnetic radiation—which classical physics treats as wave-like—actually also displays the characteristics of particles. Another experiment shows that electrons—which classical physics treats as particles—also display the characteristics of waves.

### (a) The particle character of electromagnetic radiation

The observation that electromagnetic radiation of frequency  $\nu$  can possess only the energies  $0, h\nu, 2h\nu, \dots$  suggests (and at this stage it is only a suggestion) that it can be thought of as consisting of  $0, 1, 2, \dots$  particles, each particle having an energy  $h\nu$ . Then, if one of these particles is present, the energy is  $h\nu$ , if two are present the energy is  $2h\nu$ , and so on. These particles of electromagnetic radiation are now called **photons**. The observation of discrete spectra from atoms and molecules can be pictured as the atom or molecule generating a photon

of energy  $h\nu$  when it discards an energy of magnitude  $\Delta E$ , with  $\Delta E = h\nu$ .

### Example 7A.2 Calculating the number of photons

Calculate the number of photons emitted by a 100 W yellow lamp in 1.0 s. Take the wavelength of yellow light as 560 nm and assume 100 per cent efficiency.

**Method** Each photon has an energy  $h\nu$ , so the total number of photons needed to produce an energy  $E$  is  $E/h\nu$ . To use this equation, we need to know the frequency of the radiation (from  $\nu = c/\lambda$ ) and the total energy emitted by the lamp. The latter is given by the product of the power ( $P$ , in watts) and the time interval for which the lamp is turned on ( $E = P\Delta t$ ).

**Answer** The number of photons is

$$N = \frac{E}{h\nu} = \frac{P\Delta t}{h(c/\lambda)} = \frac{\lambda P\Delta t}{hc}$$

Substitution of the data gives

$$N = \frac{(5.60 \times 10^{-7} \text{ m}) \times (100 \text{ J s}^{-1}) \times (1.0 \text{ s})}{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 2.8 \times 10^{20}$$

Note that it would take the lamp nearly 40 min to produce 1 mol of these photons.

*A note on good practice* To avoid rounding and other numerical errors, it is best to carry out algebraic calculations first, and to substitute numerical values into a single, final formula. Moreover, an analytical result may be used for other data without having to repeat the entire calculation.

**Self-test 7A.4** How many photons does a monochromatic (single frequency) infrared rangefinder of power 1 mW and wavelength 1000 nm emit in 0.1 s?

Answer:  $5 \times 10^{14}$

So far, the existence of photons is only a suggestion. Experimental evidence for their existence comes from the measurement of the energies of electrons produced in the **photoelectric effect**. This effect is the ejection of electrons from metals when they are exposed to ultraviolet radiation. The experimental characteristics of the photoelectric effect are as follows:

- No electrons are ejected, regardless of the intensity of the radiation, unless its frequency exceeds a threshold value characteristic of the metal.
- The kinetic energy of the ejected electrons increases linearly with the frequency of the incident radiation but is independent of the intensity of the radiation.
- Even at low light intensities, electrons are ejected immediately if the frequency is above the threshold.

**Figure 7A.11** In the photoelectric effect, it is found that no electrons are ejected when the incident radiation has a frequency below a value characteristic of the metal, and, above that value, the kinetic energy of the photoelectrons varies linearly with the frequency of the incident radiation.

Figure 7A.11 illustrates the first and second characteristics.

These observations strongly suggest that the photoelectric effect depends on the ejection of an electron when it is involved in a collision with a particle-like projectile that carries enough energy to eject the electron from the metal. If we suppose that the projectile is a photon of energy  $h\nu$ , where  $\nu$  is the frequency of the radiation, then the conservation of energy requires that the kinetic energy of the ejected electron ( $E_k = \frac{1}{2}m_e v^2$ ) should obey

$$E_k = \frac{1}{2}m_e v^2 = h\nu - \Phi \quad \text{Photoelectric effect} \quad (7A.13)$$

In this expression,  $\Phi$  (uppercase phi) is a characteristic of the metal called its **work function**, the energy required to remove an electron from the metal to infinity (Fig. 7A.12), the analogue of the ionization energy of an individual atom or molecule. We

**Figure 7A.12** The photoelectric effect can be explained if it is supposed that the incident radiation is composed of photons that have energy proportional to the frequency of the radiation. (a) The energy of the photon is insufficient to drive an electron out of the metal. (b) The energy of the photon is more than enough to eject an electron, and the excess energy is carried away as the kinetic energy of the photoelectron.

can now see that the existence of photons accounts for the three observations we have summarized:

- Photoejection cannot occur if  $h\nu < \Phi$  because the photon brings insufficient energy.
- Equation 7A.13 predicts that the kinetic energy of an ejected electron should increase linearly with frequency.
- When a photon collides with an electron, it gives up all its energy, so we should expect electrons to appear as soon as the collisions begin, provided the photons have sufficient energy.

A practical application of eqn 7A.13 is that it provides a technique for the determination of Planck's constant, for the slopes of the lines in Fig. 7A.11 are all equal to  $h$ .

### Example 7A.3 Calculating the maximum wavelength capable of photoejection

A photon of radiation of wavelength 305 nm ejects an electron from a metal with a kinetic energy of 1.77 eV. Calculate the maximum wavelength of radiation capable of ejecting an electron from the metal.

**Method** Use eqn 7A.13 rearranged into  $\Phi = h\nu - E_k$  with  $\nu = c/\lambda$  to calculate the work function of the metal from the data. The threshold for photoejection, the frequency able to remove the electron but not give it any excess energy, then corresponds to radiation of frequency  $\nu_{\min} = \Phi/h$ . Use this value of the frequency to calculate the maximum wavelength capable of photoejection.

**Answer** From the expression for the work function  $\Phi = h\nu - E_k$  the minimum frequency for photoejection is

$$\nu_{\min} = \frac{\Phi}{h} = \frac{h\nu - E_k}{h} \stackrel{\nu=c/\lambda}{=} \frac{c}{\lambda} - \frac{E_k}{h}$$

The maximum wavelength is therefore

$$\lambda_{\max} = \frac{c}{\nu_{\min}} = \frac{c}{c/\lambda - E_k/h} = \frac{1}{1/\lambda - E_k/hc}$$

Now we substitute the data. The kinetic energy of the electron is

$$E_k = 1.77 \text{ eV} \times (1.602 \times 10^{-19} \text{ J eV}^{-1}) = 2.83 \dots \times 10^{-19} \text{ J}$$

$$\frac{E_k}{hc} = \frac{2.83 \dots \times 10^{-19} \text{ J}}{(6.626 \times 10^{-34} \text{ Js}) \times (2.998 \times 10^8 \text{ m s}^{-1})} = 1.42 \dots \times 10^6 \text{ m}^{-1}$$

Therefore, with  $1/\lambda = 1/305 \text{ nm} = 3.27 \dots \times 10^6 \text{ m}^{-1}$ ,

$$\lambda_{\max} = \frac{1}{(3.27 \dots \times 10^6 \text{ m}^{-1}) - (1.42 \dots \times 10^6 \text{ m}^{-1})} = 5.40 \times 10^{-7} \text{ m}$$

or 540 nm.

**Self-test 7A.5** When ultraviolet radiation of wavelength 165 nm strikes a certain metal surface, electrons are ejected with a speed of  $1.24 \text{ Mm s}^{-1}$ . Calculate the speed of electrons ejected by radiation of wavelength 265 nm.

Answer:  $735 \text{ km s}^{-1}$

## (b) The wave character of particles

Although contrary to the long-established wave theory of light, the view that light consists of particles had been held before, but discarded. No significant scientist, however, had taken the view that matter is wave-like. Nevertheless, experiments carried out in 1925 forced people to consider that possibility. The crucial experiment was performed by the American physicists Clinton Davisson and Lester Germer, who observed the diffraction of electrons by a crystal (Fig. 7A.13). **Diffraction** is the interference caused by an object in the path of waves. Depending on whether the interference is constructive or destructive, the result is a region of enhanced or diminished intensity of the wave. Davisson and Germer's success was a lucky accident, because a chance rise of temperature caused their polycrystalline sample to anneal, and the ordered planes of atoms then acted as a diffraction grating. At almost the same time, G.P. Thomson, working in Scotland, showed that a beam of electrons was diffracted when passed through a thin gold foil.

The Davisson–Germer experiment, which has since been repeated with other particles (including  $\alpha$  particles and molecular hydrogen), shows clearly that particles have wave-like properties, and the diffraction of neutrons is a well-established technique for investigating the structures and dynamics of condensed phases (Topic 18A). We have also seen that waves of electromagnetic radiation have particle-like properties. Thus we are brought to the heart of modern

**Figure 7A.13** The Davisson–Germer experiment. The scattering of an electron beam from a nickel crystal shows a variation of intensity characteristic of a diffraction experiment in which waves interfere constructively and destructively in different directions.

**Figure 7A.14** An illustration of the de Broglie relation between momentum and wavelength. The wave is associated with a particle. A particle with high momentum corresponds to a wave with a short wavelength, and vice versa.

physics. When examined on an atomic scale, the classical concepts of particle and wave melt together, particles taking on the characteristics of waves, and waves the characteristics of particles.

Some progress towards coordinating these properties had already been made by the French physicist Louis de Broglie when, in 1924, he suggested that any particle, not only photons, travelling with a linear momentum  $p = mv$  (with  $m$  the mass and  $v$  the speed of the particle) should have in some sense a wavelength given by what is now called the **de Broglie relation**:

$$\lambda = \frac{h}{p} \quad \text{de Broglie relation} \quad (7A.14)$$

That is, a particle with a high linear momentum has a short wavelength (Fig. 7A.14). Macroscopic bodies have such high momenta even when they are moving slowly (because their mass is so great), that their wavelengths are undetectably small, and the wavelike properties cannot be observed. This undetectability is why, in spite of its deficiencies, classical mechanics can be used to explain the behaviour of macroscopic bodies. It is necessary to invoke quantum mechanics only for microscopic systems, such as atoms and molecules, in which masses are small.

#### Example 7A.4 Estimating the de Broglie wavelength

Estimate the wavelength of electrons that have been accelerated from rest through a potential difference of 40 kV.

**Method** To use the de Broglie relation, we need to know the linear momentum,  $p$ , of the electrons. To calculate the linear momentum, we note that the energy acquired by an electron accelerated through a potential difference  $\Delta\phi$  is  $e\Delta\phi$ , where  $e$  is the magnitude of its charge. At the end of the period of acceleration, all the acquired energy is in the form of kinetic energy,  $E_k = \frac{1}{2}m_e v^2 = p^2/2m_e$ , so we can determine  $p$  by setting  $p^2/2m_e$  equal to  $e\Delta\phi$ . As before, carry through the calculation algebraically before substituting the data.

**Answer** The expression  $p^2/2m_e = e\Delta\phi$  solves to  $p = (2m_e e\Delta\phi)^{1/2}$ ; then, from the de Broglie relation  $\lambda = h/p$ ,

$$\lambda = \frac{h}{(2m_e e\Delta\phi)^{1/2}}$$

Substitution of the data and the fundamental constants (from inside the front cover) gives

$$\lambda = \frac{6.626 \times 10^{-34} \text{ J s}}{\{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (1.609 \times 10^{-19} \text{ C}) \times (4.0 \times 10^4 \text{ V})\}^{1/2}} \\ = 6.1 \times 10^{-12} \text{ m}$$

For the manipulation of units we have used  $1 \text{ V C} = 1 \text{ J}$  and  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . The wavelength of 6.1 pm is shorter than typical bond lengths in molecules (about 100 pm). Electrons accelerated in this way are used in the technique of electron diffraction for the visualization of biological systems (*Impact* I7.1) and the determination of the structures of solid surfaces (Topic 22A).

**Self-test 7A.6** Calculate the wavelength of (a) a neutron with a translational kinetic energy equal to  $kT$  at 300 K, (b) a tennis ball of mass 57 g travelling at  $80 \text{ km h}^{-1}$ .

Answer: (a) 178 pm, (b)  $5.2 \times 10^{-34} \text{ m}$

We now have to conclude that not only has electromagnetic radiation the character classically ascribed to particles, but electrons (and all other particles) have the characteristics classically ascribed to waves. This joint particle and wave character of matter and radiation is called **wave–particle duality**.

## Checklist of concepts

- 1. A **black body** is an object capable of emitting and absorbing all wavelengths of radiation uniformly.
- 2. The vibrations of atoms can take up energy only in discrete amounts.

- 3. Atomic and molecular spectra show that atoms and molecules can take up energy only in discrete amounts.
- 4. The **photoelectric effect** establishes the view that electromagnetic radiation, regarded in classical physics as wavelike, consists of particles (photons).
- 5. The diffraction of electrons establishes the view that electrons, regarded in classical physics as particles, are wavelike with a wavelength given by the **de Broglie relation**.
- 6. **Wave-particle duality** is the recognition that the concepts of particle and wave blend together.

## Checklist of equations

Property	Equation	Comment	Equation number
Planck distribution	$\rho(\lambda, T) = 8\pi hc / \{\lambda^5 (e^{hc/\lambda kT} - 1)\}$		7A.6
Heat capacity	$C_{V,m}(T) = 3Rf(T)$	$f = f_E$ or $f_D$	
Einstein formula	$f_E(T) = (\theta_E / T)^2 \{e^{\theta_E/2T} / (e^{\theta_E/T} - 1)\}^2$	Einstein temperature: $\theta_E = h\nu/k$	7A.9
Debye formula	$f_D(T) = 3(T/\theta_D)^3 \int_0^{\theta_D/T} x^4 e^x / (e^x - 1)^2 dx$	Debye temperature: $\theta_D = h\nu_D/k$	7A.11
Bohr frequency condition	$\Delta E = h\nu$	Conservation of energy	7A.12
Photoelectric effect	$E_k = \frac{1}{2} m_e v^2 = h\nu - \Phi$	$\Phi$ is the work function	7A.13
de Broglie relation	$\lambda = h/p$	$\lambda$ is the wavelength of a particle of linear momentum $p$	7A.14

### ► Why do you need to know this material?

Quantum theory provides the essential foundation for understanding of the properties of electrons in atoms and molecules.

### ► What is the key idea?

All the dynamical properties of a system are contained in the wavefunction, which is obtained by solving the Schrödinger equation.

### ► What do you need to know already?

You need to be aware of the shortcomings of classical physics that drove the development of quantum theory (Topic 7A).

Wave-particle duality (Topic 7A) strikes at the heart of classical physics, where particles and waves are treated as entirely distinct entities. Experiments have also shown that the energies of electromagnetic radiation and of matter cannot be varied continuously, and that for small objects the discreteness of energy is highly significant. In classical mechanics, in contrast, energies can be varied continuously. Such total failure of classical physics for small objects implied that its basic concepts are false. A new mechanics—quantum mechanics—had to be devised to take its place.

A new mechanics can be constructed from the ashes of classical physics by supposing that, rather than travelling along a definite path, a particle is distributed through space like a wave. This remark may seem mysterious: it will be interpreted more fully shortly. The mathematical representation of the wave that in quantum mechanics replaces the classical concept of trajectory is called a **wavefunction**,  $\psi$  (psi), a function that contains all the dynamical information about a system, such as its location and momentum.

## 7B.1 The Schrödinger equation

In 1926, the Austrian physicist Erwin Schrödinger proposed an equation for finding the wavefunction of any system. The **time-independent Schrödinger equation** for a particle of mass  $m$  moving in one dimension with energy  $E$  in a system that does not change with time (for instance, its volume remains constant) is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi \quad \text{Time-independent Schrödinger equation} \quad (7B.1)$$

The factor  $V(x)$  is the potential energy of the particle at the point  $x$ ; because the total energy  $E$  is the sum of potential and kinetic energies, the first term must be related (in a manner we explore later) to the kinetic energy of the particle;  $\hbar = h/2\pi$  (which is read  $h$ -cross or  $h$ -bar) is a convenient modification of Planck's constant with the value  $1.055 \times 10^{-34}$  J s. Three simple but important general forms of the potential energy are (the explicit forms are found in the corresponding Topics):

- For a particle moving freely in one dimension the potential energy is constant, so  $V(x) = V$ . It is often convenient to write  $V = 0$  (Topic 8A).
- For a particle free to oscillate to-and-fro near a point  $x_0$ ,  $V(x) \propto (x - x_0)^2$  (Topic 8B).
- For two electric charges  $Q_1$  and  $Q_2$  separated by a distance  $x$ ,  $V(x) \propto Q_1 Q_2 / x$  (*Foundations B*).

The following *Justification* shows that the Schrödinger equation is plausible and the discussions later in the chapter will help to overcome its apparent arbitrariness. For the present, we

Table 7B.1 The Schrödinger equation

Expression	Equation	Comment
Time-independent Schrödinger equation	$\hat{H}\psi = E\psi$	General case
	$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi(x) = E\psi(x)$	One dimension
	$-\frac{\hbar^2}{2m} \left( \frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} \right) + V(x, y)\psi(x, y) = E\psi(x, y)$	Two dimensions
	$-\frac{\hbar^2}{2m} \nabla^2\psi + V\psi = E\psi$	Three dimensions
Laplacian operator	$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$	
	$\nabla^2 = \frac{1}{r} \frac{\partial^2}{\partial r^2} r + \frac{1}{r^2} \Lambda^2$ $= \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2$ $= \frac{1}{r^2} \frac{\partial}{\partial r} r^2 \frac{\partial}{\partial r} + \frac{1}{r^2} \Lambda^2$	Alternative forms
Legendrian operator	$\Lambda^2 = \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial \phi^2} + \frac{1}{\sin\theta} \frac{\partial}{\partial \theta} \sin\theta \frac{\partial}{\partial \theta}$	
Time-dependent Schrödinger equation	$\hat{H}\Psi = i\hbar \frac{\partial \Psi}{\partial t}$	

shall treat the equation simply as a quantum-mechanical postulate that replaces Newton's postulate of his apparently equally arbitrary equation of motion (that force = mass × acceleration). Various ways of expressing the Schrödinger equation, of incorporating the time-dependence of the wavefunction, and of extending it to more dimensions, are collected in Table 7B.1. In the Topics of Chapter 8 we solve the equation for a number of important cases; in this chapter we are mainly concerned with its significance, the interpretation of its solutions, and seeing how it implies that energy is quantized.

### Justification 7B.1 The plausibility of the Schrödinger equation

The Schrödinger equation can be seen to be plausible by noting that it implies the de Broglie relation (eqn 7A.14,  $p = h/\lambda$ ) for a freely moving particle. After writing  $V(x) = V$ , we can rearrange eqn 7B.1 into

$$\frac{d^2\psi}{dx^2} = \frac{2m}{\hbar^2} (V - E)\psi$$

General strategies for solving differential equations of this and other types that occur frequently in physical chemistry are treated in *Mathematical background 4* at the end of Chapter 8; we need only the simplest procedures in this Topic. In this case a solution is

$$\psi = \cos kx \quad k = \left\{ \frac{2m(E - V)}{\hbar^2} \right\}^{1/2}$$

We now recognize that  $\cos kx$  is a wave of wavelength  $\lambda = 2\pi/k$ , as can be seen by comparing  $\cos kx$  with the standard form of a harmonic wave,  $\cos(2\pi x/\lambda)$  (*Foundations C*). The quantity  $E - V$  is equal to the kinetic energy of the particle,  $E_k$ , so  $k = (2mE_k/\hbar^2)^{1/2}$ , which implies that  $E_k = k^2\hbar^2/2m$ . Because  $E_k = p^2/2m$  (*Foundations B*), it follows that  $p = \hbar k$ . Therefore, the linear momentum is related to the wavelength of the wavefunction by

$$p = \frac{2\pi}{\lambda} \times \frac{h}{2\pi} = \frac{h}{\lambda}$$

which is the de Broglie relation.

## 7B.2 The Born interpretation of the wavefunction

A central principle of quantum mechanics is that *the wavefunction contains all the dynamical information about the system it describes*. Here we concentrate on the information it carries about the location of the particle.

The interpretation of the wavefunction in terms of the location of the particle is based on a suggestion made by Max Born. He made use of an analogy with the wave theory of light, in which the square of the amplitude of an electromagnetic wave in a region is interpreted as its intensity and therefore (in quantum terms) as a measure of the probability of finding a photon present in the region. The **Born interpretation** of the wavefunction focuses on the square of the wavefunction (or the square modulus,  $|\psi|^2 = \psi^*\psi$ , if  $\psi$  is complex; see *Mathematical background 3*). For a one-dimensional system (Fig. 7B.1):

If the wavefunction of a particle has the value  $\psi$  at some point  $x$ , then the probability of finding the particle between  $x$  and  $x + dx$  is proportional to  $|\psi|^2 dx$ .

Born interpretation

Thus,  $|\psi|^2$  is the **probability density**, and to obtain the probability it must be multiplied by the length of the infinitesimal region  $dx$ . The wavefunction  $\psi$  itself is called the **probability amplitude**. For a particle free to move in three dimensions (for example, an electron near a nucleus in an atom), the

**Figure 7B.1** The wavefunction  $\psi$  is a probability amplitude in the sense that its square modulus ( $\psi^*\psi$  or  $|\psi|^2$ ) is a probability density. The probability of finding a particle in the region  $dx$  located at  $x$  is proportional to  $|\psi|^2 dx$ . We represent the probability density by the density of shading in the superimposed band.

**Figure 7B.2** The Born interpretation of the wavefunction in three-dimensional space implies that the probability of finding the particle in the volume element  $d\tau = dx dy dz$  at some location  $r$  is proportional to the product of  $d\tau$  and the value of  $|\psi|^2$  at that location.

wavefunction depends on the point  $r$  with coordinates  $x$ ,  $y$ , and  $z$ , and the interpretation of  $\psi(r)$  is as follows (Fig. 7B.2):

If the wavefunction of a particle has the value  $\psi$  at some point  $r$ , then the probability of finding the particle in an infinitesimal volume  $d\tau = dx dy dz$  at that point is proportional to  $|\psi|^2 d\tau$ .

The Born interpretation does away with any worry about the significance of a negative (and, in general, complex) value of  $\psi$  because  $|\psi|^2$  is real and never negative. There is no *direct* significance in the negative (or complex) value of a wavefunction: only the square modulus, a positive quantity, is directly physically significant, and both negative and positive regions of a wavefunction may correspond to a high probability of finding a particle in a region (Fig. 7B.3). However, later we shall see that the presence of positive and negative regions of a wavefunction is of great *indirect* significance, because it gives rise to the possibility of constructive and destructive interference between different wavefunctions.

**Figure 7B.3** The sign of a wavefunction has no direct physical significance: the positive and negative regions of this wavefunction both correspond to the same probability distribution (as given by the square modulus of  $\psi$  and depicted by the density of the shading).

### Example 7B.1 Interpreting a wavefunction

In Topic 9A it is shown that the wavefunction of an electron in the lowest energy state of a hydrogen atom is proportional to  $e^{-r/a_0}$ , with  $a_0$  a constant and  $r$  the distance from the nucleus. Calculate the relative probabilities of finding the electron inside a region of volume  $\delta V = 1.0 \text{ pm}^3$ , which is small even on the scale of the atom, located at (a) the nucleus, (b) a distance  $a_0$  from the nucleus.

**Method** The region of interest is so small on the scale of the atom that we can ignore the variation of  $\psi$  within it and write the probability,  $P$ , as proportional to the probability density ( $\psi^2$ ; note that  $\psi$  is real) evaluated at the point of interest multiplied by the volume of interest,  $\delta V$ . That is,  $P \propto \psi^2 \delta V$ , with  $\psi^2 \propto e^{-2r/a_0}$ .

**Answer** In each case  $\delta V = 1.0 \text{ pm}^3$ . (a) At the nucleus,  $r = 0$ , so

$$P \propto e^0 \times (1.0 \text{ pm}^3) = (1.0) \times (1.0 \text{ pm}^3)$$

(b) At a distance  $r = a_0$  in an arbitrary direction,

$$P \propto e^{-2} \times (1.0 \text{ pm}^3) = (0.14) \times (1.0 \text{ pm}^3)$$

Therefore, the ratio of probabilities is  $1.0/0.14 = 7.1$ . Note that it is more probable (by a factor of 7) that the electron will be found at the nucleus than in a volume element of the same size located at a distance  $a_0$  from the nucleus. The negatively charged electron is attracted to the positively charged nucleus, and is likely to be found close to it.

*A note on good practice* The square of a wavefunction is a probability density, and (in three dimensions) has the dimensions of  $1/\text{length}^3$ . It becomes a (unitless) probability when multiplied by a volume. In general, we have to take into account the variation of the amplitude of the wavefunction over the volume of interest, but here we are supposing that the volume is so small that the variation of  $\psi$  in the region can be ignored.

**Self-test 7B.1** The wavefunction for the electron in its lowest energy state in the ion  $\text{He}^+$  is proportional to  $e^{-2r/a_0}$ . Repeat the calculation for this ion. Any comment?

Answer: 55; more compact wavefunction

### (a) Normalization

A mathematical feature of the Schrödinger equation is that if  $\psi$  is a solution, then so is  $N\psi$ , where  $N$  is any constant. This feature is confirmed by noting that  $\psi$  occurs in every term in eqn 7B.1, so any constant factor can be cancelled. This freedom to vary the wavefunction by a constant factor means that it is always possible to find a **normalization constant**,  $N$ , such that the proportionality of the Born interpretation becomes an equality.

We find the normalization constant by noting that, for a normalized wavefunction  $N\psi$ , the probability that a particle is in the region  $dx$  is equal to  $(N\psi^*)(N\psi)dx$  (we are taking  $N$  to be real). Furthermore, the sum over all space of these individual probabilities must be 1 (the probability of the particle being somewhere is 1). Expressed mathematically, the latter requirement is

$$N^2 \int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (7B.2)$$

Wavefunctions for which the integral in eqn 7B.2 exists (in the sense of having a finite value) are said to be 'square-integrable'. It follows that

$$N = \frac{1}{\left( \int_{-\infty}^{\infty} \psi^* \psi dx \right)^{1/2}} \quad (7B.3)$$

Therefore, by evaluating the integral, we can find the value of  $N$  and hence 'normalize' the wavefunction. From now on, unless we state otherwise, we always use wavefunctions that have been normalized to 1; that is, from now on we assume that  $\psi$  already includes a factor which ensures that (in one dimension)

$$\int_{-\infty}^{\infty} \psi^* \psi dx = 1 \quad (7B.4a)$$

In three dimensions, the wavefunction is normalized if

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \psi^* \psi dx dy dz = 1 \quad (7B.4b)$$

or, more succinctly, if

$$\int \psi^* \psi d\tau = 1 \quad \text{Normalization integral} \quad (7B.4c)$$

where  $d\tau = dx dy dz$  and the limits of this definite integral are not written explicitly: in all such integrals, the integration is over all the space accessible to the particle. For systems with spherical symmetry it is best to work in spherical polar coordinates (*The chemist's toolkit* 7B.1), so the explicit form of eqn 7B.4c is

$$\int_0^{\infty} \int_0^{\pi} \int_0^{2\pi} \psi^* \psi r^2 dr \sin\theta d\theta d\phi = 1 \quad (7B.4d)$$

#### The chemist's toolkit 7B.1 Spherical polar coordinates

For systems with spherical symmetry it is best to work in spherical polar coordinates  $r$ ,  $\theta$ , and  $\phi$  (Sketch 1)

$$x = r \sin\theta \cos\phi, \quad y = r \sin\theta \sin\phi, \quad z = r \cos\theta$$

Spherical polar coordinates

Sketch 1 The spherical polar coordinates used for discussing systems with spherical symmetry.

where:

- $r$ , the radius, ranges from 0 to  $\infty$
- $\theta$ , the colatitude, ranges from 0 to  $\pi$
- $\phi$ , the azimuth, ranges from 0 to  $2\pi$

That these ranges cover space is illustrated in Sketch 2. Standard manipulations then yield

$$d\tau = r^2 \sin\theta dr d\theta d\phi$$

Sketch 2 The surface of a sphere is covered by allowing  $\theta$  to range from 0 to  $\pi$ , and then sweeping that arc around a complete circle by allowing  $\phi$  to range from 0 to  $2\pi$ .

In these coordinates, the integral of a function  $f(r, \theta, \phi)$  over all space takes the form

$$\int_0^\infty \int_0^\pi \int_0^{2\pi} f(r, \theta, \phi) r^2 dr \sin \theta d\theta d\phi$$

where the limits on the first integral sign refer to  $r$ , those on the second to  $\theta$ , and those on the third to  $\phi$ .

### Example 7B.2 Normalizing a wavefunction

Normalize the wavefunction used for the hydrogen atom in Example 7B.1.

**Method** We need to find the factor  $N$  that guarantees that the integral in eqn 7B.4c is equal to 1. Because the system is spherical, it is most convenient to use spherical coordinates (*The chemist's toolkit* 7B.1) and to carry out the integrations specified in eqn 7B.4d. Relevant integrals are found in the *Resource section*.

**Answer** The integration required is the product of three factors:

$$\int \psi^* \psi d\tau = N^2 \int_0^\infty \overbrace{r^2}^{\frac{1}{4}a_0^3} e^{-2r/a_0} dr \int_0^\pi \overbrace{\sin \theta}^2 d\theta \int_0^{2\pi} \overbrace{d\phi}^{2\pi} = \pi a_0^3 N^2$$

Therefore, for this integral to equal 1, we must set

$$N = \left( \frac{1}{\pi a_0^3} \right)^{1/2}$$

and the normalized wavefunction is

$$\psi = \left( \frac{1}{\pi a_0^3} \right)^{1/2} e^{-r/a_0}$$

Note that because  $a_0$  is a length, the dimensions of  $\psi$  are  $1/\text{length}^{3/2}$  and therefore those of  $\psi^2$  are  $1/\text{length}^3$  (for instance,  $1/\text{m}^3$ ) as is appropriate for a probability density.

If Example 7B.1 is now repeated, we can obtain the actual probabilities of finding the electron in the volume element at each location, not just their relative values. Given (from inside the front cover) that  $a_0 = 52.9$  pm, the results are (a)  $2.2 \times 10^{-6}$ , corresponding to 1 chance in about 500 000 inspections of finding the electron in the test volume, and (b)  $2.9 \times 10^{-7}$ , corresponding to 1 chance in 3.4 million.

**Self-test 7B.2** Normalize the wavefunction given in Self-test 7B.1.

Answer:  $N = (8/\pi a_0^3)^{1/2}$

### (b) Constraints on the wavefunction

The Born interpretation puts severe restrictions on the acceptability of wavefunctions. The principal constraint is that  $\psi$  must not be infinite over a finite region. If it were, it would not be square-integrable, and the normalization constant would be zero. The normalized function would then be zero everywhere, except where it is infinite, which would be unacceptable (the particle must be somewhere). Note that infinitely sharp spikes are acceptable provided they have zero width.

The requirement that  $\psi$  is finite everywhere rules out many possible solutions of the Schrödinger equation, because many mathematically acceptable solutions rise to infinity and are therefore physically unacceptable. We could imagine a solution of the Schrödinger equation that gives rise to more than one value of  $|\psi|^2$  at a single point. The Born interpretation implies that such solutions are unacceptable, because it would be absurd to have more than one probability that a particle is at the same point. This restriction is expressed by saying that the wavefunction must be *single-valued*; that is, have only one value at each point of space.

The Schrödinger equation itself also implies some mathematical restrictions on the type of functions that can occur. Because it is a second-order differential equation, the second derivative of  $\psi$  must be well-defined if the equation is to be applicable everywhere. We can take the second derivative of a function only if it is continuous (so there are no sharp steps in it, Fig. 7B.4) and if its first derivative, its slope, is continuous (so there are no kinks in the wavefunction).

There are cases, and we shall meet them, where acceptable wavefunctions have kinks. These cases arise when the potential energy has peculiar properties, such as rising abruptly to infinity. When the potential energy is smoothly well-behaved and finite, the slope of the wavefunction must be continuous; if the potential energy becomes infinite, then the slope of the wavefunction need not be continuous. There are only two cases

**Figure 7B.4** The wavefunction must satisfy stringent conditions for it to be acceptable: (a) unacceptable because it is not continuous; (b) unacceptable because its slope is discontinuous; (c) unacceptable because it is not single-valued; (d) unacceptable because it is infinite over a finite region.

of this behaviour in elementary quantum mechanics, and the peculiarity will be mentioned when we meet them.

At this stage we see that  $\psi$ :

- must not be infinite over a non-infinitesimal region
- must be single-valued
- must be continuous
- must have a continuous slope.

Constraints on the wavefunction

### (c) Quantization

The restrictions just noted are so severe that acceptable solutions of the Schrödinger equation do not in general exist for arbitrary values of the energy  $E$ . In other words, a particle may possess only certain energies, for otherwise its wavefunction would be physically unacceptable. That is, *as a consequence of the restrictions on its wavefunction, the energy of a particle is quantized*. We can find the acceptable energies by solving the Schrödinger equation for motion of various kinds, and selecting the solutions that conform to the restrictions listed above. That task is taken forward in Chapter 8.

## 7B.3 The probability density

Once we have obtained the normalized wavefunction, we can then proceed to determine the probability density. As an example, consider a particle of mass  $m$  free to move parallel to the  $x$ -axis with zero potential energy. The Schrödinger equation is obtained from eqn 7B.1 by setting  $V=0$ , and is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} = E\psi(x) \quad (7B.5)$$

As shown in the following *Justification*, the solutions of this equation have the form

$$\psi(x) = Ae^{ikx} + Be^{-ikx} \quad E = \frac{k^2\hbar^2}{2m} \quad (7B.6)$$

where  $A$  and  $B$  are constants. (See *Mathematical background 3* at the end of this chapter for more on complex numbers.)

#### Justification 7B.2 The wavefunction of a free particle in one dimension

To verify that  $\psi(x)$  in eqn 7B.6 is a solution of eqn 7B.5, we simply substitute it into the left-hand side of the equation and show that  $E = k^2\hbar^2/2m$ . To begin, we write

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} (Ae^{ikx} + Be^{-ikx})$$

Because  $de^{\pm ax}/dx = \pm ae^{\pm ax}$  and  $i^2 = -1$ , the second derivatives evaluate to

$$-\frac{\hbar^2}{2m} \{A(ik)^2 e^{ikx} + B(-ik)^2 e^{-ikx}\} = \frac{\hbar^2}{2m} \overbrace{k^2}^E \overbrace{(Ae^{ikx} + Be^{-ikx})}^{\psi(x)} = E\psi(x)$$

We see in Topic 8A what determines the values of  $A$  and  $B$ ; here we can treat them as arbitrary constants that we can vary at will. Suppose that  $B=0$  in eqn 7B.6, then the wavefunction is simply

$$\psi(x) = Ae^{ikx} \quad (7B.7)$$

Where is the particle? To find out, we calculate the probability density:

$$|\psi(x)|^2 = (Ae^{ikx})^* (Ae^{ikx}) = (A^* e^{-ikx})(Ae^{ikx}) = |A|^2 \quad (7B.8)$$

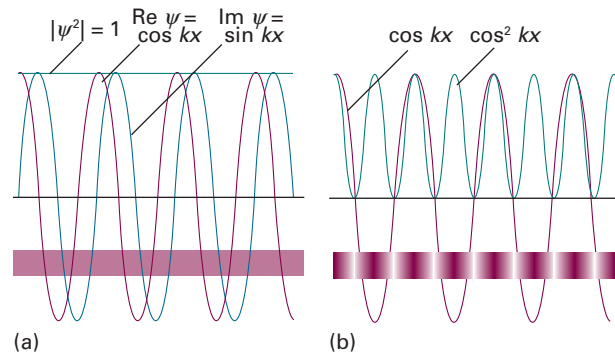

This probability density is independent of  $x$ ; so, wherever we look in a region of fixed length located anywhere along the  $x$ -axis, there is an equal probability of finding the particle (Fig. 7B.5a). In other words, if the wavefunction of the particle is given by eqn 7B.7, then we cannot predict where we will find it. The same would be true if the wavefunction in eqn 7B.6 had  $A=0$ ; then the probability density would be  $|B|^2$ , a constant.

Now suppose that in the wavefunction  $A=B$ . Then, because  $\cos kx = \frac{1}{2}(e^{ikx} + e^{-ikx})$  (*Mathematical background 3*), eqn 7B.6 becomes

$$\psi(x) = A(e^{ikx} + e^{-ikx}) = 2A \cos kx \quad (7B.9)$$

The probability density now has the form

$$|\psi(x)|^2 = (2A \cos kx)^* (2A \cos kx) = 4|A|^2 \cos^2 kx \quad (7B.10)$$

**Figure 7B.5** (a) The square modulus of a wavefunction corresponding to the wavefunction in eqn 7B.7 is a constant; so it corresponds to a uniform probability of finding the particle anywhere. (b) The probability distribution corresponding to the wavefunction in eqn 7B.7.

This function is illustrated in Fig. 7B.5b. As we see, the probability density periodically varies between 0 and  $4|A|^2$ . The locations where the probability density is zero correspond to *nodes* in the wavefunction. Specifically, a **node** is a point where a wavefunction passes *through* zero. The location where a wavefunction approaches zero without actually passing through zero is not a node.

To calculate the probability of finding the system in a region of space that is not infinitesimal we sum (that is, we integrate) the probability density over the region of space of interest. For example, for a one-dimensional wavefunction, the probability  $P$  of finding the particle between  $x_1$  and  $x_2$  is given by

$$P = \int_{x_1}^{x_2} |\psi(x)|^2 dx \quad \text{One-dimensional region} \quad \text{Probability} \quad (7B.11)$$

### Example 7B.3 Determining a probability

The lowest-energy electrons of a carbon nanotube can be described by the normalized wavefunction  $(2/L)^{1/2} \sin(\pi x/L)$ , where  $L$  is the length of the nanotube. What is the probability of finding the electron between  $x=L/4$  and  $x=L/2$ ?

**Method** Use eqn 7B.11 and the normalized wavefunction to write an expression for the probability of finding the electron in the region of interest. Relevant integrals are given in the *Resource section*.

**Answer** From eqn 7B.11 and the wavefunction provided, the expression for the probability is

$$P = \int_{L/4}^{L/2} \left( \frac{2}{L} \right) \sin^2(\pi x/L) dx$$

It follows that

$$P \stackrel{\text{Integral T.2}}{=} \left( \frac{2}{L} \right) \left( \frac{x}{2} - \frac{\sin(2\pi x/L)}{4\pi/L} \right) \Bigg|_{L/4}^{L/2} = \left( \frac{2}{L} \right) \left( \frac{L}{4} - \frac{L}{8} - 0 + \frac{L}{4\pi} \right) = 0.409$$

There is a chance of about 41 per cent that the electron will be found between  $x=L/4$  and  $x=L/2$  along the nanotube.

**Self-test 7B.3** The next higher energy wavefunction of the electron in the nanotube is described by the normalized wavefunction  $(2/L)^{1/2} \sin(2\pi x/L)$ . What is the probability of finding the electron between  $x=L/4$  and  $x=L/2$ ?

Answer: 0.25

## Checklist of concepts

- 1. A **wavefunction** is a mathematical function that contains all the dynamical information about a system.
- 2. The **Schrödinger equation** is a second-order differential equation used to calculate the wavefunction of a system.
- 3. According to the **Born interpretation**, the probability density is proportional to the square of the wavefunction.
- 4. A wavefunction is **normalized** if the integral of its square is equal to 1.
- 5. A wavefunction must be single-valued, continuous, not infinite over a non-infinitesimal region of space, and have a continuous slope.
- 6. The quantization of energy stems from the constraints that an acceptable wavefunction must satisfy.
- 7. A **node** is a point where a wavefunction passes through zero.

### ► Why do you need to know this material?

The wavefunction is the central feature in quantum mechanics, so you need to know how to extract dynamical information from it. The procedures described here allow you to predict the results of measurements of observables.

### ► What is the key idea?

The wavefunction is obtained by solving the Schrödinger equation, and the dynamical information it contains is extracted by determining the eigenvalues of hermitian operators.

### ► What do you need to know already?

You need to know that the state of a system is fully described by a wavefunction (Topic 7B). You also need to be familiar with elementary integration (*Mathematical background 1*) and manipulation of complex functions (*Mathematical background 3*).

A wavefunction contains all the information it is possible to obtain about the dynamical properties of the particle (for example, its location and momentum). The Born interpretation

(Topic 7B) tells us as much as we can know about location, but how do we extract any additional dynamical information?

## 7C.1 Operators

To formulate a systematic way of extracting information from the wavefunction, we first note that any Schrödinger equation may be written in the succinct form

$$\hat{H}\psi = E\psi \quad \text{Operator form of Schrödinger equation} \quad (7C.1a)$$

with (in one dimension)

$$\hat{H} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \quad \text{Hamiltonian operator} \quad (7C.1b)$$

The quantity  $\hat{H}$  (commonly read aitch-hat) is an **operator**, something that carries out a mathematical operation on the function  $\psi$ . In this case, the operation is to take the second derivative of  $\psi$  and (after multiplication by  $-\hbar^2/2m$ ) to add the result to the outcome of multiplying  $\psi$  by  $V(x)$ .

The operator  $\hat{H}$  plays a special role in quantum mechanics, and is called the **hamiltonian operator** after the nineteenth-century mathematician William Hamilton, who developed a form of classical mechanics which, it subsequently turned out, is well suited to the formulation of quantum mechanics. The hamiltonian operator is the operator corresponding to the total energy of the system, the sum of the kinetic and potential energies. Consequently, we can infer that the first term in eqn 7C.1b (the term proportional to the second derivative) must be the operator for the kinetic energy.

### (a) Eigenvalue equations

When the Schrödinger equation is written as in eqn 7C.1a, it is seen to be an **eigenvalue equation**, an equation of the form

$$(\text{Operator})(\text{function}) = (\text{constant factor}) \times (\text{same function}) \quad (7C.2a)$$

If we denote a general operator by  $\hat{\Omega}$  (where  $\Omega$  is uppercase omega) and a constant factor by  $\omega$  (lowercase omega), then an eigenvalue equation has the form

$$\hat{\Omega}\psi = \omega\psi \quad \text{Eigenvalue equation} \quad (7C.2b)$$

The factor  $\omega$  is called the **eigenvalue** of the operator. The eigenvalue in eqn 7C.1a is the energy. The function  $\psi$  in an equation of this kind is called an **eigenfunction** of the operator  $\hat{\Omega}$  and is different for each eigenvalue. So, in this technical language, we would write eqn 7C.2a as

$$(\text{Operator})(\text{eigenfunction}) = (\text{eigenvalue}) \times (\text{eigenfunction}) \quad (7C.2c)$$

The eigenfunction in eqn 7C.1a is the wavefunction corresponding to the energy  $E$ . It follows that another way of saying ‘solve the Schrödinger equation’ is to say ‘find the eigenvalues and eigenfunctions of the hamiltonian operator for the system’.

### Example 7C.1 Identifying an eigenfunction

Show that  $e^{ax}$  is an eigenfunction of the operator  $d/dx$ , and find the corresponding eigenvalue. Show that  $e^{ax^2}$  is not an eigenfunction of  $d/dx$ .

**Method** We need to operate on the function with the operator and check whether the result is a constant factor times the original function.

**Answer** For  $\hat{\Omega} = d/dx$  (the operation ‘differentiate with respect to  $x$ ’) and  $\psi = e^{ax}$ :

$$\hat{\Omega}\psi = \frac{d}{dx} e^{ax} = ae^{ax} = a\psi$$

Therefore  $e^{ax}$  is indeed an eigenfunction of  $d/dx$ , and its eigenvalue is  $a$ . For  $\psi = e^{ax^2}$ ,

$$\hat{\Omega}\psi = \frac{d}{dx} e^{ax^2} = 2axe^{ax^2} = 2ax \times \psi$$

which is not an eigenvalue equation of  $\hat{\Omega}$ . Even though the same function  $\psi$  occurs on the right,  $\psi$  is now multiplied by a variable factor ( $2ax$ ), not a constant factor. Alternatively, if the right hand side is written  $2a(xe^{ax^2})$ , we see that it is a constant ( $2a$ ) times a *different* function.

**Self-test 7C.1** Is the function  $\cos ax$  an eigenfunction of (a)  $d/dx$ , (b)  $d^2/dx^2$ ?

Answer: (a) No, (b) yes

## (b) The construction of operators

The importance of eigenvalue equations is that the pattern

$$(\text{Energy operator})\psi = (\text{energy}) \times \psi$$

exemplified by the Schrödinger equation is repeated for other **observables**, or measurable properties of a system, such as the momentum or the electric dipole moment. Thus, it is often the case that we can write

$$\begin{aligned} & (\text{Operator corresponding to an observable})\psi \\ & = (\text{value of observable}) \times \psi \end{aligned}$$

The symbol  $\hat{\Omega}$  in eqn 7C.2b is then interpreted as an operator (for example, the hamiltonian operator) corresponding to an observable (for example, the energy), and the eigenvalue  $\omega$  is the value of that observable (for example, the value of the energy,  $E$ ). Therefore, if we know both the wavefunction  $\psi$  and the operator  $\hat{\Omega}$  corresponding to the observable  $\Omega$  of interest, and the wavefunction is an eigenfunction of the operator  $\hat{\Omega}$ , then we can predict the outcome of an observation of the property  $\Omega$  (for example, an atom’s energy) by picking out the factor  $\omega$  in the eigenvalue equation, eqn 7C.2b.

A basic postulate of quantum mechanics tells us how to set up the operator corresponding to a given observable:

Observables,  $\Omega$ , are represented by operators,  $\hat{\Omega}$ , built from the following position and momentum operators:

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx} \quad \text{Specification of operators} \quad (7C.3)$$

That is, the operator for location along the  $x$ -axis is multiplication (of the wavefunction) by  $x$  and the operator for linear momentum parallel to the  $x$ -axis is proportional to taking the derivative (of the wavefunction) with respect to  $x$ .

### Example 7C.2 Determining the value of an observable

What is the linear momentum of a free particle described by the wavefunction  $\psi(x) = Ae^{ikx} + Be^{-ikx}$  (eqn 7B.6) with (a)  $B=0$ , (b)  $A=0$ ?

**Method** We operate on  $\psi$  with the operator corresponding to linear momentum (eqn 7C.3), and inspect the result. If the outcome is the original wavefunction multiplied by a constant (that is, we generate an eigenvalue equation), then the constant is identified with the value of the observable.

**Answer** (a) With  $B=0$ ,

$$\hat{p}_x\psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} A \frac{de^{ikx}}{dx} = \frac{\hbar}{i} A \times ike^{ikx} = \overbrace{k\hbar}^{\text{Eigenvalue}} \psi$$

This is an eigenvalue equation, and by comparing it with eqn 7C.2b we find that  $p_x = +k\hbar$ .

(b) For the wavefunction with  $A=0$ ,

$$\hat{p}_x\psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{\hbar}{i} B \frac{de^{-ikx}}{dx} = \frac{\hbar}{i} A \times (-ik)e^{ikx} = \overbrace{-k\hbar}^{\text{Eigenvalue}} \psi$$

The magnitude of the linear momentum is the same in each case ( $k\hbar$ ), but the signs are different: in (a) the particle is travelling to the right (positive  $x$ ) but in (b) it is travelling to the left (negative  $x$ ).

**Self-test 7C.2** The operator for the angular momentum of a particle travelling in a circle in the  $xy$ -plane is  $\hat{l}_z = (\hbar/i)d/d\phi$ , where  $\phi$  is its angular position. What is the angular momentum of a particle described by the wavefunction  $e^{-2i\phi}$ ?

Answer:  $l_z = -2\hbar$

We use the definitions in eqn 7C.3 to construct operators for other spatial observables. For example, suppose we wanted the operator for a potential energy of the form  $V(x) = \frac{1}{2}k_f x^2$ , with  $k_f$  a constant (later, we shall see that this potential energy describes the vibrations of atoms in molecules). Then it follows from eqn 7C.3 that the operator corresponding to  $V(x)$  is multiplication by  $x^2$ :

$$\hat{V}(x) = \frac{1}{2}k_f x^2 \times \quad (7C.4)$$

In normal practice, the multiplication sign is omitted. To construct the operator for kinetic energy, we make use of the classical relation between kinetic energy and linear momentum, which in one dimension is  $E_k = p_x^2/2m$  (Foundations B). Then, by using the operator for  $p_x$  in eqn 7C.3 we find:

$$\hat{E}_k = \frac{1}{2m} \left( \frac{\hbar}{i} \frac{d}{dx} \right) \left( \frac{\hbar}{i} \frac{d}{dx} \right) = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (7C.5)$$

It follows that the operator for the total energy, the hamiltonian operator, is

$$\hat{H} = \hat{E}_k + \hat{V} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + \hat{V}(x) \quad \text{Hamiltonian operator} \quad (7C.6)$$

with  $\hat{V}(x)$  the multiplicative operator in eqn 7C.4 (or some other appropriate expression for the potential energy).

The expression for the kinetic energy operator, eqn 7C.5, enables us to develop an important point about the Schrödinger equation. In mathematics, the second derivative of a function is a measure of its curvature: a large second derivative indicates a sharply curved function (Fig. 7C.1). It follows that a sharply curved wavefunction is associated with a high kinetic energy, and one with a low curvature is associated with a low kinetic energy. This interpretation is consistent with the de Broglie relation, which predicts a short wavelength (a sharply curved wavefunction) when the linear momentum (and hence the kinetic energy) is high. However, it extends the interpretation to wavefunctions that do not spread through space and resemble those shown in Fig. 7C.1. The curvature of a wavefunction in general varies from place to place. Wherever a wavefunction is sharply curved, its contribution to the total kinetic energy is large (Fig. 7C.2). Wherever the wavefunction is not sharply curved, its contribution to the overall kinetic energy is low. As we shall shortly see, the observed kinetic energy of the particle is an integral of

**Figure 7C.1** Even if the wavefunction does not have the form of a periodic wave, it is still possible to infer from it the average kinetic energy of a particle by noting its average curvature. This figure shows two wavefunctions: the sharply curved function corresponds to a higher kinetic energy than the less sharply curved function.

**Figure 7C.2** The observed kinetic energy of a particle is an average of contributions from the entire space covered by the wavefunction. Sharply curved regions contribute a high kinetic energy to the average; slightly curved regions contribute only a small kinetic energy.

all the contributions of the kinetic energy from each region. Hence, we can expect a particle to have a high kinetic energy if the average curvature of its wavefunction is high. Locally there can be both positive and negative contributions to the kinetic energy (because the curvature can be either positive,  $\cup$ , or negative,  $\cap$ ), but the average is always positive (see Problem 7C.12).

The association of high curvature with high kinetic energy will turn out to be a valuable guide to the interpretation of wavefunctions and the prediction of their shapes. For example, suppose we need to know the wavefunction of a particle with a given total energy and a potential energy that decreases with increasing  $x$  (Fig. 7C.3). Because the difference  $E - V = E_k$  increases from left to right, the wavefunction must become more sharply curved as  $x$  increases: its wavelength decreases as the local contributions to its kinetic energy increase. We can therefore guess that the wavefunction will look like the function sketched in the illustration, and more detailed calculation confirms this to be so.

**Figure 7C.3** The wavefunction of a particle in a potential decreasing towards the right and hence subjected to a constant force to the right. Only the real part of the wavefunction is shown, the imaginary part is similar, but displaced to the right.

### (c) Hermitian operators

All the quantum mechanical operators that correspond to observables have a very special mathematical property: they are ‘hermitian’. An **hermitian operator** is one for which the following relation is true:

$$\int \psi_i^* \hat{\Omega} \psi_j \, d\tau = \left\{ \int \psi_j^* \hat{\Omega} \psi_i \, d\tau \right\}^* \quad \text{Definition Hermiticity (7C.7)}$$

That is, the same result is obtained by letting the operator act on  $\psi_j$  and then integrating or by letting it act on  $\psi_i$  instead, integrating, and then taking the complex conjugate of the result. One trivial consequence of hermiticity is that it reduces the number of integrals we need to evaluate. However, as we shall see, hermiticity has much more profound implications.

It is easy to confirm that the position operator ( $x \times$ ) is hermitian because we are free to change the order of the factors in the integrand:

$$\int \psi_i^* x \psi_j \, d\tau = \int \psi_j x \psi_i^* \, d\tau = \left\{ \int \psi_j^* x \psi_i \, d\tau \right\}^*$$

The demonstration that the linear momentum operator is hermitian is more involved because we cannot just alter the order of functions we differentiate; but it is hermitian, as we show in the following *Justification*.

#### Justification 7C.1 The hermiticity of the linear momentum operator

Our task is to show that

$$\int \psi_i^* \hat{p}_x \psi_j \, d\tau = \left\{ \int \psi_j^* \hat{p}_x \psi_i \, d\tau \right\}^*$$

with  $\hat{p}_x$  given in eqn 7C.3. To do so, we use ‘integration by parts’ (see *Mathematical background 1*), the relation

$$\int f \frac{dg}{dx} \, dx = fg - \int g \frac{df}{dx} \, dx$$

In the present case we write

$$\begin{aligned} \int \psi_i^* \hat{p}_x \psi_j \, d\tau &= \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_i^* \frac{d\psi_j}{dx} \, dx \\ &= \frac{\hbar}{i} \left[ \psi_i^* \psi_j \right]_{-\infty}^{\infty} - \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} \, dx \end{aligned}$$

The first term on the right of the second equality is zero, because all wavefunctions are either zero or converge to the same value at infinity in either direction, so we are left with

$$\begin{aligned} \int \psi_i^* \hat{p}_x \psi_j \, d\tau &= -\frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j \frac{d\psi_i^*}{dx} \, dx = \left\{ \frac{\hbar}{i} \int_{-\infty}^{\infty} \psi_j^* \frac{d\psi_i}{dx} \, dx \right\}^* \\ &= \left\{ \int \psi_j^* \hat{p}_x \psi_i \, d\tau \right\}^* \end{aligned}$$

as we set out to prove. In the final line we have used  $(\psi^*)^* = \psi$ .

Hermitian operators are enormously important by virtue of two properties:

- The eigenvalues of hermitian operators are real:  $\omega^* = \omega$  (as we prove in the following *Justification*).
- The eigenfunctions of hermitian operators are ‘orthogonal’ in the sense defined below.

All observables have real values (in the mathematical sense, such as  $x=2$  m and  $E=10$  J), so all observables are represented by hermitian operators.

#### Justification 7C.2 The reality of eigenvalues

For a wavefunction  $\psi$  that is normalized and is an eigenfunction of an hermitian operator  $\hat{\Omega}$  with eigenvalue  $\omega$ , we can write

$$\int \psi^* \hat{\Omega} \psi \, d\tau = \int \psi^* \omega \psi \, d\tau = \omega \int \psi^* \psi \, d\tau = \omega$$

However, by taking the complex conjugate we can write

$$\omega^* = \left\{ \int \psi^* \hat{\Omega} \psi \, d\tau \right\}^* \stackrel{\text{hermiticity}}{=} \int \psi^* \hat{\Omega} \psi \, d\tau = \omega$$

The conclusion that  $\omega^* = \omega$  confirms that  $\omega$  is real.

### (d) Orthogonality

To say that two different functions  $\psi_i$  and  $\psi_j$  are **orthogonal** means that the integral (over all space) of their product is zero:

$$\int \psi_i^* \psi_j \, d\tau = 0 \quad \text{for } i \neq j \quad \text{Definition Orthogonality (7C.8)}$$

A general feature of quantum mechanics which we prove in the following *Justification* is that *wavefunctions corresponding to different eigenvalues of a hermitian operator are orthogonal*. For example, the hamiltonian operator is hermitian (it corresponds to an observable, the energy). Therefore, if  $\psi_1$  corresponds to one energy, and  $\psi_2$  corresponds to a different energy, then we know at once that the two functions are orthogonal and that the integral (over all space) of their product is zero.

#### Justification 7C.3 The orthogonality of wavefunctions

Suppose we have two eigenfunctions of  $\hat{\Omega}$ , with unequal eigenvalues:

$$\hat{\Omega}\psi_i = \omega_i\psi_i \quad \text{and} \quad \hat{\Omega}\psi_j = \omega_j\psi_j$$

with  $\omega_i$  not equal to  $\omega_j$ . Multiply the first of these eigenvalue equations on both sides by  $\psi_j^*$  and the second by  $\psi_i^*$ , and integrate over all space:

$$\int \psi_j^* \hat{\Omega}\psi_i \, d\tau = \omega_i \int \psi_j^* \psi_i \, d\tau$$

$$\int \psi_i^* \hat{\Omega}\psi_j \, d\tau = \omega_j \int \psi_i^* \psi_j \, d\tau$$

Now take the complex conjugate of the first of these two expressions (noting that, by the hermiticity of  $\hat{\Omega}$ , the eigenvalues are real):

$$\left\{ \int \psi_j^* \hat{\Omega}\psi_i \, d\tau \right\}^* = \omega_i \int \psi_j \psi_i^* \, d\tau = \omega_i \int \psi_i^* \psi_j \, d\tau$$

However, by hermiticity, the first term on the left is

$$\left\{ \int \psi_j^* \hat{\Omega}\psi_i \, d\tau \right\}^* = \int \psi_i^* \hat{\Omega}\psi_j \, d\tau = \omega_j \int \psi_i^* \psi_j \, d\tau$$

Subtraction of this line from the preceding line then gives

$$0 = (\omega_i - \omega_j) \int \psi_i^* \psi_j \, d\tau$$

But we know that the two eigenvalues are not equal, so the integral must be zero, as we set out to prove.

The property of orthogonality is of great importance in quantum mechanics because it enables us to eliminate a large number of integrals from calculations. Orthogonality plays a

central role in the theory of chemical bonding (Chapter 10) and spectroscopy (Chapters 12–14). Sets of functions that are normalized and mutually orthogonal are called **orthonormal**.

#### Example 7C.3 Verifying orthogonality

It is shown in Topic 8A that two possible wavefunctions for an electron confined to a one-dimensional quantum dot (a collection of atoms with dimensions in the range of nanometres and of great interest in nanotechnology) are of the form  $\sin x$  and  $\sin 2x$ . These two wavefunctions are eigenfunctions of the kinetic energy operator, which is hermitian, and correspond to different eigenvalues:

$$\hat{E}_k \sin x = -\frac{\hbar^2}{2m_e} \frac{d^2 \sin x}{dx^2} = \frac{\hbar^2}{2m_e} \sin x$$

$$\hat{E}_k \sin 2x = -\frac{\hbar^2}{2m_e} \frac{d^2 \sin 2x}{dx^2} = \frac{2\hbar^2}{m_e} \sin 2x$$

Verify that the two wavefunctions are mutually orthogonal.

**Method** To verify the orthogonality of two functions, we integrate their product,  $\sin 2x \sin x$ , over all space, which we may take to span from  $x=0$  to  $x=2\pi$ , because both functions repeat themselves outside that range. Hence proving that the integral of their product is zero within that range implies that the integral over the whole of space is also zero (Fig. 7C.4). Relevant integrals are given in the *Resource section*.

**Figure 7C.4** The integral of the function  $f(x) = \sin 2x \sin x$  is equal to the area (tinted) below the green curve, and is zero, as can be inferred by symmetry. The function, and the value of the integral, repeats itself for all replications of the section between 0 and  $2\pi$ , so the integral from  $-\infty$  to  $+\infty$  is zero.

**Answer** It follows that, for  $a=2$  and  $b=1$ , and given the fact that  $\sin 0=0$ ,  $\sin 2\pi=0$ , and  $\sin 6\pi=0$ ,

$$\int_0^{2\pi} \sin 2x \sin x \, dx \stackrel{\text{Integral T.5}}{=} \frac{\sin x}{2} \Big|_0^{2\pi} - \frac{\sin 3x}{6} \Big|_0^{2\pi} = 0$$

and the two functions are mutually orthogonal.

**Self-test 7C.3** When the electron is excited to higher energies, its wavefunction may become  $\sin 3x$ . Confirm that the functions  $\sin x$  and  $\sin 3x$  are mutually orthogonal.

$$\text{Answer: } \int_0^{2\pi} \sin 3x \sin x \, dx = 0$$

## 7C.2 Superpositions and expectation values

Suppose that the wavefunction of a free particle is  $\psi(x) = 2A \cos kx$  (this is one of the possibilities treated in Topic 7B, eqn 7B.9). What is the linear momentum of the particle it describes? We quickly run into trouble if we use the operator technique. When we operate with  $\hat{p}_x$ , we find

$$\hat{p}_x \psi = \frac{\hbar}{i} \frac{d\psi}{dx} = \frac{2\hbar}{i} A \frac{d \cos kx}{dx} = -\frac{2k\hbar}{i} A \sin kx \quad (7C.9)$$

This expression is not an eigenvalue equation, because the function on the right ( $\sin kx$ ) is different from that on the left ( $\cos kx$ ).

When the wavefunction of a particle is not an eigenfunction of an operator, the property to which the operator corresponds does not have a definite value. However, in the current example the momentum is not completely indefinite because the cosine wavefunction is a **linear combination**, or sum,<sup>1</sup> of  $e^{ikx}$  and  $e^{-ikx}$ , and these two functions, as we have seen, individually correspond to definite momentum states. We say that the total wavefunction is a **superposition** of more than one wavefunction. Symbolically we can write the superposition as

$$\psi = \underbrace{\psi_{\rightarrow}}_{\substack{\text{Particle with} \\ \text{linear momentum} \\ +k\hbar}} + \underbrace{\psi_{\leftarrow}}_{\substack{\text{Particle with} \\ \text{linear momentum} \\ -k\hbar}}$$

The interpretation of this composite wavefunction is that if the momentum of the particle is repeatedly measured in a long series of observations, then its magnitude will be found to be  $k\hbar$  in all the measurements (because that is the value for each component of the wavefunction). However, because the two component wavefunctions occur equally in the superposition, half the measurements will show that the particle is moving to the right ( $p_x = +k\hbar$ ), and half the measurements will show that it is moving to the left ( $p_x = -k\hbar$ ). According to quantum mechanics, we cannot predict in which direction the particle will in fact be found to be travelling; all we can say is that, in a long series

<sup>1</sup> A linear combination is more general than a sum, for it includes weighted sums of the form  $ax + by + \dots$  where  $a, b, \dots$  are constants. A sum is a linear combination with  $a = b = \dots = 1$ .

of observations, if the particle is described by this wavefunction, then there are equal probabilities of finding the particle travelling to the right and to the left.

The same interpretation applies to any wavefunction written as a linear combination of eigenfunctions of an operator. Thus, suppose the wavefunction is known to be a superposition of many different linear momentum eigenfunctions and written as the linear combination

$$\psi = c_1 \psi_1 + c_2 \psi_2 + \dots = \sum_k c_k \psi_k \quad \text{Linear combination of basis functions} \quad (7C.10)$$

where the  $c_k$  are numerical (possibly complex) coefficients and the  $\psi_k$  correspond to different momentum states. The functions  $\psi_k$  are said to form a **complete set** in the sense that any arbitrary function can be expressed as a linear combination of them. Then according to quantum mechanics:

- When the momentum is measured, in a single observation one of the eigenvalues corresponding to the  $\psi_k$  that contribute to the superposition will be found.
- The probability of measuring a particular eigenvalue in a series of observations is proportional to the square modulus ( $|c_k|^2$ ) of the corresponding coefficient in the linear combination.
- The average value of a large number of observations is given by the expectation value,  $\langle \Omega \rangle$ , of the operator corresponding to the observable of interest.

Physical interpretation

The **expectation value** of an operator  $\hat{\Omega}$  is defined as

$$\langle \Omega \rangle = \int \psi^* \hat{\Omega} \psi \, d\tau \quad \text{Definition} \quad \text{Expectation value} \quad (7C.11)$$

This formula is valid only for normalized wavefunctions. As we see in the following *Justification*, an expectation value is the weighted average of a large number of observations of a property.

### Justification 7C.4 The expectation value of an operator

If  $\psi$  is an eigenfunction of  $\hat{\Omega}$  with eigenvalue  $\omega$ , the expectation value of  $\hat{\Omega}$  is

$$\langle \Omega \rangle = \int \psi^* \overbrace{\hat{\Omega} \psi}^{\omega \psi} \, d\tau = \int \psi^* \omega \psi \, d\tau = \omega \int \psi^* \psi \, d\tau = \omega$$

because  $\omega$  is a constant and may be taken outside the integral, and the resulting integral is equal to 1 for a normalized wavefunction. The interpretation of this expression is that, because every observation of the property  $\Omega$  results in the value  $\omega$  (because the wavefunction is an eigenfunction of  $\hat{\Omega}$ ), the mean value of all the observations is also  $\omega$ .

A wavefunction that is not an eigenfunction of the operator of interest can be written as a linear combination of

eigenfunctions. For simplicity, suppose the wavefunction is the sum of two eigenfunctions (the general case, eqn 7C.10, can be developed analogously). Then

$$\begin{aligned}\langle \Omega \rangle &= \int (c_1\psi_1 + c_2\psi_2)^* \hat{\Omega} (c_1\psi_1 + c_2\psi_2) d\tau \\ &= \int (c_1\psi_1 + c_2\psi_2)^* (c_1\hat{\Omega}\psi_1 + c_2\hat{\Omega}\psi_2) d\tau \\ &= \int (c_1\psi_1 + c_2\psi_2)^* (c_1\omega_1\psi_1 + c_2\omega_2\psi_2) d\tau \\ &= c_1^*c_1\omega_1 \int \overbrace{\psi_1^*\psi_1}^1 d\tau + c_2^*c_2\omega_2 \int \overbrace{\psi_2^*\psi_2}^1 d\tau \\ &\quad + c_1^*c_2\omega_2 \int \overbrace{\psi_1^*\psi_2}^0 d\tau + c_2^*c_1\omega_1 \int \overbrace{\psi_2^*\psi_1}^0 d\tau\end{aligned}$$

The first two integrals on the right are both equal to 1 because the wavefunctions are individually normalized. Because  $\psi_1$  and  $\psi_2$  correspond to different eigenvalues of an hermitian operator, they are orthogonal, so the third and fourth integrals on the right are zero. We can conclude that

$$\langle \Omega \rangle = |c_1|^2\omega_1 + |c_2|^2\omega_2$$

This expression shows that the expectation value is the sum of the two eigenvalues weighted by the probabilities that each one will be found in a series of measurements. Hence, the expectation value is the weighted mean of a series of observations.

#### Example 7C.4 Calculating an expectation value

Calculate the average value of the distance of an electron from the nucleus in the hydrogen atom in its state of lowest energy.

**Method** The average radius is the expectation value of the operator corresponding to the distance from the nucleus, which is multiplication by  $r$ . To evaluate  $\langle r \rangle$ , we need to know the normalized wavefunction (from *Example 7B.2*) and then evaluate the integral in eqn 7C.11.

**Answer** The average value is given by the expectation value

$$\langle r \rangle = \int \psi^* r \psi d\tau = \int r |\psi|^2 d\tau$$

which we evaluate by using spherical polar coordinates and the appropriate expression for the volume element,  $d\tau = r^2 dr \sin\theta d\theta d\phi$  (*The chemist's toolkit 7B.1*). Using the normalized function in *Example 7B.2* and a standard integral from the *Resource section*, gives

$$\langle r \rangle = \frac{1}{4\pi a_0^3} \int_0^\infty \overbrace{r^3 e^{-2r/a_0}}^{3!a_0^3/2^4} dr \int_0^\pi \overbrace{\sin\theta}^2 d\theta \int_0^{2\pi} \overbrace{d\phi}^{2\pi} = \frac{3}{2} a_0$$

Because  $a_0 = 52.9$  pm (see inside the front cover),  $\langle r \rangle = 79.4$  pm. This result means that if a very large number of measurements of the distance of the electron from the nucleus are made, then their mean value will be 79.4 pm. However, each different observation will give a different and unpredictable individual result because the wavefunction is not an eigenfunction of the operator corresponding to  $r$ .

**Self-test 7C.4** Evaluate the root mean square distance,  $\langle r^2 \rangle^{1/2}$ , of the electron from the nucleus in the hydrogen atom.

Answer:  $3^{1/2}a_0 = 91.6$  pm

The mean kinetic energy of a particle in one dimension is the expectation value of the operator given in eqn 7C.5. Therefore, we can write

$$\langle E_k \rangle = \int \psi^* \hat{E}_k \psi dx = -\frac{\hbar^2}{2m} \int \psi^* \frac{d^2\psi}{dx^2} dx \quad (7C.12)$$

This conclusion confirms the previous assertion that the kinetic energy is a kind of average over the curvature of the wavefunction: we get a large contribution to the observed value from regions where the wavefunction is sharply curved (so  $d^2\psi/dx^2$  is large) and the wavefunction itself is large (so that  $\psi^*$  is large too).

## 7C.3 The uncertainty principle

We have seen that if the wavefunction is  $Ae^{ikx}$ , then the particle it describes has a definite state of linear momentum, namely travelling to the right with momentum  $p_x = +\hbar k$ . However, we have also seen that the position of the particle described by this wavefunction is completely unpredictable. In other words, if the momentum is specified precisely, it is impossible to predict the location of the particle. This statement is one half of a special case of the **Heisenberg uncertainty principle**, one of the most celebrated results of quantum mechanics:

It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle.

Heisenberg  
uncertainty  
principle

Before discussing the principle further, we must establish its other half: that if we know the position of a particle exactly, then we can say nothing about its momentum. The argument draws on the idea of regarding a wavefunction as a superposition of eigenfunctions, and runs as follows.

If we know that the particle is at a definite location, its wavefunction must be large there and zero everywhere else (Fig. 7C.5). Such a wavefunction can be created by superimposing a large number of harmonic (sine and cosine) functions, or,

**Figure 7C.5** The wavefunction for a particle at a well-defined location is a sharply spiked function which has zero amplitude everywhere except at the particle's position.

equivalently, a number of  $e^{ikx}$  functions. In other words, we can create a sharply localized wavefunction, called a **wavepacket**, by forming a linear combination of wavefunctions that correspond to many different linear momenta. The superposition of a few harmonic functions gives a wavefunction that spreads over a range of locations (Fig. 7C.6). However, as the number of wavefunctions in the superposition increases, the wavepacket becomes sharper on account of the more complete interference between the positive and negative regions of the individual waves. When an infinite number of components are used, the wavepacket is a sharp, infinitely narrow spike, which corresponds to perfect localization of the particle. Now the particle is perfectly localized. However, we have lost all information about its momentum because, as we saw above, a measurement of the momentum will give a result corresponding to any one of the infinite number of waves in the superposition, and which one it will give is unpredictable. Hence, if we know the location of the particle precisely (implying that its wavefunction is a superposition of an infinite number of momentum eigenfunctions), then its momentum is completely unpredictable.

A quantitative version of this result is

$$\Delta p \Delta q \geq \frac{1}{2} \hbar \quad \text{Heisenberg uncertainty principle} \quad (7C.13a)$$

In this expression  $\Delta p$  is the 'uncertainty' in the linear momentum parallel to the axis  $q$ , and  $\Delta q$  is the uncertainty in position along that axis. These 'uncertainties' are precisely defined, for they are the root mean square deviations of the properties from their mean values:

$$\Delta p = \{\langle p^2 \rangle - \langle p \rangle^2\}^{1/2} \quad \Delta q = \{\langle q^2 \rangle - \langle q \rangle^2\}^{1/2} \quad (7C.13b)$$

If there is complete certainty about the position of the particle ( $\Delta q = 0$ ), then the only way that eqn 7C.13a can be satisfied is for  $\Delta p = \infty$ , which implies complete uncertainty about the momentum. Conversely, if the momentum parallel to an axis is

**Figure 7C.6** The wavefunction for a particle with an ill-defined location can be regarded as the linear combination of several wavefunctions of definite wavelength that interfere constructively in one place but destructively elsewhere. As more waves are used in the superposition (as given by the numbers attached to the curves), the location becomes more precise at the expense of uncertainty in the particle's momentum. An infinite number of waves are needed in the superposition to construct the wavefunction of the perfectly localized particle.

known exactly ( $\Delta p = 0$ ), then the position along that axis must be completely uncertain ( $\Delta q = \infty$ ).

The  $p$  and  $q$  that appear in eqn 7C.13 refer to the same direction in space. Therefore, whereas simultaneous specification of the position on the  $x$ -axis and momentum parallel to the  $x$ -axis are restricted by the uncertainty relation, simultaneous location of position on  $x$  and motion parallel to  $y$  or  $z$  are not restricted. The restrictions that the uncertainty principle implies are summarized in Table 7C.1.

#### Example 7C.5 Using the uncertainty principle

Suppose the speed of a projectile of mass 1.0 g is known to within  $1 \mu\text{m s}^{-1}$ . Calculate the minimum uncertainty in its position.

**Method** Estimate  $\Delta p$  from  $m\Delta v$ , where  $\Delta v$  is the uncertainty in the speed; then use eqn 7C.13a to estimate the minimum uncertainty in position,  $\Delta q$ .

**Answer** The minimum uncertainty in position is

$$\begin{aligned} \Delta q &= \frac{\hbar}{2m\Delta v} \\ &= \frac{1.055 \times 10^{-34} \text{ J s}}{2 \times (1.0 \times 10^{-3} \text{ kg}) \times (1 \times 10^{-6} \text{ m s}^{-1})} = 5 \times 10^{-26} \text{ m} \end{aligned}$$

where we have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . The uncertainty is completely negligible for all practical purposes concerning macroscopic objects. However, if the mass is that of an electron, then the same uncertainty in speed implies an uncertainty in position far larger than the diameter of an atom (the analogous

calculation gives  $\Delta q = 60$  m); so the concept of a trajectory, the simultaneous possession of a precise position and momentum, is untenable.

**Self-test 7C.5** Estimate the minimum uncertainty in the speed of an electron in a one-dimensional region of length  $2a_0$ .

Answer:  $500 \text{ km s}^{-1}$

**Table 7C.1** Constraints of the uncertainty principle\*

Variable 2	Variable 1					
	$x$	$y$	$z$	$p_x$	$p_y$	$p_z$
$x$						
$y$						
$z$						
$p_x$						
$p_y$						
$p_z$						

\* Pairs of observables that cannot be determined simultaneously with arbitrary precision are marked with a blue rectangle; all others are unrestricted.

The Heisenberg uncertainty principle is more general than eqn 7C.13 suggests. It applies to any pair of observables called **complementary observables**, which are defined in terms of the properties of their operators. Specifically, two observables  $\Omega_1$  and  $\Omega_2$  are complementary if

$$\hat{\Omega}_1 \hat{\Omega}_2 \psi \neq \hat{\Omega}_2 \hat{\Omega}_1 \psi \quad \text{Complementarity of observables} \quad (7C.14)$$

where the term on the left implies that  $\hat{\Omega}_2$  acts first, then  $\hat{\Omega}_1$  acts on the result, and the term on the right implies that the operations are performed in the opposite order. When the effect of two operators applied in succession depends on their order (as this equation implies), we say that they do not **commute**. The different outcomes of the effect of applying  $\hat{\Omega}_1$  and  $\hat{\Omega}_2$  in a different order are expressed by introducing the **commutator** of the two operators, which is defined as

$$[\hat{\Omega}_1, \hat{\Omega}_2] = \hat{\Omega}_1 \hat{\Omega}_2 - \hat{\Omega}_2 \hat{\Omega}_1 \quad \text{Definition Commutator} \quad (7C.15)$$

We show in the following *Justification* that the commutator of the operators for position and linear momentum is

$$[\hat{x}, \hat{p}_x] = i\hbar \quad (7C.16)$$

**Justification 7C.5** The commutator of position and momentum

To show that the operators for position and momentum do not commute (and hence are complementary observables) we consider the effect of  $\hat{x}\hat{p}_x$  (that is, the effect of  $\hat{p}_x$  followed by the

effect on the outcome of multiplication by  $x$ ) on a wavefunction  $\psi$ :

$$\hat{x}\hat{p}_x\psi = x \times \frac{\hbar}{i} \frac{d\psi}{dx}$$

Next, we consider the effect of  $\hat{p}_x\hat{x}$  on the same function (that is, the effect of multiplication by  $x$  followed by the effect of  $\hat{p}_x$  on the outcome):

$$\hat{p}_x\hat{x}\psi = \frac{\hbar}{i} \frac{d(x\psi)}{dx} = \frac{\hbar}{i} \left( \psi + x \frac{d\psi}{dx} \right)$$

For this step we have used the standard rule about differentiating a product of functions ( $d(fg)/dx = fdg/dx + gdf/dx$ ). The second expression is clearly different from the first, so the two operators do not commute. Their commutator can be inferred from the difference of the two expressions:

$$\hat{x}\hat{p}_x\psi - \hat{p}_x\hat{x}\psi = -\frac{\hbar}{i}\psi = i\hbar\psi$$

This relation is true for any wavefunction  $\psi$ , so the operator relation in eqn 7C.16 follows immediately.

The commutator in eqn 7C.16 is of such vital significance in quantum mechanics that it is taken as a fundamental distinction between classical mechanics and quantum mechanics. In fact, this commutator may be taken as a postulate of quantum mechanics, and is used to justify the choice of the operators for position and linear momentum given in eqn 7C.3.

With the concept of commutator established, the Heisenberg uncertainty principle can be given its most general form. For *any* two pairs of observables,  $\Omega_1$  and  $\Omega_2$ , the uncertainties (to be precise, the root mean square deviations of their values from the mean) in simultaneous determinations are related by

$$\Delta\Omega_1\Delta\Omega_2 \geq \frac{1}{2} |\langle [\hat{\Omega}_1, \hat{\Omega}_2] \rangle| \quad (7C.17)$$

We obtain the special case of eqn 7C.13a when we identify the observables with  $x$  and  $p_x$  and use eqn 7C.16 for their commutator. (See *Mathematical background 3* for the meaning of the  $|\dots|$  notation.)

Complementary observables are observables with non-commuting operators. With the discovery that some pairs of observables are complementary (we meet more examples in Topic 8C), we are at the heart of the difference between classical and quantum mechanics. Classical mechanics supposed, falsely as we now know, that the position and momentum of a particle could be specified simultaneously with arbitrary precision. However, quantum mechanics shows that position and momentum are complementary, and that we have to make a

choice: we can specify position at the expense of momentum, or momentum at the expense of position.

The realization that some observables are complementary allows us to make considerable progress with the calculation of atomic and molecular properties; but it does away with some of the most cherished concepts of classical physics.

## 7C.4 The postulates of quantum mechanics

Here and in Topic 7B we have developed the principles of quantum theory. They can be summarized as a series of postulates, which will form the basis for chemical applications of quantum mechanics through the text.

*The wavefunction:* All dynamical information is contained in the wavefunction  $\psi$  for the system, which is a mathematical function found by solving the Schrödinger equation for the system. In one dimension:

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V(x)\psi = E\psi$$

*The Born interpretation:* If the wavefunction of a particle has the value  $\psi$  at some point  $\mathbf{r}$ , then the probability of finding the particle in an infinitesimal volume  $d\tau = dx dy dz$  at that point is proportional to  $|\psi|^2 d\tau$ .

*Acceptable wavefunctions:* An acceptable wavefunction must be single-valued, continuous, not infinite over a finite region of space, and have a continuous slope.

*Observables:* Observables,  $\hat{Q}$ , are represented by operators,  $\hat{Q}$ , built from the following position and momentum operators:

$$\hat{x} = x \times \quad \hat{p}_x = \frac{\hbar}{i} \frac{d}{dx}$$

or, more generally, from operators that satisfy the commutation relation

$$[\hat{x}, \hat{p}_x] = i\hbar$$

*The Heisenberg uncertainty relation:* It is impossible to specify simultaneously, with arbitrary precision, both the momentum and the position of a particle and, more generally, any pair of observables with operators that do not commute.

## Checklist of concepts

- 1. The Schrödinger equation is an **eigenvalue equation**.
- 2. An **operator** carries out a mathematical operation on a function.
- 3. The **hamiltonian operator** is the operator corresponding to the total energy of the system, the sum of the kinetic and potential energies.
- 4. The wavefunction corresponding to a specific energy is an **eigenfunction** of the hamiltonian operator.
- 5. The value of an observable is an **eigenvalue** of the corresponding operator constructed from the operators for position and linear momentum.
- 6. Two different functions are **orthogonal** if the integral (over all space) of their product is zero.
- 7. **Hermitian operators** have real eigenvalues and orthogonal eigenfunctions.
- 8. **Observables** are represented by hermitian operators.
- 9. Sets of functions that are normalized and mutually orthogonal are called **orthonormal**.
- 10. When the system is not described by a single eigenfunction of an operator, it may be expressed as a **superposition** of such eigenfunctions.
- 11. The mean value of a series of observations is given by the **expectation value** of the corresponding operator.
- 12. The **uncertainty principle** restricts the precision with which complementary observables may be specified and measured simultaneously.
- 13. **Complementary observables** are observables for which the corresponding operators do not commute.

## Checklist of equations

Property	Equation	Comment	Equation number
Hermiticity	$\int \psi_i^* \hat{Q} \psi_j d\tau = \left\{ \int \psi_j^* \hat{Q} \psi_i d\tau \right\}^*$	Real eigenvalues, orthogonal eigenfunctions	7C.7
Orthogonality	$\int \psi_i^* \psi_j d\tau = 0$ for $i \neq j$	Integration over all space	7C.8

Property	Equation	Comment	Equation number
Expectation value	$\langle \Omega \rangle = \int \psi^* \hat{\Omega} \psi \, d\tau$	Definition	7C.11
Commutator of two operators	$[\hat{\Omega}_1, \hat{\Omega}_2] = \hat{\Omega}_1 \hat{\Omega}_2 - \hat{\Omega}_2 \hat{\Omega}_1$ Special case: $[\hat{x}, \hat{p}_x] = i\hbar$	The observables are complementary if $[\hat{\Omega}_1, \hat{\Omega}_2] \neq 0$	7C.15
Heisenberg uncertainty principle	$\Delta \Omega_1 \Delta \Omega_2 \geq \frac{1}{2}  \langle [\hat{\Omega}_1, \hat{\Omega}_2] \rangle $ Special case: $\Delta p \Delta q \geq \frac{1}{2} \hbar$		7C.17

# CHAPTER 7 Introduction to quantum theory

## TOPIC 7A The origins of quantum mechanics

### Discussion questions

**7A.1** Summarize the evidence that led to the introduction of quantum mechanics.

**7A.2** Explain how Planck's introduction of quantization accounted for the properties of black-body radiation.

**7A.3** Explain how Einstein's introduction of quantization accounted for the properties of heat capacities at low temperatures.

**7A.4** Explain the meaning and consequences of wave-particle duality.

### Exercises

**7A.1(a)** Calculate the size of the quantum involved in the excitation of (i) an electronic oscillation of period 1.0 fs, (ii) a molecular vibration of period 10 fs, (iii) a pendulum of period 1.0 s. Express the results in joules and kilojoules per mole.

**7A.1(b)** Calculate the size of the quantum involved in the excitation of (i) an electronic oscillation of period 2.50 fs, (ii) a molecular vibration of period 2.21 fs, (iii) a balance wheel of period 1.0 ms. Express the results in joules and kilojoules per mole.

**7A.2(a)** Calculate the energy per photon and the energy per mole of photons for radiation of wavelength (i) 600 nm (red), (ii) 550 nm (yellow), (iii) 400 nm (blue).

**7A.2(b)** Calculate the energy per photon and the energy per mole of photons for radiation of wavelength (i) 200 nm (ultraviolet), (ii) 150 pm (X-ray), (iii) 1.00 cm (microwave).

**7A.3(a)** Calculate the speed to which a stationary H atom would be accelerated if it absorbed each of the photons used in Exercise 7A.2(a).

**7A.3(b)** Calculate the speed to which a stationary  ${}^4\text{He}$  atom (mass  $4.0026m_{\text{u}}$ ) would be accelerated if it absorbed each of the photons used in Exercise 7A.2(b).

**7A.4(a)** A glow-worm of mass 5.0 g emits red light (650 nm) with a power of 0.10 W entirely in the backward direction. To what speed will it have accelerated after 10 y if released into free space and assumed to live?

**7A.4(b)** A photon-powered spacecraft of mass 10.0 kg emits radiation of wavelength 225 nm with a power of 1.50 kW entirely in the backward direction. To what speed will it have accelerated after 10.0 y if released into free space?

**7A.5(a)** A sodium lamp emits yellow light (550 nm). How many photons does it emit each second if its power is (i) 1.0 W, (ii) 100 W?

**7A.5(b)** A laser used to read CDs emits red light of wavelength 700 nm. How many photons does it emit each second if its power is (i) 0.10 W, (ii) 1.0 W?

**7A.6(a)** The work function for metallic caesium is 2.14 eV. Calculate the kinetic energy and the speed of the electrons ejected by light of wavelength (i) 700 nm, (ii) 300 nm.

**7A.6(b)** The work function for metallic rubidium is 2.09 eV. Calculate the kinetic energy and the speed of the electrons ejected by light of wavelength (i) 650 nm, (ii) 195 nm.

**7A.7(a)** In an X-ray photoelectron experiment, a photon of wavelength 150 pm ejects an electron from the inner shell of an atom and it emerges with a speed of  $21.4\text{ Mm s}^{-1}$ . Calculate the binding energy of the electron.

**7A.7(b)** In an X-ray photoelectron experiment, a photon of wavelength 121 pm ejects an electron from the inner shell of an atom and it emerges with a speed of  $56.9\text{ Mm s}^{-1}$ . Calculate the binding energy of the electron.

**7A.8(a)** To what speed must an electron be accelerated for it to have a wavelength of 100 pm? What accelerating potential difference is needed?

**7A.8(b)** To what speed must a proton be accelerated for it to have a wavelength of 100 pm? What accelerating potential difference is needed?

**7A.9(a)** To what speed must an electron be accelerated for it to have a wavelength of 3.0 cm?

**7A.9(b)** To what speed must a proton be accelerated for it to have a wavelength of 3.0 cm?

**7A.10(a)** The fine-structure constant,  $\alpha$ , plays a special role in the structure of matter; its approximate value is  $1/137$ . What is the wavelength of an electron travelling at a speed  $\alpha c$ , where  $c$  is the speed of light?

**7A.10(b)** Calculate the linear momentum of photons of wavelength 350 nm. What speed does a hydrogen molecule need to travel to have the same linear momentum?

**7A.11(a)** Calculate the de Broglie wavelength of (i) a mass of 1.0 g travelling at  $1.0\text{ cm s}^{-1}$ , (ii) the same, travelling at  $100\text{ km s}^{-1}$ , (iii) an He atom travelling at  $1000\text{ m s}^{-1}$  (a typical speed at room temperature).

**7A.11(b)** Calculate the de Broglie wavelength of an electron accelerated from rest through a potential difference of (i) 100 V, (ii) 1.0 kV, (iii) 100 kV.

### Problems

**7A.1** The Planck distribution gives the energy in the wavelength range  $d\lambda$  at the wavelength  $\lambda$ . Calculate the energy density in the range 650 nm to 655 nm inside a cavity of volume  $100\text{ cm}^3$  when its temperature is (a)  $25^\circ\text{C}$ , (b)  $3000^\circ\text{C}$ .

**7A.2** Demonstrate that the Planck distribution reduces to the Rayleigh-Jeans law at long wavelengths.

**7A.3** Derive *Wien's law*, that  $\lambda_{\text{max}}T$  is a constant, where  $\lambda_{\text{max}}$  is the wavelength corresponding to maximum in the Planck distribution at the temperature  $T$ ,

and deduce an expression for the constant as a multiple of the second radiation constant,  $c_2 = hc/k$ .

**7A.4** For a black body, the temperature and the wavelength of emission maximum,  $\lambda_{\text{max}}$ , are related by Wien's law,  $\lambda_{\text{max}}T = \frac{1}{5}c_2$ , where  $c_2 = hc/k$  (see Problem 7A.3). Values of  $\lambda_{\text{max}}$  from a small pinhole in an electrically heated container were determined at a series of temperatures, and the results are given in the following table. Deduce a value for Planck's constant.

$\theta/^\circ\text{C}$	1000	1500	2000	2500	3000	3500
$\lambda_{\text{max}}/\text{nm}$	2181	1600	1240	1035	878	763

**7A.5\*** Solar energy strikes the top of the Earth's atmosphere at a rate of  $343 \text{ W m}^{-2}$ . About 30 per cent of this energy is reflected directly back into space by the Earth or the atmosphere. The Earth-atmosphere system absorbs the remaining energy and re-radiates it into space as black-body radiation. What is the average black-body temperature of the Earth? What is the wavelength of the most plentiful of the Earth's black-body radiation? *Hint:* Use Wien's law, Problem 7A.3.

**7A.6** Use the Planck distribution to deduce the *Stefan-Boltzmann law* that the total energy density of black-body radiation is proportional to  $T^4$ , and find the constant of proportionality.

**7A.7\*** Prior to Planck's derivation of the distribution law for black-body radiation, Wien found empirically a closely related distribution function which is very nearly but not exactly in agreement with the experimental

results, namely  $\rho = (a/\lambda^5)e^{-b/\lambda kT}$ . This formula shows small deviations from Planck's at long wavelengths. (i) By fitting Wien's empirical formula to Planck's at short wavelengths determine the constants  $a$  and  $b$ . (ii) Demonstrate that Wien's formula is consistent with Wien's law (Problem 7A.3) and with the Stefan-Boltzmann law (Problem 7A.6).

**7A.8\*** The temperature of the Sun's surface is approximately 5800 K. On the assumption that the human eye evolved to be most sensitive at the wavelength of light corresponding to the maximum in the Sun's radiant energy distribution, determine the colour of light to which the eye is the most sensitive.

**7A.9** The Einstein frequency is often expressed in terms of an equivalent temperature  $\theta_E$ , where  $\theta_E = h\nu/k$ . Confirm that  $\theta_E$  has the dimensions of temperature, and express the criterion for the validity of the high-temperature form of the Einstein equation in terms of it. Evaluate  $\theta_E$  for (a) diamond, for which  $\nu = 46.5 \text{ THz}$  and (b) for copper, for which  $\nu = 7.15 \text{ THz}$ . What fraction of the Dulong and Petit value of the heat capacity does each substance reach at  $25^\circ\text{C}$ ?

## TOPIC 7B Dynamics of microscopic systems

### Discussion questions

**7B.1** Describe how a wavefunction summarizes the dynamical properties of a system and how those properties may be predicted.

**7B.2** Discuss the relation between probability amplitude, probability density, and probability.

**7B.3** Describe the constraints that the Born interpretation puts on acceptable wavefunctions.

**7B.4** What are the advantages of working with normalized wavefunctions?

### Exercises

**7B.1(a)** Consider a time-independent wavefunction of a particle moving in three-dimensional space. Identify the variables upon which the wavefunction depends.

**7B.1(b)** Consider a time-dependent wavefunction of a particle moving in two-dimensional space. Identify the variables upon which the wavefunction depends.

**7B.2(a)** Consider a time-independent wavefunction of a hydrogen atom. Identify the variables upon which the wavefunction depends. Use spherical polar coordinates.

**7B.2(b)** Consider a time-dependent wavefunction of a helium atom. Identify the variables upon which the wavefunction depends. Use spherical polar coordinates.

**7B.3(a)** An unnormalized wavefunction for a light atom rotating around a heavy atom to which it is bonded is  $\psi(\phi) = e^{i\phi}$  with  $0 \leq \phi \leq 2\pi$ . Normalize this wavefunction.

**7B.3(b)** An unnormalized wavefunction for an electron in a carbon nanotube of length  $L$  is  $\sin(2\pi x/L)$ . Normalize this wavefunction.

**7B.4(a)** For the system described in Exercise 7B.3(a), what is the probability of finding the light atom in the volume element  $d\phi$  at  $\phi = \pi$ ?

**7B.4(b)** For the system described in Exercise 7B.3(b), what is the probability of finding the electron in the range  $dx$  at  $x = L/2$ ?

**7B.5(a)** For the system described in Exercise 7B.3(a), what is the probability of finding the light atom between  $\phi = \pi/2$  and  $\phi = 3\pi/2$ ?

**7B.5(b)** For the system described in Exercise 7B.3(b), what is the probability of finding the electron between  $x = L/4$  and  $x = L/2$ ?

### Problems

**7B.1** Normalize the following wavefunctions: (i)  $\sin(n\pi x/L)$  in the range  $0 \leq x \leq L$ , where  $n = 1, 2, 3, \dots$  (this wavefunction can be used to describe delocalized electrons in a linear polyene), (ii) a constant in the range  $-L \leq x \leq L$ , (iii)  $e^{-r/a}$  in three-dimensional space (this wavefunction can be used to describe the electron in the ion  $\text{He}^+$ ), (iv)  $x e^{-r/2a}$  in three-dimensional space. *Hint:* The volume element in three dimensions is  $d\tau = r^2 dr \sin \theta d\theta d\phi$ , with  $0 \leq r < \infty$ ,  $0 \leq \theta \leq \pi$ ,  $0 \leq \phi \leq 2\pi$ .

**7B.2** Two (unnormalized) excited state wavefunctions of the H atom are

$$(i) \psi(r) = \left(2 - \frac{r}{a_0}\right) e^{-r/2a_0} \quad (ii) \psi(r, \theta, \phi) = r \sin \theta \cos \phi e^{-r/2a_0}$$

(a) Normalize both functions to 1. (b) Confirm that these two functions are mutually orthogonal.

**7B.3** A particle free to move along one dimension  $x$  (with  $0 \leq x < \infty$ ) is described by the unnormalized wavefunction  $\psi(x) = e^{-ax}$  with  $a = 2 \text{ m}^{-1}$ . What is the probability of finding the particle at a distance  $x \geq 1 \text{ m}$ ?

**7B.4** The ground-state wavefunction for a particle confined to a one-dimensional box of length  $L$  is  $\psi = (2/L)^{1/2} \sin(\pi x/L)$ . Suppose the box is

\* These problems were supplied by Charles Trapp and Carmen Giunta.

10.0 nm long. Calculate the probability that the particle is (a) between  $x=4.95$  nm and 5.05 nm, (b) between  $x=1.95$  nm and 2.05 nm, (c) between  $x=9.90$  nm and 10.00 nm, (d) in the right half of the box, (e) in the central third of the box.

**7B.5** The ground-state wavefunction of a hydrogen atom is  $\psi = (1/\pi a_0^3)^{1/2} e^{-r/a_0}$  where  $a_0 = 53$  pm (the Bohr radius). (a) Calculate the probability that the electron will be found somewhere within a small sphere of radius 1.0 pm centred on the nucleus. (b) Now suppose that the same sphere is located at  $r = a_0$ . What is the probability that the electron is inside it?

**7B.6** Atoms in a chemical bond vibrate around the equilibrium bond length. An atom undergoing vibrational motion is described by the wavefunction  $\psi(x) = Ne^{-x^2/2a^2}$ , where  $a$  is a constant and  $-\infty < x < \infty$ . (a) Normalize this function. (b) Calculate the probability of finding the particle in the range  $-a \leq x \leq a$ . *Hint:* The integral encountered in part (ii) is the error function. It is provided in most mathematical software packages.

**7B.7** Suppose that the state of the vibrating atom in Problem 7B.6 is described by the wavefunction  $\psi(x) = Nxe^{-x^2/2a^2}$ . Where is the most probable location of the particle?

## TOPIC 7C The principles of quantum theory

### Discussion questions

**7C.1** Suggest how the general shape of a wavefunction can be predicted without solving the Schrödinger equation explicitly.

**7C.2** Describe the relationship between operators and observables in quantum mechanics.

**7C.3** Account for the uncertainty relation between position and linear momentum in terms of the shape of the wavefunction.

**7C.4** Describe the properties of wavepackets in terms of the Heisenberg uncertainty principle.

### Exercises

**7C.1(a)** Construct the potential energy operator of a particle subjected to a harmonic oscillator potential (see Topic 8B).

**7C.1(b)** Construct the potential energy operator of a particle subjected to a Coulomb potential.

**7C.2(a)** Confirm that the kinetic energy operator,  $-(\hbar^2/2m)d^2/dx^2$ , is hermitian.

**7C.2(b)** The operator corresponding to the angular momentum of a particle is  $(\hbar/i)d/d\phi$ , where  $\phi$  is an angle. Is this operator hermitian?

**7C.3(a)** Functions of the form  $\sin(n\pi x/L)$  can be used to model the wavefunctions of electrons in a carbon nanotube of length  $L$ . Show that the wavefunctions  $\sin(n\pi x/L)$  and  $\sin(m\pi x/L)$ , where  $n \neq m$ , are orthogonal for a particle confined to the region  $0 \leq x \leq L$ .

**7C.3(b)** Functions of the form  $\cos(n\pi x/L)$  can be used to model the wavefunctions of electrons in metals. Show that the wavefunctions  $\cos(n\pi x/L)$  and  $\cos(m\pi x/L)$ , where  $n \neq m$ , are orthogonal for a particle confined to the region  $0 \leq x \leq L$ .

**7C.4(a)** A light atom rotating around a heavy atom to which it is bonded is described by a wavefunction of the form  $\psi(\phi) = e^{im\phi}$  with  $0 \leq \phi \leq 2\pi$  and  $m$  an integer. Show that the  $m=+1$  and  $m=+2$  wavefunctions are orthogonal.

**7C.4(b)** Repeat Exercise 7C.4(a) for the  $m=+1$  and  $m=-1$  wavefunctions.

**7C.5(a)** An electron in a carbon nanotube of length  $L$  is described by the wavefunction  $\psi(x) = \sin(2\pi x/L)$ . Compute the expectation value of the position of the electron.

**7C.5(b)** An electron in a carbon nanotube of length  $L$  is described by the wavefunction  $\psi(x) = (2/L)^{1/2} \sin(\pi x/L)$ . Compute the expectation value of the kinetic energy of the electron.

**7C.6(a)** An electron in a one-dimensional metal of length  $L$  is described by the wavefunction  $\psi(x) = \sin(\pi x/L)$ . Compute the expectation value of the momentum of the electron.

**7C.6(b)** A light atom rotating around a heavy atom to which it is bonded is described by a wavefunction of the form  $\psi(\phi) = e^{i\phi}$  with  $0 \leq \phi \leq 2\pi$ . If the operator corresponding to angular momentum is given by  $(\hbar/i)d/d\phi$ , compute the expectation value of the angular momentum of the light atom.

**7C.7(a)** Calculate the minimum uncertainty in the speed of a ball of mass 500 g that is known to be within 1.0  $\mu\text{m}$  of a certain point on a bat. What is the minimum uncertainty in the position of a bullet of mass 5.0 g that is known to have a speed somewhere between 350.000 01  $\text{m s}^{-1}$  and 350.000 00  $\text{m s}^{-1}$ ?

**7C.7(b)** An electron is confined to a linear region with a length of the same order as the diameter of an atom (about 100 pm). Calculate the minimum uncertainties in its position and speed.

**7C.8(a)** The speed of a certain proton is 0.45  $\text{Mm s}^{-1}$ . If the uncertainty in its momentum is to be reduced to 0.0100 per cent, what uncertainty in its location must be tolerated?

**7C.8(b)** The speed of a certain electron is 995  $\text{km s}^{-1}$ . If the uncertainty in its momentum is to be reduced to 0.0010 per cent, what uncertainty in its location must be tolerated?

**7C.9(a)** Determine the commutators of the operators (i)  $d/dx$  and  $1/x$ , (ii)  $d/dx$  and  $x^2$ .

**7C.9(b)** Determine the commutators of the operators  $a$  and  $a^+$ , where  $a = (x+ip)/2^{1/2}$  and  $a^+ = (x-ip)/2^{1/2}$ .

### Problems

**7C.1** Write the time-independent Schrödinger equations for (a) an electron moving in one dimension about a stationary proton and subjected to a Coulomb potential, (b) a free particle, (c) a particle subjected to a constant, uniform force.

**7C.2** Construct quantum mechanical operators for the following observables: (a) kinetic energy in one and in three dimensions, (b) the inverse separation,

$1/x$ , (c) electric dipole moment in one dimension, (d) the mean square deviations of the position and momentum of a particle (in one dimension) from the mean values.

**7C.3** Identify which of the following functions are eigenfunctions of the operator  $d/dx$ : (a)  $e^{ikx}$ , (b)  $k$ , (c)  $kx$ , (d)  $e^{-ax^2}$ . Give the corresponding eigenvalue where appropriate.

**7C.4** Determine which of the following functions are eigenfunctions of the inversion operator  $\hat{i}$  which has the effect of making the replacement  $x \rightarrow -x$ : (a)  $x^3 - kx$ , (b)  $\cos kx$ , (c)  $x^2 + 3x - 1$ . State the eigenvalue of  $\hat{i}$  when relevant.

**7C.5** Which of the functions in Problem 7C.3 are (a) also eigenfunctions of  $d^2/dx^2$  and (b) only eigenfunctions of  $d^2/dx^2$ ? Give the eigenvalues where appropriate.

**7C.6** Show that the product of a hermitian operator with itself is also a hermitian operator.

**7C.7** Calculate the average linear momentum of a particle described by the following wavefunctions: (a)  $e^{ikx}$ , (b)  $\cos kx$ , (c)  $e^{-ax^2}$ , where in each one  $x$  ranges from  $-\infty$  to  $+\infty$ .

**7C.8** The normalized wavefunctions for a particle confined to move on a circle are  $\psi(\phi) = (1/2\pi)^{1/2} e^{-im\phi}$ , where  $m = 0, \pm 1, \pm 2, \pm 3, \dots$  and  $0 \leq \phi \leq 2\pi$ . Determine  $\langle \phi \rangle$ .

**7C.9** A particle freely moving in one dimension  $x$  with  $0 \leq x < \infty$  is in a state described by the wavefunction  $\psi(x) = a^{1/2} e^{-ax/2}$ , where  $a$  is a constant. Determine the expectation value of the position operator.

**7C.10** The wavefunction of an electron in a linear accelerator is  $\psi = (\cos \chi)e^{ikx} + (\sin \chi)e^{-ikx}$ , where  $\chi$  (chi) is a parameter. (i) What is the probability that the electron will be found with a linear momentum (a)  $+k\hbar$ , (b)  $-k\hbar$ ? (c) What form would the wavefunction have if it were 90 per cent certain that the electron had linear momentum  $+k\hbar$ ? (c) Evaluate the kinetic energy of the electron.

**7C.11** Two (unnormalized) excited state wavefunctions of the H atom are (i)  $\psi = (2-r/a_0)e^{-r/2a_0}$  and (ii)  $\psi = r \sin \theta \cos \phi e^{-r/2a_0}$ . (a) Normalize both

functions to 1. (b) Confirm that these two functions are mutually orthogonal. (c) Evaluate the expectation values of  $r$  and  $r^2$  for the atom.

**7C.12** The ground-state wavefunction of a hydrogen atom is  $\psi = (1/\pi a_0^3)^{1/2} e^{-r/a_0}$ . Calculate (a) the mean potential energy and (b) the mean kinetic energy of an electron in the ground state of a hydrogenic atom.

**7C.13** Show that the expectation value of an operator that can be written as the square of a hermitian operator is positive.

**7C.14** A particle is in a state described by the wavefunction  $\psi(x) = (2a/\pi)^{1/4} e^{-ax^2}$ , where  $a$  is a constant and  $-\infty \leq x \leq \infty$ . Verify that the value of the product  $\Delta p \Delta x$  is consistent with the predictions from the uncertainty principle.

**7C.15** A particle is in a state described by the wavefunction  $\psi(x) = (2a)^{1/2} e^{-ax}$ , where  $a$  is a constant and  $0 \leq x \leq \infty$ . Determine the expectation value of the commutator of the position and momentum operators.

**7C.16** Evaluate the commutators (a)  $[\hat{H}, \hat{p}_x]$  and (b)  $[\hat{H}, \hat{x}]$  where  $\hat{H} = \hat{p}_x^2/2m + \hat{V}(x)$ . Choose (i)  $V(x) = V$ , a constant, (ii)  $V(x) = \frac{1}{2} k_f x^2$ .

**7C.17** (a) Given that any operators used to represent observables must satisfy the commutation relation in eqn 7C.16, what would be the operator for position if the choice had been made to represent linear momentum parallel to the  $x$ -axis by multiplication by the linear momentum. These different choices are all valid 'representations' of quantum mechanics. (b) With the identification of  $\hat{x}$  in this representation, what would be the operator for  $1/x$ ? *Hint:* Think of  $1/x$  as  $x^{-1}$ .

## Integrated activities

**7.1\*** A star too small and cold to shine has been found by S. Kulkarni et al. (*Science* 270, 1478 (1995)). The spectrum of the object shows the presence of methane which, according to the authors, would not exist at temperatures much above 1000 K. The mass of the star, as determined from its gravitational effect on a companion star, is roughly 20 times the mass of Jupiter. The star is considered to be a brown dwarf, the coolest ever found. (a) From available thermodynamic data, test the stability of methane at temperatures above 1000 K. (b) What is  $\lambda_{\max}$  for this star? (c) What is the energy density of the star relative to that of the Sun (6000 K)? (d) To determine whether the star will shine, estimate the fraction of the energy density of the star in the visible region of the spectrum.

**7.2** Suppose that the wavefunction of an electron in a carbon nanotube is a linear combination of  $\cos(nx)$  functions. (a) Use mathematical software, a

spreadsheet, or the *Living graphs* on the web site of this book to construct superpositions of cosine functions as

$$\psi(x) = \frac{1}{N} \sum_{k=1}^N \cos(k\pi x)$$

where the constant  $1/N$  is introduced to keep the superpositions with the same overall magnitude. Set  $x=0$  at the centre of the screen and build the superposition there. (b) Explore how the probability density  $\psi^2(x)$  changes with the value of  $N$ . (c) Evaluate the root mean square location of the packet,  $\langle x^2 \rangle^{1/2}$ . (d) Determine the probability that a given momentum will be observed.

## Mathematical background 3 Complex numbers

We describe here general properties of complex numbers and functions, which are mathematical constructs frequently encountered in quantum mechanics.

### MB3.1 Definitions

Complex numbers have the general form

$$z = x + iy \quad \text{General form of a complex number} \quad (\text{MB3.1})$$

where  $i = (-1)^{1/2}$ . The real numbers  $x$  and  $y$  are, respectively, the real and imaginary parts of  $z$ , denoted  $\text{Re}(z)$  and  $\text{Im}(z)$ . When  $y=0$ ,  $z=x$  is a real number; when  $x=0$ ,  $z=iy$  is a pure imaginary number. Two complex numbers  $z_1 = x_1 + iy_1$  and  $z_2 = x_2 + iy_2$  are equal when  $x_1 = x_2$  and  $y_1 = y_2$ . Although the general form of the imaginary part of a complex number is written  $iy$ , a specific numerical value is typically written in the reverse order; for instance, as  $3i$ .

The **complex conjugate** of  $z$ , denoted  $z^*$ , is formed by replacing  $i$  by  $-i$ :

$$z^* = x - iy \quad \text{Complex conjugate} \quad (\text{MB3.2})$$

The product of  $z^*$  and  $z$  is denoted  $|z|^2$  and is called the **square modulus** of  $z$ . From eqns MB3.1 and MB3.2,

$$|z|^2 = (x + iy)(x - iy) = x^2 + y^2 \quad \text{Square modulus} \quad (\text{MB3.3})$$

since  $i^2 = -1$ . The square modulus is a real number. The **absolute value** or **modulus** is itself denoted  $|z|$  and is given by:

$$|z| = (z^*z)^{1/2} = (x^2 + y^2)^{1/2} \quad \text{Absolute value or modulus} \quad (\text{MB3.4})$$

Since  $zz^* = |z|^2$  it follows that  $z \times (z^*/|z|^2) = 1$ , from which we can identify the (multiplicative) **inverse** of  $z$  (which exists for all nonzero complex numbers):

$$z^{-1} = \frac{z^*}{|z|^2} \quad \text{Inverse of a complex number} \quad (\text{MB3.5})$$

#### Brief illustration MB3.1 Inverse

Consider the complex number  $z = 8 - 3i$ . Its square modulus is

$$|z|^2 = z^*z = (8 - 3i)^*(8 - 3i) = (8 + 3i)(8 - 3i) = 64 + 9 = 73$$

The modulus is therefore  $|z| = 73^{1/2}$ . From eqn MB3.5, the inverse of  $z$  is

$$z^{-1} = \frac{8 + 3i}{73} = \frac{8}{73} + \frac{3}{73}i$$

### MB3.2 Polar representation

The complex number  $z = x + iy$  can be represented as a point in a plane, the **complex plane**, with  $\text{Re}(z)$  along the  $x$ -axis and  $\text{Im}(z)$  along the  $y$ -axis (Fig. MB3.1). If, as shown in the figure,  $r$  and  $\phi$  denote the polar coordinates of the point, then since  $x = r \cos \phi$  and  $y = r \sin \phi$ , we can express the complex number in **polar form** as

$$z = r(\cos \phi + i \sin \phi) \quad \text{Polar form of a complex number} \quad (\text{MB3.6})$$

The angle  $\phi$ , called the **argument** of  $z$ , is the angle that  $z$  makes with the  $x$ -axis. Because  $y/x = \tan \phi$ , it follows that the polar form can be constructed from

$$r = (x^2 + y^2)^{1/2} = |z| \quad \phi = \arctan \frac{y}{x} \quad (\text{MB3.7a})$$

To convert from polar to Cartesian form, use

$$x = r \cos \phi \quad \text{and} \quad y = r \sin \phi \quad \text{to form} \quad z = x + iy \quad (\text{MB3.7b})$$

One of the most useful relations involving complex numbers is **Euler's formula**:

$$e^{i\phi} = \cos \phi + i \sin \phi \quad \text{Euler's formula} \quad (\text{MB3.8a})$$

The simplest proof of this relation is to expand the exponential function as a power series and to collect real and imaginary terms. It follows that

$$\cos \phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi}) \quad \sin \phi = -\frac{1}{2}i(e^{i\phi} - e^{-i\phi}) \quad (\text{MB3.8b})$$

The polar form in eqn MB3.6 then becomes

$$z = re^{i\phi} \quad (\text{MB3.9})$$

Figure MB3.1 The representation of a complex number  $z$  as a point in the complex plane using Cartesian coordinates  $(x, y)$  or polar coordinates  $(r, \phi)$ .

**Brief illustration MB3.2** Polar representation

Consider the complex number  $z = 8 - 3i$ . From *Brief illustration* MB3.1,  $r = |z| = 73^{1/2}$ . The argument of  $z$  is

$$\theta = \arctan\left(\frac{-3}{8}\right) = -0.359 \text{ rad, or } -20.6^\circ$$

The polar form of the number is therefore

$$z = 73^{1/2} e^{-0.359i}$$

**MB3.3 Operations**

The following rules apply for arithmetic operations for the complex numbers  $z_1 = x_1 + iy_1$  and  $z_2 = x_2 + iy_2$ .

1. Addition:  $z_1 + z_2 = (x_1 + x_2) + i(y_1 + y_2)$  (MB3.10a)

2. Subtraction:  $z_1 - z_2 = (x_1 - x_2) + i(y_1 - y_2)$  (MB3.10b)

3. Multiplication:

$$\begin{aligned} z_1 z_2 &= (x_1 + iy_1)(x_2 + iy_2) \\ &= (x_1 x_2 - y_1 y_2) + i(x_1 y_2 + y_1 x_2) \end{aligned} \quad (\text{MB3.10c})$$

4. Division: We interpret  $z_1/z_2$  as  $z_1 z_2^{-1}$  and use eqn MB3.5 for the inverse:

$$\frac{z_1}{z_2} = z_1 z_2^{-1} = \frac{z_1 z_2^*}{|z_2|^2} \quad (\text{MB3.10d})$$

**Brief illustration MB3.3** Operations with numbers

Consider the complex numbers  $z_1 = 6 + 2i$  and  $z_2 = -4 - 3i$ . Then

$$z_1 + z_2 = (6 - 4) + (2 - 3)i = 2 - i$$

$$z_1 - z_2 = 10 + 5i$$

$$z_1 z_2 = \{6(-4) - 2(-3)\} + \{6(-3) + 2(-4)\}i = -18 - 26i$$

$$\frac{z_1}{z_2} = (6 + 2i) \left( \frac{-4 + 3i}{25} \right) = -\frac{6}{5} + \frac{2}{5}i$$

The polar form of a complex number is commonly used to perform arithmetical operations. For instance the product of two complex numbers in polar form is

$$z_1 z_2 = (r_1 e^{i\phi_1})(r_2 e^{i\phi_2}) = r_1 r_2 e^{i(\phi_1 + \phi_2)} \quad (\text{MB3.11})$$

This multiplication can be depicted in the complex plane, as shown in Fig. MB3.2.

The  $n$ th power and the  $n$ th root of a complex number are

$$z^n = (r e^{i\phi})^n = r^n e^{in\phi} \quad z^{1/n} = (r e^{i\phi})^{1/n} = r^{1/n} e^{i\phi/n} \quad (\text{MB3.12})$$

The depictions in the complex plane are shown in Fig. MB3.3.

**Figure MB3.2** The multiplication of two complex numbers depicted in the complex plane.

**Figure MB3.3** The  $n$ th powers ( $n = 1, 2, 3, 4, 5$ ) and the  $n$ th roots ( $n = 1, 2, 3, 4$ ) of a complex number depicted in the complex plane.

**Brief illustration MB3.4** Roots

To determine the 5th root of  $z = 8 - 3i$ , we note that from *Brief illustration* MB3.2 its polar form is

$$z = 73^{1/2} e^{-0.359i} = 8.544 e^{-0.359i}$$

The 5th root is therefore

$$z^{1/5} = (8.544 e^{-0.359i})^{1/5} = 8.544^{1/5} e^{-0.359i/5} = 1.536 e^{-0.0718i}$$

It follows that  $x = 1.536 \cos(-0.0718) = 1.532$  and  $y = 1.536 \sin(-0.0718) = -0.110$  (note that we work in radians), so

$$(8 - 3i)^{1/5} = 1.532 - 0.110i$$

# CHAPTER 8

## The quantum theory of motion

The three basic modes of motion—translation (motion through space), vibration, and rotation—all play an important role in chemistry because they are ways in which molecules store energy. Gas-phase molecules, for instance, undergo translational motion and their kinetic energy is a contribution to the total internal energy of a sample. Molecules can also store energy as rotational kinetic energy and transitions between their rotational energy states can be observed spectroscopically. Energy is also stored as molecular vibration, and transitions between vibrational states also give rise to spectroscopic signatures. In this Chapter we use the principles of quantum theory to calculate the properties of microscopic particles in motion.

### 8A Translation

In this Topic we see that, according to quantum theory, a particle constrained to move in a finite region of space is described by only certain wavefunctions and their corresponding energies. Hence, quantization emerges as a natural consequence of solving the Schrödinger equation and the conditions imposed on it. The solutions also bring to light a number of non-classical features of particles, especially their ability to tunnel into and through regions where classical physics would forbid them to be found.

### 8B Vibrational motion

This Topic introduces the ‘harmonic oscillator’, a simple but very important model for the description of molecular

vibrations. We see that the energies of oscillator are quantized. The acceptable wavefunctions also show that the oscillator may be found at extensions and compressions that are forbidden by classical physics.

### 8C Rotational motion

The energy of a rotating particle is quantized, but in this Topic we see that its angular momentum is also restricted to certain values. The quantization of angular momentum is a very important aspect of the quantum theory of electrons in atoms and of rotating molecules.

### What is the impact of this material?

‘Nanoscience’ is the study of atomic and molecular assemblies with dimensions ranging from 1 nm to about 100 nm and ‘nanotechnology’ is concerned with the incorporation of such assemblies into devices. We encounter several concepts of nanoscience throughout the text. In *Impact* I8.1 we explore quantum mechanical effects that render the properties of a nanometre-sized assembly dependent on its size.

### ► Why do you need to know this material?

The application of quantum theory to translation reveals the origin of quantization and other non-classical features of physical and chemical phenomena. This material is important for the discussion of atoms and molecules that are free to move within a restricted volume, such as a gas in a container.

### ► What is the key idea?

The translational energy levels of a particle confined to a finite region of space are quantized, and under certain conditions particles can pass into and through classically forbidden regions.

### ► What do you need to know already?

You should know that the wavefunction is the solution of the Schrödinger equation (Topic 7B), and be familiar with the techniques of deriving dynamical properties from the wavefunction by using operators corresponding to the observables (Topic 7C).

In this Topic we present the essential features of the solutions of the Schrödinger equation for translation, one of the basic types of motion. We see that quantization emerges as a natural consequence of the Schrödinger equation and conditions imposed on it. The solutions also bring to light a number of non-classical features of particles, especially their ability to tunnel into and through regions where classical physics would forbid them to be found.

## 8A.1 Free motion in one dimension

The Schrödinger equation for a particle of mass  $m$  moving freely in one dimension is (Topic 7B)

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} = E\psi(x) \quad \begin{array}{l} \text{Free motion} \\ \text{in one} \\ \text{dimension} \end{array} \quad \begin{array}{l} \text{Schrödinger} \\ \text{equation} \end{array} \quad (8A.1)$$

and the solutions are (as in eqn 7B.6)

$$\psi_k = Ae^{ikx} + Be^{-ikx} \quad E_k = \frac{k^2\hbar^2}{2m} \quad \begin{array}{l} \text{Free motion} \\ \text{in one} \\ \text{dimension} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{functions} \\ \text{and} \\ \text{energies} \end{array} \quad (8A.2)$$

with  $A$  and  $B$  constants. Note that we are now labelling both the wavefunctions and the energies with the index  $k$ . The wavefunctions in eqn 8A.2 are continuous, have continuous slope everywhere, are single-valued, and do not go to infinity, and so—in the absence of any other information—are acceptable for all values of  $k$ . Because the energy of the particle is proportional to  $k^2$ , all non-negative values, including zero, of the energy are permitted. *It follows that the translational energy of a free particle is not quantized.*

The values of the constants  $A$  and  $B$  depend on how the state of motion of the particle is prepared:

- If it is shot towards positive  $x$ , then its linear momentum is  $+k\hbar$  (Topic 7C), and its wavefunction is proportional to  $e^{ikx}$ . In this case  $B=0$  and  $A$  is a normalization factor.
- If the particle is shot in the opposite direction, towards negative  $x$ , then its linear momentum is  $-k\hbar$  and its wavefunction is proportional to  $e^{-ikx}$ . In this case,  $A=0$  and  $B$  is the normalization factor.

Physical interpretation

### Brief illustration 8A.1 The wavefunction of a freely-moving particle

An electron at rest that is shot out of an accelerator towards positive  $x$  through a potential difference of 1.0 V acquires a kinetic energy of 1.0 eV or 0.16 aJ ( $1.6 \times 10^{-19}$  J). The wavefunction for such a particle is given by eqn 8A.3 with  $B=0$  and  $k$  given by rearranging the expression for the energy in eqn 8A.2 into

$$k = \left( \frac{2m_e E_k}{\hbar^2} \right)^{1/2} = \left( \frac{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (1.6 \times 10^{-19} \text{ J})}{(1.055 \times 10^{-34} \text{ Js})^2} \right)^{1/2} = 5.1 \times 10^9 \text{ m}^{-1}$$

or  $5.1 \text{ nm}^{-1}$  (with  $1 \text{ nm} = 10^{-9} \text{ m}$ ). Therefore the wavefunction is  $\psi(x) = Ae^{5.1ix/\text{nm}}$ .

**Self-test 8A.1** Write the wavefunction for an electron travelling to the left (negative  $x$ ) after being accelerated through a potential difference of 10 kV.

Answer:  $\psi(x) = Be^{-510ix/\text{nm}}$

The probability density  $|\psi|^2$  is uniform if the particle is in either of the pure momentum states  $e^{ikx}$  or  $e^{-ikx}$ . According to the Born interpretation (Topic 7B), nothing further can be said about the location of the particle. That conclusion is consistent with the uncertainty principle, because if the momentum is certain, then the position cannot be specified (the operators corresponding to  $x$  and  $p$  do not commute and thus correspond to complementary observables, Topic 8C).

## 8A.2 Confined motion in one dimension

Consider a particle in a box in which a particle of mass  $m$  is confined to a finite region of space between two impenetrable walls. The potential energy is zero inside the box but rises abruptly to infinity at the walls at  $x=0$  and  $x=L$  (Fig. 8A.1).

**Figure 8A.1** A particle in a one-dimensional region with impenetrable walls. Its potential energy is zero between  $x=0$  and  $x=L$ , and rises abruptly to infinity as soon as it touches the walls.

When the particle is between the walls, the Schrödinger equation is the same as for a free particle (eqn 8A.1), so the general solutions given in eqn 8A.2 are also the same. However, it will prove convenient to use  $e^{\pm ikx} = \cos kx \pm i \sin kx$  (Mathematical background 3) to write

$$\begin{aligned} \psi_k(x) &= Ae^{ikx} + Be^{-ikx} = A(\cos kx + i \sin kx) + B(\cos kx - i \sin kx) \\ &= (A+B)\cos kx + (A-B)i \sin kx \end{aligned}$$

If we write  $C=(A-B)i$  and  $D=A+B$  the general solutions take the form

$$\psi_k(x) = C \sin kx + D \cos kx \quad \text{General solution for } 0 \leq x \leq L \quad (8A.3)$$

Outside the box the wavefunctions must be zero as the particle will not be found in a region where its potential energy is infinite:

$$\text{For } x < 0 \text{ and } x > L, \quad \psi_k(x) = 0 \quad (8A.4)$$

At this point, there are no restrictions on the value of  $k$  and all solutions appear to be acceptable.

### (a) The acceptable solutions

The requirement of the continuity of the wavefunction (Topic 7B) implies that  $\psi_k(x)$  as given by eqn 8A.3 must be zero at the walls, for it must match the wavefunction inside the material of the walls where the functions meet. That is, the wavefunction must satisfy the following two **boundary conditions**, or constraints on the function at certain locations:

$$\psi_k(0) = 0 \text{ and } \psi_k(L) = 0 \quad \text{Particle in a one-dimensional box} \quad \text{Boundary conditions} \quad (8A.5)$$

As we show in the following *Justification*, the requirement that the wavefunction satisfy these boundary conditions implies that only certain wavefunctions are acceptable and

that the only permitted wavefunctions and energies of the particle are

$$\psi_n(x) = C \sin\left(\frac{n\pi x}{L}\right) \quad n=1,2,\dots \quad (8A.6a)$$

$$E_n = \frac{n^2 h^2}{8mL^2} \quad n=1,2,\dots \quad (8A.6b)$$

where  $C$  is an as yet undetermined constant. Note that the wavefunctions and energy are now labelled with the dimensionless integer  $n$  instead of the quantity  $k$ .

### Justification 8A.1 The energy levels and wavefunctions of a particle in a one-dimensional box

From the boundary condition  $\psi_k(0)=0$  and the fact that, from eqn 8A.3,  $\psi_k(0)=D$  (because  $\sin 0=0$  and  $\cos 0=1$ ), we can conclude that  $D=0$ . It follows that the wavefunction must be of the form  $\psi_k(x)=C \sin kx$ . From the second boundary condition,  $\psi_k(L)=0$ , we know that  $\psi_k(L)=C \sin kL=0$ . We could take  $C=0$ , but doing so would give  $\psi_k(x)=0$  for all  $x$ , which would conflict with the Born interpretation (the particle must be somewhere). The alternative is to require that  $kL$  be chosen so that  $\sin kL=0$ . This condition is satisfied if

$$kL = n\pi \quad n=1,2,\dots$$

The value  $n=0$  is ruled out, because it implies  $k=0$  and  $\psi_k(x)=0$  everywhere (because  $\sin 0=0$ ), which is unacceptable. Negative values of  $n$  merely change the sign of  $\sin kL$  (because  $\sin(-x)=-\sin x$ ) and do not result in new solutions. The wavefunctions are therefore

$$\psi_n(x) = C \sin(n\pi x/L) \quad n=1,2,\dots$$

as in eqn 8A.6a. At this stage we have begun to label the solutions with the index  $n$  instead of  $k$ . Because  $k$  and  $E_k$  are related by eqn 8A.2, and  $k$  and  $n$  are related by  $kL=n\pi$ , it follows that the energy of the particle is limited to  $E_n=n^2 h^2/8mL^2$ , as in eqn 8A.6b.

We conclude that the energy of the particle in a one-dimensional box is quantized and that this quantization arises from the boundary conditions that  $\psi$  must satisfy. This is a general conclusion: *the need to satisfy boundary conditions implies that only certain wavefunctions are acceptable, and hence restricts observables to discrete values.* So far, only energy has been quantized; shortly we shall see that other physical observables may also be quantized.

We need to determine the constant  $C$  in eqn 8A.6a. To do so, we normalize the wavefunction to 1 by using a standard integral from the *Resource section*. Because the wavefunction is zero outside the range  $0 \leq x \leq L$ , we use

$$\int_0^L \psi^2 dx = C^2 \int_0^L \sin^2\left(\frac{n\pi x}{L}\right) dx \stackrel{\text{Integral T.2}}{=} C^2 \times \frac{L}{2} = 1, \quad \text{so } C = \left(\frac{2}{L}\right)^{1/2}$$

for all  $n$ . Therefore, the complete solution for the particle in a box is

$$\psi_n(x) = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{n\pi x}{L}\right) \quad \text{for } 0 \leq x \leq L \quad \text{One-dimensional box} \quad \text{Wave-functions} \quad (8A.7a)$$

$$\psi_n(x) = 0 \quad \text{for } x < 0 \text{ and } x > L$$

$$E_n = \frac{n^2 h^2}{8mL^2} \quad n=1,2,\dots \quad \text{One-dimensional box} \quad \text{Energy levels} \quad (8A.7b)$$

where the energies and wavefunctions are labelled with the quantum number  $n$ . A **quantum number** is an integer (in some cases, as we see in Topic 9B, a half-integer) that labels the state of the system. For a particle in a one-dimensional box there is an infinite number of acceptable solutions, and the quantum number  $n$  specifies the one of interest (Fig. 8A.2). As well as acting as a label, a quantum number can often be used to calculate the energy corresponding to the state and to write down the wavefunction explicitly (in the present example, by using the relations in eqn 8A.7).

**Figure 8A.2** The allowed energy levels for a particle in a box. Note that the energy levels increase as  $n^2$ , and that their separation increases as the quantum number increases. Classically, the particle is allowed to have any value of the energy in the continuum shown as a shaded area.

### Brief illustration 8A.2 The energy of a particle in a box

A long carbon nanotube can be modelled as a one-dimensional structure and its electrons described by particle-in-a-box wavefunctions. The lowest energy of an electron in a carbon nanotube of length 100 nm is given by eqn 8A.7b with  $n=1$ :

$$E_1 = \frac{(1)^2 \times \left( \frac{\text{kg m}^2 \text{ s}^{-2}}{\text{J s}} \right)^2}{8 \times (9.109 \times 10^{-31} \text{ kg}) \times (100 \times 10^{-9} \text{ m})^2} = 6.02 \times 10^{-24} \text{ J}$$

or 0.00602 zJ and its wavefunction is  $\psi_1(x) = (2/L)^{1/2} \sin(\pi x/L)$ .

**Self-test 8A.2** What are the energy and wavefunction for the next higher energy electron of the system described in this Brief illustration?

Answer:  $E_2 = 0.0241 \text{ zJ}$ ,  $\psi_2(x) = (2/L)^{1/2} \sin(2\pi x/L)$

**(b) The properties of the wavefunctions**

Figure 8A.3 shows some of the wavefunctions of a particle in a one-dimensional box. We see that:

- The wavefunctions are all sine functions with the same amplitude but different wavelengths.
- Shortening the wavelength results in a sharper average curvature of the wavefunction and therefore an increase in the kinetic energy of the particle (its only source of energy because  $V=0$  inside the box).
- The number of nodes also increases as  $n$  increase; the wavefunction  $\psi_n$  has  $n-1$  nodes.
- Increasing the number of nodes between walls of a given separation increases the average curvature of the wavefunction and hence the kinetic energy of the particle.
- The probability density for a particle in a one-dimensional box is

**Figure 8A.3** The first five normalized wavefunctions of a particle in a box. Each wavefunction is a standing wave; successive functions possess one more half wave and a correspondingly shorter wavelength.

**Figure 8A.4** (a) The first two wavefunctions, (b) the corresponding probability densities, and (c) a representation of the probability density in terms of the darkness of shading.

$$\psi_n^2(x) = \frac{2}{L} \sin^2\left(\frac{n\pi x}{L}\right) \quad (8A.8)$$

- and varies with position. The non-uniformity in the probability density is pronounced when  $n$  is small (Fig. 8A.4). The most probable locations of the particle correspond to the maxima in the probability density.

Physical interpretation

Physical interpretation

**Example 8A.1** Determining the probability of finding the particle in a finite region

The wavefunctions of an electron in a conjugated polyene can be approximated by particle-in-a-box wavefunctions. What is the probability,  $P$ , of locating the electron between  $x=0$  (the left-hand end of a molecule) and  $x=0.2$  nm in its lowest energy state in a conjugated molecule of length 1.0 nm?

**Method** According to the Born interpretation,  $\psi(x)^2 dx$  is the probability of finding the particle in the small region  $dx$  located at  $x$ ; therefore, the total probability of finding the electron in the specified region is the integral of  $\psi(x)^2 dx$  over that region, as given in eqn 7B.11. The wavefunction of the electron is given in eqn 8A.7a with  $n=1$ . The integral you need is in the *Resource section*:

**Answer** The probability of finding the particle in a region between  $x=0$  and  $x=l$  is

$$P = \int_0^l \psi_n^2 dx = \frac{2}{L} \int_0^l \sin^2\left(\frac{n\pi x}{L}\right) dx = \frac{l}{L} - \frac{1}{2n\pi} \sin\left(\frac{2n\pi l}{L}\right)$$

Now set  $n=1$ ,  $L=1.0$  nm, and  $l=0.2$  nm, which gives  $P=0.05$ . The result corresponds to a chance of 1 in 20 of finding the electron in the region. As  $n$  becomes infinite, the sine term, which is multiplied by  $1/n$ , makes no contribution to  $P$  and the classical result for a uniformly distributed particle,  $P=l/L$ , is obtained.

**Self-test 8A.3** Calculate the probability that an electron in the state with  $n=1$  will be found between  $x=0.25L$  and  $x=0.75L$  in a conjugated molecule of length  $L$  (with  $x=0$  at the left-hand end of the molecule).

Answer:  $P=0.82$

The probability density  $\psi_n^2(x)$  becomes more uniform as  $n$  increases provided we ignore the fine detail of the increasingly rapid oscillations (Fig. 8A.5). The probability density at high quantum numbers reflects the classical result that a particle bouncing between the walls spends, on the average, equal times at all points. That the quantum result corresponds to the classical prediction at high quantum numbers is an illustration of the **correspondence principle**, which states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached.

**Figure 8A.5** The probability density  $\psi^2(x)$  for large quantum number (here  $n=50$ , blue, compared with  $n=1$ , red). Notice that for high  $n$  the probability density is nearly uniform, provided we ignore the fine detail of the increasingly rapid oscillations.

### (c) The properties of observables

The linear momentum of a particle in a box is not well defined because the wavefunction  $\sin kx$  is not an eigenfunction of the linear momentum operator. However, each wavefunction is a linear combination of the linear momentum eigenfunctions  $e^{ikx}$  and  $e^{-ikx}$ . Then, because  $\sin x = (e^{ix} - e^{-ix})/2i$ , we can write

$$\psi_n(x) = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{n\pi x}{L}\right) = \frac{1}{2i} \left(\frac{2}{L}\right)^{1/2} (e^{ikx} - e^{-ikx}) \quad k = \frac{n\pi}{L} \quad (8A.9)$$

It follows from the discussion in Topic 7C that half the measurements of the linear momentum will give the value  $+k\hbar$  and  $-k\hbar$  for the other half. This detection of opposite directions of travel with equal probability is the quantum mechanical version of the classical picture that a particle in a one-dimensional box rattles from wall to wall and in any given period spends half its time travelling to the left and half travelling to the right.

Because  $n$  cannot be zero, the lowest energy that the particle may possess is not zero (as would be allowed by classical mechanics, corresponding to a stationary particle) but

$$E_1 = \frac{h^2}{8mL^2} \quad \text{Particle in a box} \quad \text{Zero-point energy} \quad (8A.10)$$

This lowest, irremovable energy is called the **zero-point energy**. The physical origin of the zero-point energy can be explained in two ways:

- The Heisenberg uncertainty principle requires a particle to possess kinetic energy if it is confined to a finite region: the location of the particle is not completely indefinite ( $\Delta x \neq \infty$ ), so the uncertainty in its momentum cannot be precisely zero ( $\Delta p \neq 0$ ). Because  $\Delta p = \langle p^2 \rangle - \langle p \rangle^2 = \langle p^2 \rangle^{1/2}$  in this case,  $\Delta p \neq 0$

Physical interpretation

implies that  $\langle p^2 \rangle \neq 0$ , which implies that the particle must always have nonzero kinetic energy.

- If the wavefunction is to be zero at the walls, but smooth, continuous, and not zero everywhere, then it must be curved, and curvature in a wavefunction implies the possession of kinetic energy.

Physical interpretation

The separation between adjacent energy levels with quantum numbers  $n$  and  $n+1$  is

$$E_{n+1} - E_n = \frac{(n+1)^2 h^2}{8mL^2} - \frac{n^2 h^2}{8mL^2} = (2n+1) \frac{h^2}{8mL^2} \quad (8A.11)$$

This separation decreases as the length of the container increases, and is very small when the container has macroscopic dimensions. The separation of adjacent levels becomes zero when the walls are infinitely far apart. Atoms and molecules free to move in normal laboratory-sized vessels may therefore be treated as though their translational energy is not quantized.

#### Example 8A.2 Estimating an absorption wavelength

$\beta$ -Carotene (**1**) is a linear polyene in which 10 single and 11 double bonds alternate along a chain of 22 carbon atoms. If we take each C–C bond length to be about 140 pm, then the length  $L$  of the molecular box in  $\beta$ -carotene is  $L = 2.94$  nm. Estimate the wavelength of the light absorbed by this molecule from its ground state to the next higher excited state.

**1**  $\beta$ -Carotene

**Method** For reasons that will be familiar from introductory chemistry, each C atom contributes one p electron to the  $\pi$ -orbitals. Use eqn 8A.11 to calculate the energy separation between the highest occupied and the lowest unoccupied levels, and convert that energy to a wavelength by using the Bohr frequency relation (eqn 7A.12).

**Answer** There are 22 C atoms in the conjugated chain; each contributes one p electron to the levels, so each level up to  $n=11$  is occupied by two electrons. The separation in energy between the ground state and the state in which one electron is promoted from  $n=11$  to  $n=12$  is

$$\begin{aligned} \Delta E &= E_{12} - E_{11} \\ &= (2 \times 11 + 1) \frac{(6.626 \times 10^{-34} \text{ Js})^2}{8 \times (9.109 \times 10^{-31} \text{ kg}) \times (2.94 \times 10^{-9} \text{ m})^2} \\ &= 1.60 \times 10^{-19} \text{ J} \end{aligned}$$

or 0.160 aJ. It follows from the Bohr frequency condition ( $\Delta E = h\nu$ ) that the frequency of radiation required to cause this transition is

$$\nu = \frac{\Delta E}{h} = \frac{1.60 \times 10^{-19} \text{ J}}{6.626 \times 10^{-34} \text{ Js}} = 2.41 \times 10^{14} \text{ s}^{-1}$$

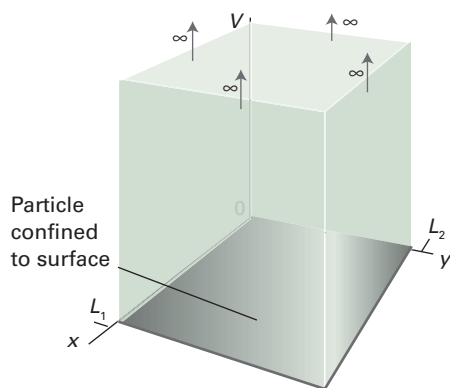

or 241 THz (1 THz =  $10^{12}$  Hz), corresponding to a wavelength  $\lambda = 1240$  nm. The experimental value is 603 THz ( $\lambda = 497$  nm), corresponding to radiation in the visible range of the electromagnetic spectrum. Considering the crudeness of the model we have adopted here, we should be encouraged that the computed and observed frequencies agree to within a factor of 2.5.

**Self-test 8A.4** Estimate a typical nuclear excitation energy in electronvolts (1 eV =  $1.602 \times 10^{-19}$  J; 1 GeV =  $10^9$  eV) by calculating the first excitation energy of a proton confined to a one-dimensional box with a length equal to the diameter of a nucleus (approximately  $1 \times 10^{-15}$  m, or 1 fm).

Answer: 0.6 GeV

### 8A.3 Confined motion in two or more dimensions

Now consider a rectangular two-dimensional region of a surface with length  $L_1$  in the  $x$ -direction and  $L_2$  in the  $y$ -direction; the potential energy is zero everywhere except at the walls, where it is infinite (Fig. 8A.6). As a result, the particle is never found at the walls and its wavefunction is zero there and everywhere outside the two-dimensional region. Between the walls, because the particle has contributions to its kinetic energy from its motion in both the  $x$  and  $y$  directions, the Schrödinger equation has two kinetic energy terms, one for each axis. For a particle of mass  $m$  the equation is

**Figure 8A.6** A two-dimensional square well. The particle is confined to the plane bounded by impenetrable walls. As soon as it touches the walls, its potential energy rises to infinity.

$$-\frac{\hbar^2}{2m} \left( \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} \right) = E\psi \quad (8A.12)$$

This is a *partial* differential equation (*Mathematical background 4*), and the resulting wavefunctions are functions of both  $x$  and  $y$ , denoted  $\psi(x, y)$ . This dependence means that the wavefunction and the corresponding probability density depend on the location in the plane, with each position specified by the values of the coordinates  $x$  and  $y$ .

#### (a) Separation of variables

A partial differential equation of the form of eqn 8A.12 can be simplified by the **separation of variables technique** (*Mathematical background 4*), which divides the equation into two or more ordinary differential equations, one for each variable. We show in the *Justification* below using this technique that the wavefunction can be written as a product of functions, one depending only on  $x$  and the other only on  $y$ :

$$\psi(x, y) = X(x)Y(y) \quad (8A.13a)$$

and that the total energy is given by

$$E = E_x + E_y \quad (8A.13b)$$

where  $E_x$  is the energy associated with the motion of the particle parallel to the  $x$ -axis, and likewise for  $E_y$  and motion parallel to the  $y$ -axis.

#### Justification 8A.2 The separation of variables technique applied to the particle in a two-dimensional box

We follow the procedure in *Mathematical background 4* and apply it to eqn 8A.12. The first step to confirm that the Schrödinger equation can be separated and the wavefunction can be factored into the product of two functions  $X$  and  $Y$  is to note that, because  $X$  is independent of  $y$  and  $Y$  is independent of  $x$ , we can write

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{\partial^2 XY}{\partial x^2} = Y \frac{d^2 X}{dx^2} \quad \frac{\partial^2 \psi}{\partial y^2} = \frac{\partial^2 XY}{\partial y^2} = X \frac{d^2 Y}{dy^2}$$

Note the replacement of the partial derivatives by ordinary derivatives in each case. Then eqn 8A.12 becomes

$$-\frac{\hbar^2}{2m} \left( Y \frac{d^2 X}{dx^2} + X \frac{d^2 Y}{dy^2} \right) = EXY$$

Next, we divide both sides by  $XY$ , and rearrange the resulting equation into

$$\frac{1}{X} \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} = -\frac{2mE}{\hbar^2}$$

The first term on the left,  $(1/X)(d^2X/dx^2)$ , is independent of  $y$ , so if  $y$  is varied only the second term on the left,  $(1/Y)(d^2Y/dy^2)$ , can change. But the sum of these two terms is a constant,  $2mE/\hbar^2$ , given by the right-hand side of the equation. Therefore, if the second term did change, then the right-hand side could not be constant. Consequently, even the second term cannot change when  $y$  is changed. In other words, the second term,  $(1/Y)(d^2Y/dy^2)$ , is a constant, which we write  $-2mE_Y/\hbar^2$ . By a similar argument, the first term,  $(1/X)(d^2X/dx^2)$ , is a constant when  $x$  changes, and we write it  $-2mE_X/\hbar^2$ , with  $E = E_X + E_Y$ . Therefore, we can write

$$\frac{1}{X} \frac{d^2X}{dx^2} = -\frac{2mE_X}{\hbar^2} \quad \frac{1}{Y} \frac{d^2Y}{dy^2} = -\frac{2mE_Y}{\hbar^2}$$

These expressions rearrange into the two ordinary (that is, single-variable) differential equations

$$-\frac{\hbar^2}{2m} \frac{d^2X}{dx^2} = E_X X \quad -\frac{\hbar^2}{2m} \frac{d^2Y}{dy^2} = E_Y Y \quad (8A.14)$$

Each of the two ordinary differential equations in eqn 8A.14 is the same as the one-dimensional particle-in-a-box Schrödinger equation (Section 8A.2). The boundary conditions are also the same, apart from the detail of requiring  $X(x)$  to be zero at  $x=0$  and  $L_1$ , and  $Y(y)$  to be zero at  $y=0$  and  $L_2$ . We can therefore adapt eqn 8A.7a without further calculation:

$$X_{n_1}(x) = \left(\frac{2}{L_1}\right)^{1/2} \sin\left(\frac{n_1\pi x}{L_1}\right) \quad \text{for } 0 \leq x \leq L_1$$

$$Y_{n_2}(y) = \left(\frac{2}{L_2}\right)^{1/2} \sin\left(\frac{n_2\pi y}{L_2}\right) \quad \text{for } 0 \leq y \leq L_2$$

Then, because  $\psi = XY$ ,

$$\begin{aligned} \psi_{n_1, n_2}(x, y) &= \frac{2}{(L_1 L_2)^{1/2}} \times \\ &\sin\left(\frac{n_1\pi x}{L_1}\right) \sin\left(\frac{n_2\pi y}{L_2}\right) \quad \text{Two-dimensional Wave-functions} \\ &\text{for } 0 \leq x \leq L_1, 0 \leq y \leq L_2 \\ \psi_{n_1, n_2}(x, y) &= 0 \quad \text{outside box} \end{aligned} \quad (8A.15a)$$

Similarly, because  $E = E_X + E_Y$ , the energy of the particle is limited to the values

$$E_{n_1, n_2} = \left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2}\right) \frac{\hbar^2}{8m} \quad \text{Two-dimensional Energy levels} \quad (8A.15b)$$

with the two quantum numbers taking the values  $n_1 = 1, 2, \dots$  and  $n_2 = 1, 2, \dots$  independently. The state of lowest energy ( $n_1 = 1, n_2 = 1$ ) and  $E_{1,1}$  is the zero-point energy.

**Figure 8A.7** The wavefunctions for a particle confined to a rectangular surface depicted as contours of equal amplitude. (a)  $n_1 = 1, n_2 = 1$ , the state of lowest energy; (b)  $n_1 = 1, n_2 = 2$ ; (c)  $n_1 = 2, n_2 = 1$ ; (d)  $n_1 = 2, n_2 = 2$ .

Some of the wavefunctions are plotted as contours in Fig. 8A.7. They are the two-dimensional versions of the wavefunctions shown in Fig. 8A.3. Whereas in one dimension the wavefunctions resemble states of a vibrating string with ends fixed, in two dimensions the wavefunctions correspond to vibrations of a rectangular plate with fixed edges.

#### Brief illustration 8A.3 The distribution of a particle in a two-dimensional box

Consider an electron confined to a square cavity of side  $L$ , and in the state with quantum numbers  $n_1 = 1, n_2 = 2$ . Because the probability density is

$$\psi_{1,2}^2(x, y) = \frac{4}{L^2} \sin^2\left(\frac{\pi x}{L}\right) \sin^2\left(\frac{2\pi y}{L}\right)$$

the most probable locations correspond to  $\sin^2(\pi x/L) = 1$  and  $\sin^2(2\pi y/L) = 1$ , or  $(x, y) = (L/2, L/4)$  and  $(L/2, 3L/4)$ . The least probable locations (the nodes, where the wavefunction passes through zero) correspond to zeroes in the probability density within the box, which occur along the line  $y = L/2$ .

**Self-test 8A.5** Determine the most probable locations of an electron in a square cavity of side  $L$  when it is in the state with quantum numbers  $n_1 = 2, n_2 = 3$ .

Answer: points  $(x = L/4 \text{ and } 3L/4; y = L/6, L/2, \text{ and } 5L/6)$

We treat a particle in a three-dimensional box in the same way. The wavefunctions have another factor (for the  $z$ -dependence), and the energy has an additional term in  $n_3^2/L_3^2$ . Solution of the Schrödinger equation by the separation of variables technique then gives

$$\psi_{n_1, n_2, n_3}(x, y, z) = \left(\frac{8}{L_1 L_2 L_3}\right)^{1/2} \sin\left(\frac{n_1 \pi x}{L_1}\right) \sin\left(\frac{n_2 \pi y}{L_2}\right) \sin\left(\frac{n_3 \pi z}{L_3}\right)$$

for  $0 \leq x \leq L_1, 0 \leq y \leq L_2, 0 \leq z \leq L_3$

Three-dimensional box    Wavefunctions    (8A.16a)

$$E_{n_1, n_2, n_3} = \left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} + \frac{n_3^2}{L_3^2}\right) \frac{h^2}{8m}$$

Three-dimensional box    Energy levels    (8A.16b)

The quantum numbers  $n_1$ ,  $n_2$ , and  $n_3$  are all positive integers 1, 2, ... that can be varied independently. The system has a zero-point energy ( $E_{1,1,1} = 3h^2/8mL^2$  for a cubic box).

### (b) Degeneracy

A special feature of the solutions arises when a two-dimensional box is not merely rectangular but square, with  $L_1 = L_2 = L$ . Then the wavefunctions and their energies are

$$\psi_{n_1, n_2}(x, y) = \frac{2}{L} \sin\left(\frac{n_1 \pi x}{L}\right) \sin\left(\frac{n_2 \pi y}{L}\right)$$

for  $0 \leq x \leq L, 0 \leq y \leq L$

Square box    Wavefunctions    (8.17a)

$$\psi_{n_1, n_2}(x, y) = 0 \quad \text{outside box}$$

$$E_{n_1, n_2} = (n_1^2 + n_2^2) \frac{h^2}{8mL^2}$$

Square box    Energy levels    (8.17b)

Consider the cases  $n_1 = 1, n_2 = 2$  and  $n_1 = 2, n_2 = 1$ :

$$\psi_{1,2} = \frac{2}{L} \sin\left(\frac{\pi x}{L}\right) \sin\left(\frac{2\pi y}{L}\right) \quad E_{1,2} = \frac{5h^2}{8mL^2}$$

$$\psi_{2,1} = \frac{2}{L} \sin\left(\frac{2\pi x}{L}\right) \sin\left(\frac{\pi y}{L}\right) \quad E_{2,1} = \frac{5h^2}{8mL^2}$$

Although the wavefunctions are different, they have the same energy. The technical term for different wavefunctions corresponding to the same energy is **degeneracy**, and in this case we say that the state with energy  $5h^2/8mL^2$  is 'doubly degenerate'. In general, if  $N$  wavefunctions correspond to the same energy, then we say that the state is ' $N$ -fold degenerate'.

The occurrence of degeneracy is related to the symmetry of the system. Figure 8A.8 shows contour diagrams of the two degenerate functions  $\psi_{1,2}$  and  $\psi_{2,1}$ . Because the box is square, one wavefunction can be converted into the other simply by rotating the plane by  $90^\circ$ . Interconversion by rotation through  $90^\circ$  is not possible when the plane is not square, and  $\psi_{1,2}$  and

**Figure 8A.8** The wavefunctions for a particle confined to a square well. Note that one wavefunction can be converted into the other by rotation of the box by  $90^\circ$ . The two functions correspond to the same energy. True degeneracy is a consequence of symmetry.

$\psi_{2,1}$  are then not degenerate. Similar arguments account for the degeneracy of states in a cubic box. Other examples of degeneracy occur in quantum mechanical systems (for instance, in the hydrogen atom, Topic 9A), and all of them can be traced to the symmetry properties of the system.

#### Brief illustration 8A.4 Degeneracies in a two-dimensional box

The energy of a particle in a two-dimensional square box of side  $L$  in the state with  $n_1 = 1, n_2 = 7$  is

$$E_{1,7} = (1^2 + 7^2) \frac{h^2}{8mL^2} = \frac{50h^2}{8mL^2}$$

This state is degenerate with the state with  $n_1 = 7$  and  $n_2 = 1$ . Thus, at first sight the energy level  $50h^2/8mL^2$  is doubly degenerate. However, in certain systems there may be states that are not apparently related by symmetry but are 'accidentally' degenerate. Such is the case here, for the state with  $n_1 = 5$  and  $n_2 = 5$  also has energy  $50h^2/8mL^2$ . Accidental degeneracy is also encountered in the hydrogen atom (Topic 9A).

**Self-test 8A.6** Find a state  $(n_1, n_2)$  for a particle in a rectangular box with sides of length  $L_1 = L$  and  $L_2 = 2L$  that is accidentally degenerate with the state  $(4,4)$ .

Answer:  $(n_1 = 2, n_2 = 8)$

## 8A.4 Tunnelling

If the potential energy of a particle does not rise to infinity when it is in the wall of the container, and  $E < V$ , the wavefunction does not decay abruptly to zero. If the walls are thin (so that the potential energy falls to zero again after a finite distance), then the wavefunction oscillates inside the box, varies

**Figure 8A.9** A particle incident on a barrier from the left has an oscillating wave function, but inside the barrier there are no oscillations (for  $E < V$ ). If the barrier is not too thick, the wavefunction is nonzero at its opposite face, and so oscillates again there. (Only the real component of the wavefunction is shown.)

smoothly inside the region representing the wall, and oscillates again on the other side of the wall outside the box (Fig. 8A.9). Hence the particle might be found on the outside of a container even though according to classical mechanics it has insufficient energy to escape. Such leakage by penetration through a classically forbidden region is called **tunnelling**.

The Schrödinger equation is used to calculate the probability of tunnelling of a particle of mass  $m$  incident from the left on a rectangular potential energy barrier that extends from  $x=0$  to  $x=L$ . On the left of the barrier ( $x < 0$ ) the wavefunctions are those of a particle with  $V=0$ , so from eqn 8A.2 we can write

$$\psi = Ae^{ikx} + Be^{-ikx} \quad k\hbar = (2mE)^{1/2} \quad \begin{array}{l} \text{Particle in a} \\ \text{rectangular} \\ \text{barrier} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{function} \\ \text{left of} \\ \text{barrier} \end{array} \quad (8A.18)$$

The Schrödinger equation for the region representing the barrier ( $0 \leq x \leq L$ ), where the potential energy is the constant  $V$ , is

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} + V\psi(x) = E\psi(x) \quad (8A.19)$$

We shall consider particles that have  $E < V$  (so, according to classical physics, the particle has insufficient energy to pass through the barrier), and therefore for which  $V - E > 0$ . The general solutions of this equation are

$$\psi = Ce^{\kappa x} + De^{-\kappa x} \quad \kappa\hbar = \{2m(V - E)\}^{1/2} \quad \begin{array}{l} \text{Particle in a} \\ \text{rectangular} \\ \text{barrier} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{function} \\ \text{inside} \\ \text{barrier} \end{array} \quad (8A.20)$$

as can be verified by differentiating  $\psi$  twice with respect to  $x$ . The important feature to note is that the two exponentials in eqn 8A.20 are now real functions, as distinct from the complex, oscillating functions for the region where  $V=0$ . To the right of the barrier ( $x > L$ ), where  $V=0$  again, the wavefunctions are

$$\psi = A'e^{ikx} \quad k\hbar = (2mE)^{1/2} \quad \begin{array}{l} \text{Particle in a} \\ \text{rectangular} \\ \text{barrier} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{function} \\ \text{right of} \\ \text{barrier} \end{array} \quad (8A.21)$$

**Figure 8A.10** When a particle is incident on a barrier from the left, the wavefunction consists of a wave representing linear momentum to the right, a reflected component representing momentum to the left, a varying but not oscillating component inside the barrier, and a (weak) wave representing motion to the right on the far side of the barrier.

Note that to the right of the barrier, the particle can only be moving to the right and therefore terms of the form  $e^{-ikx}$  do not contribute to the wavefunction in eqn 8A.21.

The complete wavefunction for a particle incident from the left consists of (Fig. 8A.10):

- an incident wave ( $Ae^{ikx}$  corresponds to positive momentum);
- a wave reflected from the barrier ( $Be^{-ikx}$  corresponds to negative momentum, motion to the left);
- the exponentially changing amplitudes inside the barrier (eqn 8A.20);
- an oscillating wave (eqn 8A.21) representing the propagation of the particle to the right after tunnelling through the barrier successfully.

Physical interpretation

The probability that a particle is travelling towards positive  $x$  (to the right) on the left of the barrier ( $x < 0$ ) is proportional to  $|A|^2$ , and the probability that it is travelling to the right on the right of the barrier ( $x > L$ ) is  $|A'|^2$ . The ratio of these two probabilities,  $|A'|^2/|A|^2$ , which reflects the probability of the particle tunnelling through the barrier, is called the **transmission probability**,  $T$ .

To determine the relationship between  $|A'|^2$  and  $|A|^2$ , we need to investigate the relationships between the coefficients  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $A'$ . Since the acceptable wavefunctions must be continuous at the edges of the barrier (at  $x=0$  and  $x=L$ , remembering that  $e^0=1$ ):

$$A + B = C + D \quad Ce^{\kappa L} + De^{-\kappa L} = A'e^{ikL} \quad (8A.22a)$$

Their slopes (their first derivatives) must also be continuous there (Fig. 8A.11):

$$ikA - ikB = \kappa C - \kappa D \quad \kappa Ce^{\kappa L} - \kappa De^{-\kappa L} = ikA'e^{ikL} \quad (8A.22b)$$

**Figure 8A.11** The wavefunction and its slope must be continuous at the edges of the barrier. The conditions for continuity enable us to connect the wavefunctions in the three zones and hence to obtain relations between the coefficients that appear in the solutions of the Schrödinger equation.

After straightforward but lengthy algebraic manipulations of the above set of equations 8A.22 (see Problem 8A.6), we find

$$T = \left\{ 1 + \frac{(e^{\kappa L} - e^{-\kappa L})^2}{16\varepsilon(1-\varepsilon)} \right\}^{-1} \quad \begin{array}{l} \text{Rectangular} \\ \text{potential} \\ \text{barrier} \end{array} \quad \begin{array}{l} \text{Transmission} \\ \text{probability} \end{array} \quad (8A.23a)$$

where  $\varepsilon = E/V$ . This function is plotted in Fig. 8A.12. The transmission probability for  $E > V$  is shown there too. The transmission probability has the following properties:

- $T \approx 0$  for  $E \ll V$ ;
- $T$  increases as  $E$  approaches  $V$ : the probability of tunnelling increases;

Physical interpretation

**Figure 8A.12** The transmission probabilities for passage through a rectangular potential barrier. The horizontal axis is the energy of the incident particle expressed as a multiple of the barrier height. The curves are labelled with the value of  $L(2mV)^{1/2}/\hbar$ . The graph on the left is for  $E < V$  and that on the right for  $E > V$ . Note that  $T > 0$  for  $E < V$  whereas classically  $T$  would be zero. However,  $T < 1$  for  $E > V$ , whereas classically  $T$  would be 1.

- $T$  approaches, but is still less than, 1 for  $E > V$ : there is still a probability of the particle being reflected by the barrier even when classically it can pass over it;
- $T \approx 1$  for  $E \gg V$ , as expected classically.

Physical interpretation

For high, wide barriers (in the sense that  $\kappa L \gg 1$ ), eqn 8A.23a simplifies to

$$T \approx 16\varepsilon(1-\varepsilon)e^{-2\kappa L} \quad \begin{array}{l} \text{Rectangular} \\ \text{potential} \\ \text{barrier; } \kappa L \gg 1 \end{array} \quad \begin{array}{l} \text{Transmission} \\ \text{probability} \end{array} \quad (8A.23b)$$

The transmission probability decreases exponentially with the thickness of the barrier and with  $m^{1/2}$ . It follows that particles of low mass are more able to tunnel through barriers than heavy ones (Fig. 8A.13). Tunnelling is very important for electrons and muons ( $m_\mu \approx 207 m_e$ ), and moderately important for protons ( $m_p \approx 1840 m_e$ ); for heavier particles it is less important.

A number of effects in chemistry (for example, the isotope-dependence of some reaction rates) depend on the ability of the proton to tunnel more readily than the deuteron. The very rapid equilibration of proton transfer reactions is also a manifestation of the ability of protons to tunnel through barriers and transfer quickly from an acid to a base. Tunnelling of protons between acidic and basic groups is also an important feature of the mechanism of some enzyme-catalysed reactions.

**Figure 8A.13** The wavefunction of a heavy particle decays more rapidly inside a barrier than that of a light particle. Consequently, a light particle has a greater probability of tunnelling through the barrier.

#### Brief illustration 8A.5 Transmission probabilities for a rectangular barrier

Suppose that a proton of an acidic hydrogen atom is confined to an acid that can be represented by a barrier of height 2.000 eV and length 100 pm. The probability that a proton with energy 1.995 eV (corresponding to 0.3195 aJ) can escape from the acid is computed using 8A.23a, with  $\varepsilon = E/V = 1.995 \text{ eV}/2.000 \text{ eV} = 0.9975$  and  $V - E = 0.005 \text{ eV}$  (corresponding to  $8.0 \times 10^{-22} \text{ J}$ ).

$$\kappa = \frac{\{2 \times (1.67 \times 10^{-27} \text{ kg}) \times (8.0 \times 10^{-22} \text{ J})\}^{1/2}}{1.055 \times 10^{-34} \text{ J s}} = 1.55 \dots \times 10^{10} \text{ m}^{-1}$$

We have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . It follows that

$$\kappa L = (1.55 \dots \times 10^{10} \text{ m}^{-1}) \times (100 \times 10^{-12} \text{ m}) = 1.55 \dots$$

Equation 8A.23a then yields

$$T = \left\{ 1 + \frac{(e^{1.55 \dots} - e^{-1.55 \dots})^2}{16 \times 0.9975 \times (1 - 0.9975)} \right\}^{-1} = 1.96 \times 10^{-3}$$

The larger the value of  $L(2mV)^{1/2}/\hbar$  (here, 31) the smaller is the value of  $T$  for energies close to, but below, the barrier height.

**Self-test 8A.7** Suppose that the junction between two semiconductors can be represented by a barrier of height 2.00 eV and length 100 pm. Calculate the probability that an electron of energy 1.95 eV can tunnel through the barrier.

Answer:  $T = 0.881$

A problem related to tunnelling is that of a particle in a square-well potential of finite depth (Fig. 8A.14). In this kind of potential, the wavefunction penetrates into the walls, where it decays exponentially towards zero, and oscillates within the well. The wavefunctions are found by ensuring, as in the discussion of tunnelling, that they and their slopes are continuous at the edges of the potential. Some of the lowest energy solutions are shown in Fig. 8A.15. A further difference from the solutions for an infinitely deep well is that there is only a finite number of bound states. Regardless of the depth and length of the well, however, there is always at least one bound state. Detailed consideration of the Schrödinger equation for the problem shows that in general the number of levels is equal to  $N$ , with

Figure 8A.14 A potential well with a finite depth.

Figure 8A.15 The lowest two bound-state wavefunctions for a particle in the well shown in Fig. 8A.14.

$$N - 1 < \frac{(8mVL)^{1/2}}{h} < N \quad (8A.24)$$

where  $V$  is the depth of the well and  $L$  is its length. We see that the deeper and wider the well, the greater the number of bound states. As the depth becomes infinite, so the number of bound states also becomes infinite, as we have already seen.

## Checklist of concepts

1. The translational energy of a free particle is not quantized.
2. The need to satisfy **boundary conditions** implies that only certain wavefunctions are acceptable and therefore restricts observables to discrete values.
3. A **quantum number** is an integer (in certain cases, a half-integer) that labels the state of the system.
4. A particle in a box possesses a **zero-point energy**, an irremovable minimum energy.
5. The **correspondence principle** states that classical mechanics emerges from quantum mechanics as high quantum numbers are reached.
6. The wavefunction for a particle in a two- or three-dimensional box is the product of wavefunctions for the particle in a one-dimensional box.
7. The energy of a particle in a two- or three-dimensional box is the sum of energies for the particle in two or three one-dimensional boxes.
8. The zero-point energy for a particle in a two-dimensional box corresponds to the state with quantum numbers  $(n_1 = 1, n_2 = 1)$ ; for three dimensions,  $(n_1 = 1, n_2 = 1, n_3 = 1)$ .
9. **Degeneracy** occurs when different wavefunctions correspond to the same energy.

- 10. The occurrence of degeneracy is a consequence of the symmetry of the system.
- 11. Penetration into or through a classically forbidden region is called **tunnelling**.
- 12. The probability of tunnelling decreases with an increase in the height and width of the potential barrier.
- 13. Light particles are more able to tunnel through barriers than heavy ones.

### ► Why do you need to know this material?

The detection and interpretation of vibrational frequencies is the basis of infrared spectroscopy (Topics 12D and 12E). Molecular vibration plays a role in the interpretation of thermodynamic properties, such as heat capacities (Topics 5E and 15F), and of the rates of chemical reactions (Topic 21C).

### ► What is the key idea?

The quantum mechanical treatment of the simplest model of vibrational motion, the harmonic oscillator, reveals that the energy is quantized and the wavefunctions are products of a polynomial and a Gaussian (bell-shaped) function.

### ► What do you need to know already?

You should know how to formulate the Schrödinger equation given a potential energy function. You should also be familiar with the concepts of tunnelling (Topic 8A) and the expectation value of an observable (Topic 7B).

Atoms in molecules and solids vibrate around their mean positions as bonds stretch, compress, and bend. Here we consider one particular type of vibrational motion, that of ‘harmonic motion’ in one dimension.

## 8B.1 The harmonic oscillator

A particle undergoes **harmonic motion**, and is said to be a **harmonic oscillator**, if it experiences a restoring force proportional to its displacement:

$$F = -k_f x \quad \text{Harmonic motion} \quad \text{Restoring force} \quad (8B.1)$$

where  $k_f$  is the **force constant**: the stiffer the ‘spring’, the greater the value of  $k_f$ . Because force is related to potential energy by  $F = -dV/dx$  (see *Foundations B*), the force in eqn 8B.1 corresponds to the particle having a potential energy

$$V(x) = \frac{1}{2} k_f x^2 \quad \text{Parabolic potential energy} \quad (8B.2)$$

when it is displaced through a distance  $x$  from its equilibrium position. This expression, which is the equation of a parabola (Fig. 8B.1), is the origin of the term ‘parabolic potential energy’ for the potential energy characteristic of a harmonic oscillator. The Schrödinger equation for the particle of mass  $m$  is therefore

**Figure 8B.1** The parabolic potential energy  $V = \frac{1}{2} k_f x^2$  of a harmonic oscillator, where  $x$  is the displacement from equilibrium. The narrowness of the curve depends on the force constant  $k_f$ : the larger the value of  $k_f$ , the narrower the well.

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} + \frac{1}{2}k_f x^2 \psi(x) = E\psi(x) \quad \text{Harmonic oscillator Schrödinger equation} \quad (8B.3)$$

We can anticipate that the energy of an oscillator will be quantized because the wavefunction has to satisfy boundary conditions (as in Topic 8A for a particle in a box): it will not be found with very large extensions because its potential energy rises to infinity there. That is, when we impose the boundary conditions  $\psi=0$  at  $x=\pm\infty$ , we can expect to find that only certain wavefunctions and their corresponding energies are possible.

### (a) The energy levels

Equation 8B.3 is a standard equation in the theory of differential equations and its solutions are well known to mathematicians.<sup>1</sup> The permitted energy levels are

$$E_\nu = \left(\nu + \frac{1}{2}\right)\hbar\omega \quad \omega = (k_f/m)^{1/2} \quad \text{Harmonic oscillator Energy levels} \quad (8B.4)$$

$\nu = 0, 1, 2, \dots$

where  $\omega$  (omega) is the frequency of oscillation of a classical harmonic oscillator of the same mass and force constant. Note that  $\omega$  is large when the force constant is large and the mass small. It follows that the separation between adjacent levels is

$$E_{\nu+1} - E_\nu = \hbar\omega \quad (8B.5)$$

which is the same for all  $\nu$ . Therefore, the energy levels form a uniform ladder of spacing  $\hbar\omega$  (Fig. 8B.2). The energy separation  $\hbar\omega$  is negligibly small for macroscopic objects (with large mass) for which classical mechanics is adequate for

**Figure 8B.2** The energy levels of a harmonic oscillator are evenly spaced with separation  $\hbar\omega$ , with  $\omega=(k_f/m)^{1/2}$ . Even in its lowest energy state, an oscillator has an energy greater than zero.

<sup>1</sup> For details, see our *Molecular quantum mechanics*, Oxford University Press, Oxford (2011).

describing vibrational motion; however, the energy separation is of great importance for objects with mass similar to that of atoms.

Because the smallest permitted value of  $\nu$  is 0, it follows from eqn 8B.4 that a harmonic oscillator has a zero-point energy

$$E_0 = \frac{1}{2}\hbar\omega \quad \text{Harmonic oscillator Zero-point energy} \quad (8B.6)$$

The mathematical reason for the zero-point energy is that  $\nu$  cannot take negative values, for if it did the wavefunction would not obey the boundary conditions. The physical reason is the same as for the particle in a box (Topic 8A): the particle is confined, its position is not completely uncertain, and therefore its momentum, and hence its kinetic energy, cannot be exactly zero. We can picture this zero-point state as one in which the particle fluctuates incessantly around its equilibrium position; classical mechanics would allow the particle to be perfectly still.

Atoms vibrate relative to one another in molecules with the bond acting like a spring. The question then arises as to what mass to use to predict the frequency of the vibration. In general, the relevant mass is a complicated combination of the masses of all the atoms that move, with each contribution weighted by the amplitude of the atom's motion. That amplitude depends on the mode of motion, such as whether the vibration is a bending motion or a stretching motion, so each mode of vibration has a characteristic 'effective mass'. For a diatomic molecule AB, however, for which there is only one mode of vibration, corresponding to the stretching and compression of the bond, the **effective mass**,  $\mu$ , has a very simple form:

$$\mu = \frac{m_A m_B}{m_A + m_B} \quad \text{Diatomic molecule Effective mass} \quad (8B.7)$$

When A is much heavier than B,  $m_B$  can be neglected in the denominator and the effective mass is  $\mu \approx m_B$ , the mass of the lighter atom. This result is plausible, for in the limit of the heavy atom being like a brick wall, only the lighter atom moves and hence determines the vibrational frequency.

#### Brief illustration 8B.1 The vibration of a diatomic molecule

The effective mass of  $^1\text{H}^{35}\text{Cl}$  is

$$\mu = \frac{m_{\text{H}} m_{\text{Cl}}}{m_{\text{H}} + m_{\text{Cl}}} = \frac{(1.0078m_u) \times (34.9688m_u)}{(1.0078m_u) + (34.9688m_u)} = 0.9796m_u$$

which is close to the mass of the proton. The force constant of the bond is  $k_f = 516.3 \text{ N m}^{-1}$ . It follows from eqn 8B.4, with  $\mu$  in place of  $m$ , that

$$\omega = \left( \frac{k_f}{\mu} \right)^{1/2} = \left( \frac{516.3 \text{ N m}^{-1}}{0.9796 \times (1.66054 \times 10^{-27} \text{ kg})} \right)^{1/2} = 5.634 \times 10^{14} \text{ s}^{-1}$$

or 563.4 THz. (We have used  $1 \text{ N} = 1 \text{ kg m s}^{-2}$ .) Therefore the separation of adjacent levels is (eqn 8B.5)

$$E_{\nu+1} - E_\nu = (1.05457 \times 10^{-34} \text{ J s}) \times (5.634 \times 10^{14} \text{ s}^{-1}) = 5.941 \times 10^{-20} \text{ J}$$

or 59.41 zJ, about 0.37 eV. This energy separation corresponds to  $36 \text{ kJ mol}^{-1}$ , which is chemically significant. The zero-point energy, eqn 8B.6, of this molecular oscillator is 29.71 zJ, which corresponds to 0.19 eV, or  $18 \text{ kJ mol}^{-1}$ .

**Self-test 8B.1** Suppose a hydrogen atom is adsorbed on the surface of a gold nanoparticle by a bond of force constant  $855 \text{ N m}^{-1}$ . Calculate its zero-point vibrational energy.

Answer: 37.7 zJ, 22.7 kJ mol<sup>-1</sup>, 0.24 eV

The result in *Brief illustration* 8B.1 implies that excitation requires radiation of frequency  $\nu = \Delta E/h = 90 \text{ THz}$  and wavelength  $\lambda = c/\nu = 3.3 \mu\text{m}$ . It follows that transitions between adjacent vibrational energy levels of molecules are stimulated by or emit infrared radiation (Topics 12D and 12E).

## (b) The wavefunctions

Like the particle in a box (Topic 8A), a particle undergoing harmonic motion is trapped in a symmetrical well in which the potential energy rises to large values (and ultimately to infinity) for sufficiently large displacements (compare Figs. 8A.1 and 8B.1). However, there are two important differences:

- Because the potential energy climbs towards infinity only as  $x^2$  and not abruptly, the wavefunction approaches zero more slowly at large displacements than for the particle in a box.
- As the kinetic energy of the oscillator depends on the displacement in a more complex way (on account of the variation of the potential energy), the curvature of the wavefunction also varies in a more complex way.

Physical interpretation

The detailed solution of eqn 8B.3 confirms these points and shows that the wavefunctions for a harmonic oscillator have the form

$$\psi(x) = N \times (\text{polynomial in } x) \times (\text{bell-shaped Gaussian function})$$

where  $N$  is a normalization constant. A Gaussian function is a bell-shaped function of the form  $e^{-x^2}$  (Fig. 8B.3). The precise form of the wavefunctions is

Figure 8B.3 The graph of the Gaussian function,  $f(x) = e^{-x^2}$ .

$$\psi_\nu(x) = N_\nu H_\nu(y) e^{-y^2/2} \quad y = \frac{x}{\alpha} \quad \alpha = \left( \frac{\hbar^2}{mk_f} \right)^{1/4} \quad \begin{array}{l} \text{Harmonic} \\ \text{oscillator} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{functions} \end{array} \quad (8B.8)$$

The factor  $H_\nu(y)$  is a **Hermite polynomial**; the form of these polynomials and some of their properties are listed in Table 8B.1. Hermite polynomials, which are members of a class of functions called 'orthogonal polynomials', have a wide range of important properties which allow a number of quantum mechanical calculations to be done with relative ease. Note that the first few Hermite polynomials are very simple: for instance,  $H_0(y) = 1$  and  $H_1(y) = 2y$ .

Because  $H_0(y) = 1$ , the wavefunction for the ground state (the lowest energy state, with  $\nu = 0$ ) of the harmonic oscillator is

$$\psi_0(x) = N_0 e^{-y^2/2} = N_0 e^{-x^2/2\alpha^2} \quad \begin{array}{l} \text{Harmonic} \\ \text{oscillator} \end{array} \quad \begin{array}{l} \text{Ground-state} \\ \text{wavefunction} \end{array} \quad (8B.9a)$$

Table 8B.1 The Hermite polynomials,  $H_\nu(y)$ \*

$\nu$	$H_\nu(y)$
0	1
1	$2y$
2	$4y^2 - 2$
3	$8y^3 - 12y$
4	$16y^4 - 48y^2 + 12$
5	$32y^5 - 160y^3 + 120y$
6	$64y^6 - 480y^4 + 720y^2 - 120$

\* The Hermite polynomials are solutions of the differential equation

$$H_\nu'' - 2yH_\nu' + 2\nu H_\nu = 0$$

where primes denote differentiation. They satisfy the recursion relation

$$H_{\nu+1} - 2yH_\nu + 2\nu H_{\nu-1} = 0$$

An important integral is

$$\int_{-\infty}^{\infty} H_\nu H_{\nu'} e^{-y^2} dy = \begin{cases} 0 & \text{if } \nu' \neq \nu \\ \pi^{1/2} 2^\nu \nu! & \text{if } \nu' = \nu \end{cases}$$

**Figure 8B.4** The normalized wavefunction and probability density (shown also by shading) for the lowest energy state of a harmonic oscillator.

and the corresponding probability density is

$$\psi_0^2(x) = N_0^2 e^{-y^2} = N_0^2 e^{-x^2/\alpha^2} \quad \begin{array}{l} \text{Harmonic} \\ \text{oscillator} \end{array} \quad \begin{array}{l} \text{Ground-state} \\ \text{probability} \\ \text{density} \end{array} \quad (8B.9b)$$

The wavefunction and the probability density are shown in Fig. 8B.4. Both curves have their largest values at zero displacement (at  $x=0$ ), so they capture the classical picture of the zero-point energy as arising from the ceaseless fluctuation of the particle about its equilibrium position.

The wavefunction for the first excited state of the oscillator, the state with  $\nu=1$ , is

$$\begin{aligned} \psi_1(x) &= N_1 (2y) e^{-y^2/2} \\ &= N_1 \left( \frac{2}{\alpha} \right) x e^{-x^2/2\alpha^2} \end{aligned} \quad \begin{array}{l} \text{Harmonic} \\ \text{oscillator} \end{array} \quad \begin{array}{l} \text{First excited-} \\ \text{state} \\ \text{wavefunction} \end{array} \quad (8B.10)$$

This function has a node at zero displacement ( $x=0$ ), and the probability density has maxima at  $x=\pm\alpha$  (Fig. 8B.5).

**Figure 8B.5** The normalized wavefunction and probability density (shown also by shading) for the first excited state of a harmonic oscillator.

### Example 8B.1 Confirming that a wavefunction is a solution of the Schrödinger equation

Confirm that the ground-state wavefunction (eqn 8B.9a) is a solution of the Schrödinger equation, eqn 8B.3.

**Method** Substitute the wavefunction given in eqn 8B.9a into eqn 8B.3. Use the definition of  $\alpha$  given in eqn 8B.8 to determine the energy on the right-hand side of eqn 8B.3 and confirm that it matches the zero-point energy given in eqn 8B.6.

**Answer** We need to evaluate the second derivative of the ground-state wavefunction:

$$\begin{aligned} \frac{d}{dx} N_0 e^{-x^2/2\alpha^2} &= -N_0 \left( \frac{x}{\alpha^2} \right) e^{-x^2/2\alpha^2} \\ \frac{d^2}{dx^2} N_0 e^{-x^2/2\alpha^2} &= \frac{d}{dx} \left\{ -N_0 \left( \frac{x}{\alpha^2} \right) e^{-x^2/2\alpha^2} \right\} \\ &= -\frac{N_0}{\alpha^2} e^{-x^2/2\alpha^2} + N_0 \left( \frac{x}{\alpha^2} \right)^2 e^{-x^2/2\alpha^2} \\ &= -(1/\alpha^2) \psi_0 + (x^2/\alpha^4) \psi_0 \end{aligned}$$

Substituting  $\psi_0$  into eqn 8B.3 and using the definition of  $\alpha$  (eqn 8B.8), we obtain

$$\frac{\hbar^2}{2m} \left( \frac{mk_f}{\hbar^2} \right)^{1/2} \psi_0 - \frac{\hbar^2}{2m} \left( \frac{mk_f}{\hbar^2} \right) x^2 \psi_0 + \frac{1}{2} k_f x^2 \psi_0 = E \psi_0$$

and therefore

$$\frac{\hbar}{2} \left( \frac{k_f}{m} \right)^{1/2} \psi_0 - \frac{1}{2} k_f x^2 \psi_0 + \frac{1}{2} k_f x^2 \psi_0 = E \psi_0$$

The second and third terms on the left-hand side (in blue) cancel and we obtain  $E = \frac{1}{2} \hbar (k_f/m)^{1/2}$  in accord with eqn 8B.6 for the zero-point energy.

**Self-test 8B.2** Confirm that the wavefunction in eqn 8B.10 is a solution of eqn 8B.3 and determine its energy.

Answer: yes, with  $E = \frac{3}{2} \hbar \omega$

The shapes of several wavefunctions are shown in Fig. 8B.6 and the corresponding probability densities are shown in Fig. 8B.7. At high quantum numbers, harmonic oscillator wavefunctions have their largest amplitudes near the turning points of the classical motion (the locations at which  $V=E$ , so the kinetic energy is zero). We see classical properties emerging in the correspondence principle limit of high quantum numbers (Topic 8A), for a classical particle is most likely to be found at the turning points (where it travels most slowly) and is least likely to be found at zero displacement (where it travels most rapidly).

**Figure 8B.6** The normalized wavefunctions for the first five states of a harmonic oscillator. Note that the number of nodes is equal to  $\nu$  and that alternate wavefunctions are symmetrical or asymmetrical about  $y=0$  (zero displacement).

Note the following features of the wavefunctions:

- The Gaussian function goes very strongly to zero as the displacement increases (in either direction, extension or compression), so all the wavefunctions approach zero at large displacements.
- The exponent  $y^2$  is proportional to  $x^2 \times (mk_f)^{1/2}$ , so the wavefunctions decay more rapidly for large masses and stiff springs.
- As  $\nu$  increases, the Hermite polynomials become larger at large displacements (as  $x^\nu$ ), so the wavefunctions grow large before the Gaussian function damps them down to zero: as a result, the wavefunctions spread over a wider range as  $\nu$  increases (Fig. 8B.7).

Physical interpretation

**Figure 8B.7** The probability densities for the first five states of a harmonic oscillator and the state with  $\nu=18$ . Note how the regions of highest probability density move towards the turning points of the classical motion as  $\nu$  increases.

### Example 8B.2 Normalizing a harmonic oscillator wavefunction

Find the normalization constant for the harmonic oscillator wavefunctions.

**Method** Normalization is carried out by evaluating the integral of  $|\psi|^2$  over all space and then finding the normalization factor from eqn 7B.3 ( $N=1/(\int \psi^* \psi d\tau)^{1/2}$ ). The normalized wavefunction is then equal to  $N\psi$ . In this one-dimensional problem, the volume element is  $dx$  and the integration is from  $-\infty$  to  $+\infty$ . The wavefunctions are expressed in terms of the dimensionless variable  $y=x/\alpha$ , so begin by expressing the integral in terms of  $y$  by using  $dx=\alpha dy$ . The integrals required are given in Table 8B.1.

**Answer** The unnormalized wavefunction is

$$\psi_\nu(x) = H_\nu(y) e^{-y^2/2}$$

It follows from the integrals given in Table 8B.1 that

$$\int_{-\infty}^{\infty} \psi_\nu^* \psi_\nu dx = \alpha \int_{-\infty}^{\infty} \psi_\nu^* \psi_\nu dy = \alpha \int_{-\infty}^{\infty} H_\nu^2(y) e^{-y^2} dy = \alpha \pi^{1/2} 2^\nu \nu!$$

where  $\nu! = \nu(\nu-1)(\nu-2)\dots 1$ . Therefore,

$$N_\nu = \left( \frac{1}{\alpha \pi^{1/2} 2^\nu \nu!} \right)^{1/2}$$

Note that, unlike the normalization constant for a particle in a box, for a harmonic oscillator  $N_\nu$  is different for each value of  $\nu$ .

**Self-test 8B.3** Confirm, by explicit evaluation of the integral, that  $\psi_0$  and  $\psi_1$  are orthogonal.

Answer: Show that  $\int_{-\infty}^{\infty} \psi_0^* \psi_1 dx = 0$  by using the information in Table 8B.1

## 8B.2 The properties of oscillators

The average value of a property is calculated by evaluating the expectation value of the corresponding operator (eqn 7C.11,  $\langle \Omega \rangle = \int \psi^* \hat{\Omega} \psi d\tau$ ). Now that we know the wavefunctions of the harmonic oscillator, we can start to explore its properties by evaluating integrals of the type

$$\langle \Omega \rangle = \int_{-\infty}^{\infty} \psi_\nu^* \hat{\Omega} \psi_\nu dx \quad (8B.11)$$

(Here and henceforth, the wavefunctions are all taken to be normalized to 1.) When the explicit wavefunctions are substituted, the integrals look fearsome, but the Hermite polynomials have many simplifying features.

**(a) Mean values**

We show in the following example that the mean displacement,  $\langle x \rangle$ , and the mean square displacement,  $\langle x^2 \rangle$ , of the oscillator when it is in the state with quantum number  $\nu$  are

$$\langle x \rangle = 0 \quad \text{Harmonic oscillator} \quad \text{Mean displacement} \quad (8B.12a)$$

$$\langle x^2 \rangle = \left(\nu + \frac{1}{2}\right) \frac{\hbar}{(mk_f)^{1/2}} \quad \text{Harmonic oscillator} \quad \text{Mean square displacement} \quad (8B.12b)$$

The result for  $\langle x \rangle$  shows that the oscillator is equally likely to be found on either side of  $x=0$  (like a classical oscillator). The result for  $\langle x^2 \rangle$  shows that the mean square displacement increases with  $\nu$ . This increase is apparent from the probability densities in Fig. 8B.7, and corresponds to the classical amplitude of swing increasing as the oscillator becomes more highly excited.

**Example 8B.3** Calculating properties of a harmonic oscillator

Consider the harmonic oscillator motion of the H–Cl molecule in *Brief illustration* 8B.1. Calculate the mean displacement of the oscillator when it is in a state with quantum number  $\nu$ .

**Method** Normalized wavefunctions must be used to calculate the expectation value. The operator for position along  $x$  is multiplication by the value of  $x$  (Topic 7C). The resulting integral can be evaluated either

- by inspection (the integrand is the product of an odd and an even function), or
- by explicit evaluation using the formulas in Table 8B.1.

The former procedure makes use of the definitions that an even function is one for which  $f(-x) = f(x)$  and an odd function is one for which  $f(-x) = -f(x)$ . Therefore, the product of an odd and even function is itself odd, and the integral of an odd function over a symmetrical range about  $x=0$  is zero. The latter procedure using explicit integration is illustrated here to give practice in the calculation of expectation values. We shall need the relation  $x = \alpha y$ , which implies that  $dx = \alpha dy$ .

**Answer** The integral we require is

$$\begin{aligned} \langle x \rangle &= \int_{-\infty}^{\infty} \psi_\nu^* x \psi_\nu dx = N_\nu^2 \int_{-\infty}^{\infty} (H_\nu e^{-y^2/2}) x (H_\nu e^{-y^2/2}) dx \\ &= \alpha^2 N_\nu^2 \int_{-\infty}^{\infty} (H_\nu e^{-y^2/2}) y (H_\nu e^{-y^2/2}) dy \\ &= \alpha^2 N_\nu^2 \int_{-\infty}^{\infty} H_\nu y H_\nu e^{-y^2} dy \end{aligned}$$

Now use the recursion relation (Table 8B.1) to form

$$yH_\nu = \nu H_{\nu-1} + \frac{1}{2} H_{\nu+1}$$

which turns the integral into

$$\int_{-\infty}^{\infty} H_\nu y H_\nu e^{-y^2} dy = \nu \int_{-\infty}^{\infty} H_\nu H_{\nu-1} e^{-y^2} dy + \frac{1}{2} \int_{-\infty}^{\infty} H_\nu H_{\nu+1} e^{-y^2} dy$$

Both integrals are zero (See Table 8B.1), so  $\langle x \rangle = 0$ . The mean displacement is zero because displacements on either side of the equilibrium position occur with equal probability.

**Self-test 8B.4** Calculate the mean square displacement,  $\langle x^2 \rangle$ , of the H–Cl bond distance from its equilibrium position by using the recursion relation in Table 8B.1 twice.

Answer:  $(\nu + \frac{1}{2}) \times 115 \text{ pm}^2$ ; eqn 9.12b, with  $\mu$  in place of  $m$

The mean potential energy of an oscillator, the expectation value of  $V = \frac{1}{2} k_f x^2$ , can now be calculated very easily:

$$\langle V \rangle = \frac{1}{2} k_f \langle x^2 \rangle = \frac{1}{2} \left(\nu + \frac{1}{2}\right) \hbar \left(\frac{k_f}{m}\right)^{1/2}$$

or

$$\langle V \rangle = \frac{1}{2} \left(\nu + \frac{1}{2}\right) \hbar \omega \quad \text{Harmonic oscillator} \quad \text{Mean potential energy} \quad (8B.13a)$$

Because the total energy in the state with quantum number  $\nu$  is  $(\nu + \frac{1}{2}) \hbar \omega$ , it follows that

$$\langle V \rangle = \frac{1}{2} E_\nu \quad \text{Harmonic oscillator} \quad \text{Mean potential energy} \quad (8B.13b)$$

The total energy is the sum of the potential and kinetic energies, so it follows at once that the mean kinetic energy of the oscillator is (as could also be shown using the kinetic energy operator)

$$\langle E_k \rangle = \frac{1}{2} E_\nu \quad \text{Harmonic oscillator} \quad \text{Mean kinetic energy} \quad (8B.13c)$$

The result that the mean potential and kinetic energies of a harmonic oscillator are equal (and therefore that both are equal to half the total energy) is a special case of the **virial theorem**:

If the potential energy of a particle has the form  $V = ax^b$ , then its mean potential and kinetic energies are related by

$$2\langle E_k \rangle = b\langle V \rangle \quad \text{Virial theorem} \quad (8B.14)$$

For a harmonic oscillator  $b=2$ , so  $\langle E_k \rangle = \langle V \rangle$ , as we have found. The virial theorem is a short cut to the establishment of a number of useful results, and we use it elsewhere (for example, in Topic 9A).

## (b) Tunnelling

An oscillator may be found at extensions with  $V > E$ , which are forbidden by classical physics, for they correspond to negative kinetic energy; this is an example of the phenomenon of tunnelling (Topic 8A). As shown in *Example 8B.4*, for the lowest energy state of the harmonic oscillator, there is about an 8 per cent chance of finding the oscillator stretched beyond its classical limit and an 8 per cent chance of finding it with a classically forbidden compression. These tunnelling probabilities are independent of the force constant and mass of the oscillator.

### Example 8B.4 Calculating the tunnelling probability for the harmonic oscillator

Calculate the probability that the ground-state harmonic oscillator will be found in a classically forbidden region.

**Method** Find the expression for the classical turning point,  $x_{\text{tp}}$ , where the kinetic energy vanishes, by equating the potential energy to the total energy  $E$  of the harmonic oscillator. The probability of finding the oscillator stretched beyond a displacement  $x_{\text{tp}}$  is the sum of the probabilities  $\psi^2 dx$  of finding it in any of the intervals  $dx$  lying between  $x_{\text{tp}}$  and infinity, so evaluate the integral

$$P = \int_{x_{\text{tp}}}^{\infty} \psi_0^2 dx$$

The variable of integration is best expressed in terms of  $y = x/\alpha$  and the integral to be evaluated is a special case of the *error function*,  $\text{erf } z$ , defined as

$$\text{erf}(z) = 1 - \frac{2}{\pi^{1/2}} \int_z^{\infty} e^{-y^2} dy$$

and evaluated for some values of  $z$  in Table 8B.2 (this function is commonly available in mathematical software packages). By symmetry, the probability of being found stretched into a classically forbidden region is the same as that of being found compressed into a classically forbidden region.

**Answer** According to classical mechanics, the turning point,  $x_{\text{tp}}$ , of an oscillator occurs when its kinetic energy is zero, which is when its potential energy  $\frac{1}{2}k_f x^2$  is equal to its total energy  $E$ . This equality occurs when

$$x_{\text{tp}}^2 = \frac{2E}{k_f} \quad \text{or} \quad x_{\text{tp}} = \pm \left( \frac{2E}{k_f} \right)^{1/2}$$

with  $E$  given by eqn 8B.4. The variable of integration in the integral  $P$  is best expressed in terms of  $y = x/\alpha$  with  $\alpha = (\hbar^2/mk_f)^{1/4}$ , and then the right-hand turning point lies at

$$y_{\text{tp}} = \frac{x_{\text{tp}}}{\alpha} = \left\{ \frac{2(\nu + \frac{1}{2})\hbar\omega}{\alpha^2 k_f} \right\}^{1/2} \stackrel{\omega = (k_f/m)^{1/2}}{=} (2\nu + 1)^{1/2}$$

For the state of lowest energy ( $\nu=0$ ),  $y_{\text{tp}} = 1$  and the probability of being beyond that point is

$$P = \int_{x_{\text{tp}}}^{\infty} \psi_0^2 dx = \alpha N_0^2 \int_1^{\infty} e^{-y^2} dy$$

The normalization constant  $N_0$  is calculated from the expression for  $N_\nu$  in *Example 8B.2* ( $N_\nu = 1/(\alpha \pi^{1/2} 2^\nu \nu!)^{1/2}$ ):

$$N_0 = \left( \frac{1}{\alpha \pi^{1/2} 2^0 0!} \right)^{1/2} = \left( \frac{1}{\alpha \pi^{1/2}} \right)^{1/2}$$

The integral in the expression for  $P$  is written in terms of the error function  $\text{erf}(1)$  as

$$\text{erf}(1) = 1 - \frac{2}{\pi^{1/2}} \int_1^{\infty} e^{-y^2} dy \quad \text{so} \quad \int_1^{\infty} e^{-y^2} dy = \frac{1}{2} \pi^{1/2} (1 - \text{erf}(1))$$

It follows that

$$P = \alpha \times \frac{N_0^2}{\alpha \pi^{1/2}} \times \frac{1}{2} \pi^{1/2} (1 - \text{erf}(1)) = \frac{1}{2} \left( \frac{0.843}{1 - \text{erf}(1)} \right) = 0.079$$

In 7.9 per cent of a large number of observations, any oscillator in the state with quantum number  $\nu=0$  will be found stretched to a classically forbidden extent. There is the same probability of finding the oscillator with a classically forbidden compression. The total probability of finding the oscillator tunneled into a classically forbidden region (stretched or compressed) is about 16 per cent.

**Self-test 8B.5** Calculate the probability that a harmonic oscillator in the state with quantum number  $\nu=1$  will be found at a classically forbidden extension. (Follow the argument given in *Example 8B.4* and use the method of integration by parts (*Mathematical background 1*) to obtain an integral that can be expressed in terms of the error function.)

Answer:  $P=0.056$

Table 8B.2 The error function, erf(z)\*

$z$	erf( $z$ )
0	0
0.01	0.0113
0.05	0.0564
0.10	0.1125
0.50	0.5205
1.00	0.8427
1.50	0.9661
2.00	0.9953

\*More values are available in mathematical software packages.

The probability of finding the oscillator in classically forbidden regions decreases quickly with increasing  $\nu$ , and vanishes entirely as  $\nu$  approaches infinity, as we would expect from the correspondence principle. Macroscopic oscillators (such as pendulums) are in states with very high quantum numbers, so the tunnelling probability is wholly negligible and classical mechanics is reliable. Molecules, however, are normally in their vibrational ground states, and for them the probability is very significant and classical mechanics is misleading.

## Checklist of concepts

- 1. A particle undergoing **harmonic motion** is called a **harmonic oscillator** and experiences a restoring force proportional to its displacement;
- 2. The potential energy of a harmonic oscillator is a parabolic function of the displacement from equilibrium.
- 3. The energy levels of a harmonic oscillator form an evenly spaced ladder.
- 4. The wavefunctions of a harmonic oscillator are products of a **Hermite polynomial** and a Gaussian (bell-shaped) function.
- 5. There is a **zero-point energy**, an irremovable minimum energy, which is consistent with, and can be interpreted in terms of, the uncertainty principle.
- 6. The probability of finding the harmonic oscillator in classically forbidden regions is significant for the ground vibrational state ( $\nu=0$ ) but decreases quickly with increasing  $\nu$ .

## Checklist of equations

Property	Equation	Comment	Equation number
Energy levels of harmonic oscillator	$E_\nu = (\nu + \frac{1}{2})\hbar\omega$ , $\omega = (k_f/m)^{1/2}$	$\nu = 0, 1, 2, \dots$	8B.4
Zero-point energy of harmonic oscillator	$E_0 = \frac{1}{2}\hbar\omega$		8B.6
Wavefunction of harmonic oscillator	$\psi_\nu(x) = N_\nu H_\nu(y) e^{-y^2/2}$ $y = x/\alpha$ , $\alpha = (\hbar^2/mk_f)^{1/4}$ $N_\nu = (1/\alpha \pi^{1/2} 2^\nu \nu!)^{1/2}$	$\nu = 0, 1, 2, \dots$	8B.8
Mean displacement of harmonic oscillator	$\langle x \rangle = 0$		8B.12a
Mean square displacement of harmonic oscillator	$\langle x^2 \rangle = (\nu + \frac{1}{2})\hbar / (mk_f)^{1/2}$		8B.12b
Virial theorem	$2\langle E_k \rangle = b\langle V \rangle$	$V = ax^b$	8B.14

### ► Why do you need to know this material?

The investigation of rotational motion introduces the concept of angular momentum, which is central to the description of the electronic structure of atoms and molecules and the interpretation of details observed in molecular spectra.

### ► What is the main idea?

The energy and the angular momentum of a rotating object are quantized.

### ► What do you need to know already?

You should know the postulates of quantum mechanics (Topic 7C), and be familiar with the concept of angular momentum in classical physics (*Foundations B*).

This Topic provides a quantum mechanical description of rotation in two and three dimensions. The concepts developed here form the basis for discussion of atomic structure (Topics 9A and 9B) and molecular rotation (Topic 12B).

## 8C.1 Rotation in two dimensions

We consider a particle of mass  $m$  constrained to move in a circular path (a ‘ring’) of radius  $r$  in the  $xy$ -plane with constant potential energy, which may be taken to be zero (Fig. 8C.1). The total energy is equal to the kinetic energy, because  $V=0$  everywhere. We can therefore write  $E=p^2/2m$ . According to classical mechanics (*Foundations B*), the **angular momentum**,  $J_z$ , around the  $z$ -axis (which lies perpendicular to the  $xy$ -plane) is  $J_z=\pm pr$ , so the energy can be expressed as  $J_z^2/2mr^2$ . Because  $mr^2$  is the **moment of inertia**,  $I$ , of the mass on its path, it follows that

$$E = \frac{J_z^2}{2I} \quad I = mr^2 \quad \text{Particle on a ring, classical expression} \quad \text{Energy} \quad (8C.1)$$

We shall now see that not all the values of the angular momentum are permitted in quantum mechanics, and therefore that both angular momentum and rotational energy are quantized.

### (a) The qualitative origin of quantized rotation

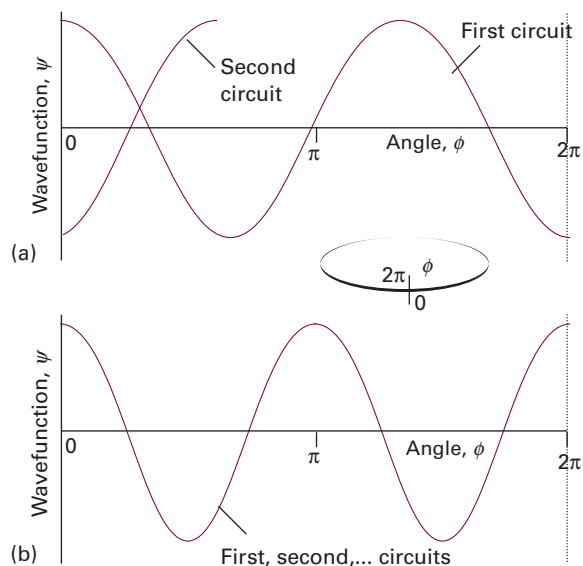

Because  $J_z=\pm pr$ , and since the de Broglie relation gives  $p=h/\lambda$  (Topic 7A) the angular momentum about the  $z$ -axis is

$$J_z = \pm \frac{hr}{\lambda} \quad (8C.2)$$

Opposite signs correspond to opposite directions of travel. This equation shows that the shorter the wavelength of the particle on a circular path of given radius, the greater the angular momentum of the particle. It follows that if we can see why the wavelength is restricted to discrete values, then we shall understand why the angular momentum is quantized.

**Figure 8C.1** The angular momentum of a particle of mass  $m$  on a circular path of radius  $r$  in the  $xy$ -plane is represented by a vector  $\mathbf{J}$  with the single non-zero component  $J_z$  of magnitude  $pr$  perpendicular to the plane.

**Figure 8C.2** Two solutions of the Schrödinger equation for a particle on a ring. The circumference has been opened out into a straight line; the points at  $\phi=0$  and  $2\pi$  are identical. The solution in (a) is unacceptable because it is not single-valued. Moreover, on successive circuits it interferes destructively with itself, and does not survive. The solution in (b) is acceptable: it is single-valued, and on successive circuits it reproduces itself.

Suppose for the moment that  $\lambda$  can take an arbitrary value. In that case, the wavefunction depends on the azimuthal angle  $\phi$  as shown in Fig. 8C.2a. When  $\phi$  increases beyond  $2\pi$ , the wavefunction continues to change, but for an arbitrary wavelength it gives rise to a different value at a given point after each circuit, which is unacceptable because a wavefunction must be single-valued. An acceptable solution is obtained only if the wavefunction reproduces itself on successive circuits, as in Fig. 8C.2b. Because only some wavefunctions have this property, it follows that only some angular momenta are acceptable and therefore that only certain rotational energies are allowed. That is, the energy of the particle is quantized. Specifically, an integer number of wavelengths must fit the circumference of the ring (which is  $2\pi r$ ):

$$n\lambda = 2\pi r \quad n=0, 1, 2, \dots \quad (8C.3)$$

The value  $n=0$  corresponds to  $\lambda=\infty$ ; a ‘wave’ of infinite wavelength has a constant height at all values of  $\phi$ . It follows from eqns 8C.2 and 8C.3 that the angular momentum is therefore limited to the values

$$J_z = \pm \frac{hr}{\lambda} = \pm \frac{nh}{2\pi r} = \pm \frac{nh}{2\pi} \quad n=0, 1, 2, \dots$$

The sign of  $J_z$  (which indicated the sense of the rotation) can be absorbed into the quantum number by replacing  $n$  by  $m_l=0, \pm 1, \pm 2, \dots$  where we have allowed  $m_l$  (the conventional notation for this quantum number) to have positive and negative integer

values. At the same time we recognize the presence of  $h/2\pi=\hbar$  and obtain

$$J_z = m_l \hbar \quad m_l = 0, \pm 1, \pm 2, \dots \quad \text{Particle on a ring} \quad \text{Angular momenta} \quad (8C.4)$$

Positive values of  $m_l$  correspond to rotation in a clockwise sense around the  $z$ -axis (as viewed in the direction of increasing  $z$ , Fig. 8C.3) and negative values of  $m_l$  correspond to counter-clockwise rotation around  $z$ . It then follows from eqns 8C.1 and 8C.4 that the energy is limited to the values

$$E_{m_l} = \frac{m_l^2 \hbar^2}{2I} \quad m_l = 0, \pm 1, \pm 2, \dots \quad \text{Particle on a ring} \quad \text{Energy levels} \quad (8C.5)$$

We explore this result further by noting that:

- The energies, labelled by  $m_l$ , are quantized because  $m_l$  must be an integer.
- The occurrence of  $m_l$  as its square means that the energy of rotation is independent of the sense of rotation (the sign of  $m_l$ ), as we expect physically. That is, states with a given nonzero value of  $|m_l|$  are doubly degenerate.
- The state described by  $m_l=0$  is non-degenerate, consistent with the interpretation that, when  $m_l$  is zero, the particle has an infinite wavelength and is ‘stationary’; the question of the direction of rotation does not arise.
- There is no zero-point energy in this system: the lowest possible energy is  $E_0=0$ .

Physical interpretation

### (b) The solutions of the Schrödinger equation

To obtain the wavefunctions for the particle on a ring and to confirm that the energies from eqn 8C.5 are correct, we need

**Figure 8C.3** The angular momentum of a particle confined to a plane can be represented by a vector of length  $|m_l|$  units along the  $z$ -axis and with an orientation that indicates the direction of motion of the particle. The direction is given by the right-hand screw rule, so (a) corresponds to  $m_l > 0$ , clockwise as seen from below and (b) corresponds to  $m_l < 0$ , anticlockwise as seen from below.

to solve the Schrödinger equation explicitly. We show in the following *Justification* that the normalized wavefunctions and corresponding energies are

$$\psi_{m_l}(\phi) = \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \quad m_l = 0, \pm 1, \pm 2, \dots \quad \begin{array}{l} \text{Particle} \\ \text{on a} \\ \text{ring} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{functions} \end{array} \quad (8C.6a)$$

$$E_{m_l} = \frac{m_l^2 \hbar^2}{2I} \quad \begin{array}{l} \text{Particle on a ring} \\ \text{Energy levels} \end{array} \quad (8C.6b)$$

The wavefunction with  $m_l = 0$  is  $\psi_0(\phi) = 1/(2\pi)^{1/2}$ , corresponding to uniform amplitude around the ring, and its energy is  $E_0 = 0$ .

### Justification 8C.1 The solutions of the Schrödinger equation for a particle on a ring

The hamiltonian for a particle of mass  $m$  travelling on a circle in the  $xy$ -plane (with  $V=0$ ) is the same as that for free motion in a plane (eqn 8A.1 of Topic 8A),

$$\hat{H} = -\frac{\hbar^2}{2m} \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) \quad (8C.7)$$

but with the constraint to a path of constant radius  $r$ . It is always a good idea to use coordinates that reflect the full symmetry of the system, so we introduce the coordinates  $r$  and  $\phi$  (*The chemist's toolkit* 8C.1). By standard manipulations we can write

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \phi^2} \quad (8C.8)$$

However, because the radius of the path is fixed, the (blue) derivatives with respect to  $r$  can be discarded. Only the last term in eqn 8C.8 then survives and the hamiltonian becomes simply

$$\hat{H} = -\frac{\hbar^2}{2mr^2} \frac{d^2}{d\phi^2} \quad \begin{array}{l} \text{Particle on a ring} \\ \text{Hamiltonian} \end{array} \quad (8C.9a)$$

The partial derivative has been replaced by a complete derivative because  $\phi$  is now the only variable. The moment of inertia,  $I = mr^2$  has appeared automatically so  $\hat{H}$  may be written

$$\hat{H} = -\frac{\hbar^2}{2I} \frac{d^2}{d\phi^2} \quad \begin{array}{l} \text{Particle on a ring} \\ \text{Hamiltonian} \end{array} \quad (8C.9b)$$

and the Schrödinger equation is

$$-\frac{\hbar^2}{2I} \frac{d^2\psi}{d\phi^2} = E\psi \quad \begin{array}{l} \text{Particle on} \\ \text{a ring} \end{array} \quad \begin{array}{l} \text{Schrödinger} \\ \text{equation} \end{array} \quad (8C.10a)$$

We rewrite this equation as

$$\frac{d^2\psi}{d\phi^2} = -\frac{2IE}{\hbar^2} \psi$$

For a given energy,  $2IE/\hbar^2$  is a constant, which for convenience (and an eye on the future) we write as  $m_l^2$ . At this stage  $m_l$  is just a dimensionless number with no restrictions. Then the equation becomes

$$\frac{d^2\psi}{d\phi^2} = -m_l^2 \psi \quad (8C.10b)$$

The (unnormalized) general solutions of this equation are

$$\psi_{m_l}(\phi) = e^{im_l\phi} \quad (8C.11)$$

as can be verified by substitution.

We now select the acceptable solutions from among these general solutions by imposing the condition that the wavefunction should be single-valued. That is, the wavefunction  $\psi$  must satisfy a **cyclic boundary condition**, and match at points separated by a complete revolution:  $\psi(\phi + 2\pi) = \psi(\phi)$ . On substituting the general wavefunction into this condition, we find

$$\begin{aligned} \psi_{m_l}(\phi + 2\pi) &= e^{im_l(\phi + 2\pi)} = e^{im_l\phi} e^{2\pi im_l} = \psi_{m_l}(\phi) e^{2\pi im_l} \\ &= \psi_{m_l}(\phi) (e^{\pi i})^{2m_l} \end{aligned}$$

As  $e^{i\pi} = -1$  (Euler's formula, *Mathematical background* 3), this relation is equivalent to

$$\psi_{m_l}(\phi + 2\pi) = (-1)^{2m_l} \psi_{m_l}(\phi)$$

Because cyclic boundary conditions require  $(-1)^{2m_l} = 1$ ,  $2m_l$  must be a positive or a negative even integer (including 0), and therefore  $m_l$  must be an integer:  $m_l = 0, \pm 1, \pm 2, \dots$

We now normalize the wavefunction by finding the normalization constant  $N$  given by eqn 7B.3 ( $N = (\int_{-\infty}^{\infty} \psi^* \psi dx)^{-1/2}$ ), which in this case becomes:

$$N = \frac{1}{\left( \int_0^{2\pi} \psi^* \psi d\phi \right)^{1/2}} = \frac{1}{\left( \int_0^{2\pi} e^{-im_l\phi} e^{im_l\phi} d\phi \right)^{1/2}} = \frac{1}{(2\pi)^{1/2}} \quad (8C.12)$$

and the normalized wavefunctions for a particle on a ring are those given by eqn 8C.6a. The expression for the energies of the states (eqn 8C.6b) is obtained by rearranging the relation  $m_l^2 = 2IE/\hbar^2$  into  $E = m_l^2 \hbar^2 / 2I$ .

### The chemist's toolkit 8C.1 Cylindrical coordinates

For systems with cylindrical symmetry it is best to work in **cylindrical coordinates**,  $r$ ,  $\phi$ , and  $z$  (Sketch 1), with

$$x = r \cos \theta \quad y = r \sin \phi$$

and where

$$\begin{array}{lll} r \text{ ranges from} & \phi \text{ ranges from} & z \text{ ranges from} \\ 0 \text{ to } \infty & 0 \text{ to } 2\pi & -\infty \text{ to } \infty \end{array}$$

Sketch 1 Cylindrical coordinates

The volume element is

$$d\tau = r dr d\phi dz$$

For motion in a plane we set  $z=0$  and for the volume element use

$$d\tau = r dr d\phi$$

### Example 8C.1 Using the particle-on-a-ring model

The particle-on-a-ring model is a crude but illustrative model of cyclic, conjugated molecular systems. Treat the  $\pi$  electrons in benzene as particles freely moving over a circular ring of carbon atoms and calculate the minimum energy required for the excitation of a  $\pi$  electron. The carbon–carbon bond length in benzene is 140 pm.

**Method** Because each carbon atom contributes one  $\pi$  electron, six electrons in the conjugated system move along the perimeter of the ring. Each state is occupied by two electrons, so only the  $m_l=0, +1$ , and  $-1$  states are occupied (with the last two being degenerate). The minimum energy required for excitation corresponds to a transition of an electron from the  $m_l=+1$  (or  $-1$ ) state to the  $m_l=+2$  (or  $-2$ ) state. Use eqn 8C.6b, and the mass of the electron, to calculate the energies of the states.

**Answer** From eqn 8C.6b, the energy separation between the  $m_l=+1$  and the  $m_l=+2$  states is

$$\begin{aligned} \Delta E = E_{+2} - E_{+1} &= (4-1) \times \frac{(1.055 \times 10^{-34} \text{ J s})^2}{2 \times (9.109 \times 10^{-31} \text{ kg}) \times (1.40 \times 10^{-10} \text{ m})^2} \\ &= 9.35 \times 10^{-19} \text{ J} \end{aligned}$$

Therefore the minimum energy required to excite an electron is 0.935 aJ or 563 kJ mol<sup>-1</sup>. This energy separation corresponds to an absorption frequency of 1.41 PHz (1 PHz = 10<sup>15</sup> Hz) and a wavelength of 213 nm; the experimental value for a transition of this kind is 260 nm. That such a primitive model gives relatively good agreement is encouraging. In addition, even though the model is primitive, it gives insight into the origin of the quantized  $\pi$  electron energy levels in cyclic conjugated systems (Topic 10D).

*A note on good practice* Note that, when quoting the value of  $m_l$ , it is good practice always to give the sign, even if  $m_l$  is positive. Thus, we write  $m_l=+1$ , not  $m_l=1$ .

**Self-test 8C.1** Use the particle on a ring model to calculate the minimum energy required for the excitation of a  $\pi$  electron in coronene, C<sub>24</sub>H<sub>12</sub> (1). Assume that the radius of the ring is three times the carbon–carbon bond length in benzene and that the electrons are confined to the periphery of the molecule.

1 Coronene  
(model ring in red)

Answer: For transition from  $m_l=+3$  to  $m_l=+4$ :  
 $\Delta E = 0.0147 \text{ zJ}$  or  $8.83 \text{ J mol}^{-1}$

### (c) Quantization of angular momentum

We have seen that the angular momentum around the  $z$ -axis is quantized and confined to the values given in eqn 8C.4 ( $J_z = m_l \hbar$ ). The wavefunction for the particle on a ring is given by eqn 8C.6a:

$$\psi_{m_l}(\phi) = \frac{e^{im_l\phi}}{(2\pi)^{1/2}} = \frac{1}{(2\pi)^{1/2}} (\cos m_l\phi + i \sin m_l\phi)$$

Therefore, as  $|m_l|$  increases, the increasing angular momentum is associated with:

- an increase in the number of nodes in the real ( $\cos m_l\phi$ ) and imaginary ( $\sin m_l\phi$ ) parts of the wavefunction (the complex function does not have nodes but each of its real and imaginary components does);
- a decrease in the wavelength and, by the de Broglie relation, an increase in the linear momentum with which the particle travels round the ring (Fig. 8C.4).

**Figure 8C.4** The real parts of the wavefunctions of a particle on a ring. As shorter wavelengths are achieved, the magnitude of the angular momentum around the  $z$ -axis grows in steps of  $\hbar$ .

**Brief illustration 8C.1** Nodes in the wavefunction

Whereas the  $m_l=0$  ground-state wavefunction has no nodes, the  $m_l=+1$  wavefunction

$$\psi_{+1}(\phi) = \frac{e^{i\phi}}{(2\pi)^{1/2}} = \frac{1}{(2\pi)^{1/2}} (\cos\phi + i\sin\phi)$$

has nodes at  $\phi = \pi/2$  and  $3\pi/2$  in its real part and at  $\phi = 0$  and  $\pi$  in its imaginary part. An increase in the number of nodes results in greater curvature of the (real and imaginary parts of the) wavefunction, consistent with an increase in kinetic and, in this case, total energy. Note that the sense of rotation (clockwise seen along the  $z$ -axis) is reflected in the fact that the imaginary component precedes the real component in phase: the real chases the imaginary.

**Self-test 8C.2** Determine the number of nodes in the real and imaginary parts of the wavefunction for a state of general  $m_l$ .

Answer:  $2m_l$  nodes each in real and imaginary part

As we show in the following *Justification*, we can come to the same conclusion about quantization of the  $z$ -component of angular momentum more formally by using the argument about the relation between eigenvalues and the values of observables established in Topic 7C.

**Justification 8C.2** The quantization of angular momentum

In classical mechanics, the angular momentum  $\mathbf{l}$  of a particle with position  $\mathbf{r}$  and linear momentum  $\mathbf{p}$  is given by the vector product  $\mathbf{l} = \mathbf{r} \times \mathbf{p}$  (see *Mathematical background 5* following Chapter 9 for a reminder about vector products). For motion restricted to two dimensions, with  $\mathbf{i}$  and  $\mathbf{j}$  denoting unit vectors (vectors of length 1) pointing along the positive directions on the  $x$ - and  $y$ -axes, respectively,

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} \quad \mathbf{p} = p_x\mathbf{i} + p_y\mathbf{j}$$

where  $p_x$  is the component of linear momentum parallel to the  $x$ -axis and  $p_y$  is the component parallel to the  $y$ -axis. Therefore,

$$\mathbf{l} = \mathbf{r} \times \mathbf{p} = (x\mathbf{i} + y\mathbf{j}) \times (p_x\mathbf{i} + p_y\mathbf{j}) = (xp_y - yp_x)\mathbf{k}$$

where  $\mathbf{k}$  is the unit vector pointing along the positive  $z$ -axis. For a particle rotating in the  $xy$ -plane, the angular momentum vector lies entirely along the  $z$ -axis with a magnitude given by  $|xp_y - yp_x|$  (Fig. 8C.5).

The operators for the linear momentum components  $p_x$  and  $p_y$  are given in Topic 7C, so the operator for angular momentum about the  $z$ -axis is

$$\hat{l}_z = \frac{\hbar}{i} \left( x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) \quad \text{z-Component of the angular momentum operator} \quad (8C.13a)$$

**Figure 8C.5** The classical angular momentum  $\mathbf{l}$  of a particle with position  $\mathbf{r}$  and linear momentum  $\mathbf{p}$  is given by the vector product  $\mathbf{l} = \mathbf{r} \times \mathbf{p}$ . For the motion restricted to the  $xy$ -plane as depicted here,  $\mathbf{r} = x\mathbf{i} + y\mathbf{j}$ ,  $\mathbf{p} = p_x\mathbf{i} + p_y\mathbf{j}$ , and  $\mathbf{l} = (xp_y - yp_x)\mathbf{k}$ , with  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  denoting unit vectors along the positive  $x$ -,  $y$ -, and  $z$ -axes.

When expressed in terms of the cylindrical coordinates  $r$  and  $\phi$  (*The chemist's toolkit 8C.1*), this equation becomes

$$\hat{l}_z = \frac{\hbar}{i} \frac{\partial}{\partial \phi} \quad (8C.13b)$$

With the angular momentum operator available, we can test if the wavefunction in eqn 8B.6a is an eigenfunction. Because the wavefunction depends on only the coordinate  $\phi$ , the partial derivative in eqn 8C.13b can be replaced by a complete derivative and we find

$$\hat{l}_z \psi_{m_l} = \frac{\hbar}{i} \frac{d}{d\phi} \psi_{m_l} = \frac{\hbar}{i} \frac{d}{d\phi} \frac{e^{im_l\phi}}{(2\pi)^{1/2}} = im_l \frac{\hbar}{i} \frac{e^{im_l\phi}}{(2\pi)^{1/2}} = m_l \hbar \psi_{m_l} \quad (8C.14)$$

That is,  $\psi_{m_l}$  is an eigenfunction of  $\hat{l}_z$ , and corresponds to an angular momentum  $m_l \hbar$ , in accord with eqn 8C.4. When  $m_l$  is positive, the angular momentum is positive (clockwise rotation when seen from below); when  $m_l$  is negative, the angular momentum is negative (anticlockwise when seen from below). These features are the origin of the vector representation of angular momentum, in which the magnitude is represented by the length of a vector and the direction of motion by its orientation (Fig. 8C.6)

**Figure 8C.6** The basic ideas of the vector representation of angular momentum: the magnitude of the angular momentum is represented by the length of the vector, and the orientation of the motion in space is represented by the orientation of the vector (using the right-hand screw rule).

When the particle is in a state of precisely known angular momentum  $m_l\hbar$  its location around the ring is completely unknown because the probability density is uniform:

$$\begin{aligned}\psi_m^* \psi_m &= \left( \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right)^* \left( \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right) \\ &= \left( \frac{e^{-im_l\phi}}{(2\pi)^{1/2}} \right) \left( \frac{e^{im_l\phi}}{(2\pi)^{1/2}} \right) = \frac{1}{2\pi}\end{aligned}$$

Angular momentum and angular position are a pair of complementary observables (in the sense defined in Topic 7C), and the inability to specify them simultaneously with arbitrary precision is another example of the uncertainty principle.

## 8C.2 Rotation in three dimensions

We now consider a particle of mass  $m$  that is free to move anywhere on the surface of a sphere of radius  $r$ . The sphere can be thought of as a three-dimensional stack of rings with the additional freedom for the particle to migrate from one ring to another. The cyclic boundary condition for the particle on each ring leads to the quantum number  $m_l$  that is encountered for motion on an individual ring. The requirement that the wavefunction must match as a path is traced over the poles as well as around the equator of the sphere surrounding the central point introduces a second cyclic boundary condition and therefore a second quantum number (Fig. 8C.7).

### (a) The wavefunctions

The hamiltonian operator for motion in three dimensions (Table 7B.1) is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2 + V \quad \begin{array}{l} \text{Three} \\ \text{dimensions} \end{array} \quad \begin{array}{l} \text{Hamiltonian} \\ \text{operator} \end{array} \quad (8C.15a)$$

**Figure 8C.7** The wavefunction of a particle on the surface of a sphere must satisfy two cyclic boundary conditions. This requirement leads to two quantum numbers for its state of angular momentum.

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad \begin{array}{l} \text{Three} \\ \text{dimensions} \end{array} \quad \begin{array}{l} \text{Laplacian} \end{array} \quad (8C.15b)$$

The laplacian,  $\nabla^2$  (read ‘del squared’), is a convenient abbreviation for the sum of the three second derivatives. For the particle confined to a spherical surface,  $V=0$  wherever it is free to travel and  $r$  is a constant. To take advantage of the symmetry of the problem and the fact that  $r$  is constant for a particle on a sphere, we use spherical polar coordinates (*The chemist’s toolkit* 7B.1). The wavefunction is therefore a function of the colatitude  $\theta$ , and the azimuth  $\phi$ , and we write it  $\psi(\theta, \phi)$ . The Schrödinger equation is therefore

$$-\frac{\hbar^2}{2m} \nabla^2 \psi = E\psi \quad \begin{array}{l} \text{Particle on} \\ \text{a sphere} \end{array} \quad \begin{array}{l} \text{Schrödinger} \\ \text{equation} \end{array} \quad (8C.16)$$

This Schrödinger equation is solved by using the technique of separation of variables (*Mathematical background* 4), which confirms that, as shown in the following *Justification*, the wavefunction can be written as a product of functions

$$\psi(\theta, \phi) = \Theta(\theta)\Phi(\phi) \quad (8C.17)$$

where  $\Theta$  is a function only of  $\theta$  and  $\Phi$  is a function only of  $\phi$ . As confirmed in the *Justification*, the  $\Phi$  are the solutions for a particle on a ring (Section 8C.1) and the overall solutions are specified by the **orbital angular momentum quantum number**  $l$  and the **magnetic quantum number**  $m_l$ . These quantum numbers are restricted to the values

$$l = 0, 1, 2, \dots \quad m_l = l, l-1, \dots, -l$$

The quantum number  $l$  is a non-negative integer and, for a given value of  $l$ , there are  $2l+1$  permitted values of  $m_l$ .

### Justification 8C.3 The solutions of the Schrödinger equation for a particle on a sphere

Because  $r$  is constant, we can discard the part of the laplacian that involves differentiation with respect to  $r$ , and so write the Schrödinger equation as

$$-\frac{\hbar^2}{2mr^2} \Lambda^2 \psi = E\psi \quad \begin{array}{l} \text{Particle on} \\ \text{a sphere} \end{array} \quad \begin{array}{l} \text{Schrödinger} \\ \text{equation} \end{array} \quad (8C.18)$$

The moment of inertia,  $I = mr^2$ , has appeared. This expression can be rearranged into

$$\Lambda^2 \psi = -\varepsilon \psi \quad \varepsilon = \frac{2IE}{\hbar^2}$$

To verify that this expression is separable, we try the substitution  $\psi = \Theta\Phi$  and use the form of the laplacian in Table 7B.1:

$$\Lambda^2 \Theta\Phi = \frac{1}{\sin^2\theta} \frac{\partial^2(\Theta\Phi)}{\partial \phi^2} + \frac{1}{\sin\theta} \frac{\partial}{\partial \theta} \sin\theta \frac{\partial(\Theta\Phi)}{\partial \theta} = -\varepsilon \Theta\Phi$$

We now use the fact that  $\Theta$  and  $\Phi$  are each functions of one variable, so the partial derivatives become complete derivatives:

$$\frac{\Theta}{\sin^2\theta} \frac{d^2\Phi}{d\phi^2} + \frac{\Phi}{\sin\theta} \frac{d}{d\theta} \sin\theta \frac{d\Theta}{d\theta} = -\varepsilon\Theta\Phi$$

Division through by  $\Theta\Phi$  and multiplication by  $\sin^2\theta$  gives

$$\frac{1}{\Phi} \frac{d^2\Phi}{d\phi^2} + \frac{\sin\theta}{\Theta} \frac{d}{d\theta} \sin\theta \frac{d\Theta}{d\theta} = -\varepsilon \sin^2\theta$$

and, after minor rearrangement,

$$\frac{1}{\Phi} \frac{d^2\Phi}{d\phi^2} + \frac{\sin\theta}{\Theta} \frac{d}{d\theta} \sin\theta \frac{d\Theta}{d\theta} + \varepsilon \sin^2\theta = 0$$

The first term on the left depends only on  $\phi$  and the remaining two terms depend only on  $\theta$ . By the argument presented in *Mathematical background 4*, each term is equal to a constant. Thus, if we set the first term equal to the constant  $-m_l^2$  (using a notation chosen with an eye to the future), the separated equations are

$$\frac{1}{\Phi} \frac{d^2\Phi}{d\phi^2} = -m_l^2 \quad \frac{\sin\theta}{\Theta} \frac{d}{d\theta} \sin\theta \frac{d\Theta}{d\theta} + \varepsilon \sin^2\theta = m_l^2$$

The first of these two equations is the same as that encountered for the particle on a ring and has the same solutions:

$$\Phi = \frac{1}{(2\pi)^{1/2}} e^{im_l\phi} \quad m_l = 0, \pm 1, \pm 2, \dots$$

(Shortly we shall see that  $m_l$  is in fact bounded for a three-dimensional system.) The second equation is new, but its solutions are well known to mathematicians as ‘associated Legendre functions’. The cyclic boundary condition for the matching of the wavefunction at  $\phi=0$  and  $2\pi$  restricts  $m_l$  to positive and negative integer values (including 0), as for a particle on a ring. The additional requirement that the wavefunction also match on a journey over the poles (Fig. 8C.7) results in the introduction of the second quantum number,  $l$ , with non-negative integer values. However, the presence of the quantum number  $m_l$  in the second equation implies that the ranges of the two quantum numbers are linked, and it turns out that for a given value of  $l$ ,  $m_l$  ranges in integer steps from  $-l$  to  $+l$ , as quoted in the text.

The normalized wavefunctions  $\psi(\theta, \phi)$  for a given  $l$  and  $m_l$  are usually denoted  $Y_{l,m_l}(\theta, \phi)$  and are called the **spherical harmonics** (Table 8C.1). They are as fundamental to the description of waves on spherical surfaces as the harmonic (sine and cosine) functions are to the description of waves on lines and planes. These important functions satisfy the equation<sup>1</sup>

$$\Lambda^2 Y_{l,m_l}(\theta, \phi) = -l(l+1) Y_{l,m_l}(\theta, \phi) \quad (8C.19)$$

<sup>1</sup> For a full account of the solution, see our *Molecular quantum mechanics* (2011).

**Table 8C.1** The spherical harmonics,  $Y_{l,m_l}(\theta, \phi)$

$l$	$m_l$	$Y_{l,m_l}(\theta, \phi)$
0	0	$\left(\frac{1}{4\pi}\right)^{1/2}$
1	0	$\left(\frac{3}{4\pi}\right)^{1/2} \cos\theta$
	$\pm 1$	$\mp \left(\frac{3}{8\pi}\right)^{1/2} \sin\theta e^{\pm i\phi}$
2	0	$\left(\frac{5}{16\pi}\right)^{1/2} (3\cos^2\theta - 1)$
	$\pm 1$	$\mp \left(\frac{15}{8\pi}\right)^{1/2} \cos\theta \sin\theta e^{\pm i\phi}$
	$\pm 2$	$\left(\frac{15}{32\pi}\right)^{1/2} \sin^2\theta e^{\pm 2i\phi}$
3	0	$\left(\frac{7}{16\pi}\right)^{1/2} (5\cos^3\theta - 3\cos\theta)$
	$\pm 1$	$\mp \left(\frac{21}{64\pi}\right)^{1/2} (5\cos^2\theta - 1)\sin\theta e^{\pm i\phi}$
	$\pm 2$	$\left(\frac{105}{32\pi}\right)^{1/2} \sin^2\theta \cos\theta e^{\pm 2i\phi}$
	$\pm 3$	$\mp \left(\frac{35}{64\pi}\right)^{1/2} \sin^3\theta e^{\pm 3i\phi}$

Figure 8C.8 is a representation of the spherical harmonics for  $l=0$  to 4 and  $m_l=0$ ; the use of different tints of shading, which correspond to different signs of the wavefunction, emphasizes

**Figure 8C.8** A representation of the wavefunctions of a particle on the surface of a sphere that emphasizes the location of angular nodes: different colours of shading correspond to different signs of the wavefunction. Note that the number of nodes increases as the value of  $l$  increases. All these wavefunctions correspond to  $m_l=0$ ; a path round the vertical  $z$ -axis of the sphere does not cut through any nodes.

the location of the angular nodes (the positions at which the wavefunction passes through zero). Note that:

- There are no angular nodes around the  $z$ -axis for functions with  $m_l=0$ . The spherical harmonic with  $l=0$ ,  $m_l=0$  has no nodes at all: it is a 'wave' of constant height at all positions of the surface.
- The spherical harmonic with  $l=1$ ,  $m_l=0$  has a single angular node at  $\theta=\pi/2$ ; therefore, the equatorial plane is a nodal plane.
- The spherical harmonic with  $l=2$ ,  $m_l=0$  has two angular nodes.

Physical interpretation

### Brief illustration 8C.2 The angular nodes of the spherical harmonics

For the spherical harmonic with  $l=2$ ,  $m_l=0$ , the angular nodes correspond to angles where (see Table 8C.1)  $3 \cos^2\theta - 1 = 0$ , or  $\cos \theta = \pm 1/3^{1/2}$ . The angular nodes are therefore at  $54.7^\circ$  and  $125.3^\circ$ .

**Self-test 8C.3** Find the angular nodes for the spherical harmonic  $l=3$ ,  $m_l=0$ .

Answer:  $\theta = 39.2^\circ, 90^\circ, 140.8^\circ$

## (b) The energies

In general, the number of angular nodes is equal to  $l$ . As the number of nodes increases, the wavefunctions become more buckled, and with this increasing curvature we can anticipate that the kinetic energy of the particle (and therefore its total energy because the potential energy is zero) increases.

With the wavefunctions  $\psi$  identified as the spherical harmonics  $Y$ , eqn 8C.18, the Schrödinger equation for the particle on a sphere, can be written as

$$-\frac{\hbar^2}{2mr^2} \underbrace{\nabla^2 Y_{l,m_l}}^{-l(l+1)Y_{l,m_l}} = E\psi, \text{ or } l(l+1) \frac{\hbar^2}{2I} Y_{l,m_l} = E_{l,m_l} Y_{l,m_l}$$

where we have allowed for the possibility that the energies depend on the two quantum numbers. By equating the terms in blue we can conclude that the allowed energies of the particle are

$$E_{l,m_l} = l(l+1) \frac{\hbar^2}{2I} \quad \text{Particle on a sphere} \quad \text{Energy levels} \quad (8C.20)$$

According to this equation:

- The energies are quantized because  $l=0, 1, 2, \dots$
- The energies are independent of the value of  $m_l$ , and henceforth we shall denote them simply as  $E_l$ .

Physical interpretation

- Because there are  $2l+1$  different wavefunctions (one for each value of  $m_l$ ) that correspond to the same energy, it follows that a level with quantum number  $l$  is  $(2l+1)$ -fold degenerate.
- There is no zero-point energy, and  $E_0=0$ .

Physical interpretation

### Example 8C.2 Using the rotational energy levels

Under certain circumstances, the particle on a sphere is a reasonable model for the description of the rotation of diatomic molecules. Consider, for example, the rotation of a  $^1\text{H}^{127}\text{I}$  molecule: because of the large difference in atomic masses, it is appropriate to picture the  $^1\text{H}$  atom as orbiting a stationary  $^{127}\text{I}$  atom at a distance  $r=160$  pm, the equilibrium bond distance. Determine the energies and degeneracies of the lowest four energy levels of an  $^1\text{H}^{127}\text{I}$  molecule freely rotating in three dimensions. What is the frequency of the transition between the lowest two rotational levels?

**Method** Because in this model the  $^{127}\text{I}$  atom is stationary, the moment of inertia is  $I = m_{\text{H}} r^2$ , with  $r=160$  pm. The rotational energies are given in eqn 8C.20; but for reasons that are developed in Topic 12B, the angular momentum quantum number of rotating molecules is denoted  $J$  in place of  $l$ , and we use that symbol here. The degeneracy of a level with quantum number  $J$  is  $2J+1$ , the analogue of  $2l+1$ . A transition between two rotational levels can be brought about by the emission or absorption of a photon with a frequency given by the Bohr frequency condition (Topic 7A,  $h\nu = \Delta E$ ).

**Answer** The moment of inertia is

$$I = \underbrace{(1.675 \times 10^{-27} \text{ kg})}_{m_{\text{H}}} \times \underbrace{(1.60 \times 10^{-12} \text{ m})^2}_{r^2} = 4.29 \times 10^{-47} \text{ kg m}^2$$

It follows that

$$\frac{\hbar^2}{2I} = \frac{(1.055 \times 10^{-34} \text{ Js})^2}{2 \times (4.29 \times 10^{-47} \text{ kg m}^2)} = 1.30 \times 10^{-22} \text{ J}$$

or 0.130 zJ. We now draw up the following table, where the molar energies are obtained by multiplying the individual energies by Avogadro's constant:

$J$	$E/\text{zJ}$	$E/(\text{J mol}^{-1})$	Degeneracy
0	0	0	1
1	0.260	156	3
2	0.780	470	5
3	1.56	939	7

The energy separation between the two lowest rotational energy levels ( $J=0$  and 1) is  $2.60 \times 10^{-22}$  J, which corresponds to a photon frequency of

$$\nu = \frac{\Delta E}{h} = \frac{2.60 \times 10^{-22} \text{ J}}{6.626 \times 10^{-34} \text{ Js}} = 3.92 \times 10^{11} \text{ s}^{-1} = 392 \text{ GHz}$$

Radiation of this frequency belongs to the microwave region of the electromagnetic spectrum, so microwave spectroscopy is used to study molecular rotations (Topic 12C). Because the transition frequencies depend on the moment of inertia and frequencies can be measured with great precision, microwave spectroscopy is a very precise technique for the determination of bond lengths.

**Self-test 8C.4** What is the frequency of the transition between the lowest two rotational levels in  ${}^2\text{H}^{127}\text{I}$ ? (Same bond length as  ${}^1\text{H}^{127}\text{I}$ .)

Answer: 196 GHz

### (c) Angular momentum

The energy of a rotating particle is related classically to its angular momentum  $J$  by  $E=J^2/2I$  (eqn 8C.1). Therefore, by comparing this equation with eqn 8C.20, we can deduce that because the energy is quantized, then so too is the magnitude of the angular momentum, and confined to the values

$$\{l(l+1)\}^{1/2} \hbar \quad l=0,1,2,\dots \quad \begin{array}{l} \text{Particle} \\ \text{on a} \\ \text{sphere} \end{array} \quad \begin{array}{l} \text{Magnitude} \\ \text{of angular} \\ \text{momentum} \end{array} \quad (8\text{C.21a})$$

We show in the following *Justification* that the angular momentum about the  $z$ -axis is also quantized, with the values

$$m_l \hbar \quad m_l = l, l-1, \dots, -l \quad \begin{array}{l} \text{Particle} \\ \text{on a} \\ \text{sphere} \end{array} \quad \begin{array}{l} z\text{-Component} \\ \text{of angular} \\ \text{momentum} \end{array} \quad (8\text{C.21b})$$

#### Justification 8C.4 The $z$ -component of angular momentum for a particle on a sphere

The operator for the  $z$ -component of the angular momentum in polar coordinates is

$$\hat{l}_z = \frac{\hbar}{i} \frac{\partial}{\partial \phi}$$

With this operator available, we can test if the wavefunction in eqn 8C.17 is an eigenfunction:

$$\hat{l}_z \psi = \hat{l}_z \Theta \Phi = \frac{\hbar}{i} \frac{\partial}{\partial \phi} \Theta \Phi = \Theta \frac{\hbar}{i} \frac{d}{d\phi} \Phi = \Theta \times m_l \hbar \Phi = m_l \hbar \psi$$

The partial derivative has been replaced above by a full derivative because  $\Theta$  is independent of  $\phi$  and we have used the result, as given in *Justification 8C.1*, that  $\Phi \propto e^{im_l \phi}$ . Therefore, the wavefunctions are eigenfunctions of  $\hat{l}_z$ , and correspond to an angular momentum around the  $z$ -axis of  $m_l \hbar$ , in accord with eqn 8C.21b.

#### Brief illustration 8C.3 The magnitude of the angular momentum

The lowest four rotational energy levels of the  ${}^1\text{H}^{127}\text{I}$  molecule of *Example 8C.2* correspond to  $J=0, 1, 2, 3$ . Using equations 8C.21a and 8C.21b, we can draw up the following table:

$J$	Magnitude of angular momentum/ $\hbar$	Degeneracy	$z$ -Component of angular momentum/ $\hbar$
0	0	1	0
1	$2^{1/2}$	3	+1, 0, -1
2	$6^{1/2}$	5	+2, +1, 0, -1, -2
3	$12^{1/2}$	7	+3, +2, +1, 0, -1, -2, -3

**Self-test 8C.5** What is the degeneracy and magnitude of the angular momentum for  $J=5$ ?

Answer: 11,  $30^{1/2} \hbar$

### (d) Space quantization

The result that  $m_l$  is confined to the values  $l, l-1, \dots, -l$  for a given value of  $l$  means that the component of angular momentum about the  $z$ -axis—the contribution to the total angular momentum of rotation around that axis—may take only  $2l+1$  values. If we represent the angular momentum by a vector of length  $\{l(l+1)\}^{1/2} \hbar$ , then it follows that this vector must be oriented so that its projection on the  $z$ -axis is  $m_l \hbar$  and that it can have only  $2l+1$  orientations rather than the continuous range of orientations of a rotating classical body (Fig. 8C.9). The remarkable implication is that *the orientation of a rotating body is quantized*.

**Figure 8C.9** The permitted orientations of angular momentum when  $l=2$ . We shall see soon that this representation is too specific because the azimuthal orientation of the vector (its angle around  $z$ ) is indeterminate.

**Figure 8C.10** (a) The experimental arrangement for the Stern–Gerlach experiment: the magnet provides an inhomogeneous field. (b) The classically expected result. (c) The observed outcome using silver atoms.

The quantum mechanical result that a rotating body may not take up an arbitrary orientation with respect to some specified axis (for example, an axis defined by the direction of an externally applied electric or magnetic field) is called **space quantization**. It was confirmed by an experiment first performed by Otto Stern and Walther Gerlach in 1921, who shot a beam of silver atoms through an inhomogeneous magnetic field (Fig. 8C.10). The idea behind the experiment was that a silver atom behaves like a magnet and interacts with the applied field (a point explored in more detail in the discussion of ‘spin’ in Topic 9B.). According to classical mechanics, because the orientation of the angular momentum can take any value, the associated magnet can take any orientation. Because the direction in which the magnet is driven by the inhomogeneous field depends on the magnet’s orientation, it follows that a broad band of atoms is expected to emerge from the region where the magnetic field acts. According to quantum mechanics, however, because the orientation of the angular momentum is quantized, the associated magnet lies in a number of discrete orientations, so several sharp bands of atoms are expected.

In their first experiment, Stern and Gerlach appeared to confirm the classical prediction. However, the experiment is difficult because collisions between the atoms in the beam blur the bands. When the experiment was repeated with a beam of very low intensity (so that collisions were less frequent), they observed discrete bands, and so confirmed the quantum prediction.

### (e) The vector model

Throughout the preceding discussion, we have referred to the  $z$ -component of angular momentum (the component about an arbitrary axis, which is conventionally denoted  $z$ ), and have made no reference to the  $x$ - and  $y$ -components (the

components about the two axes perpendicular to  $z$ ). The reason for this omission is found by examining the operators for the three components, each one being given by a term like that in eqn 8C.13a:

$$\begin{aligned}\hat{l}_x &= \frac{\hbar}{i} \left( y \frac{\partial}{\partial z} - z \frac{\partial}{\partial y} \right) \\ \hat{l}_y &= \frac{\hbar}{i} \left( z \frac{\partial}{\partial x} - x \frac{\partial}{\partial z} \right) \\ \hat{l}_z &= \frac{\hbar}{i} \left( x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) = \frac{\hbar}{i} \frac{\partial}{\partial \phi}\end{aligned}\quad \begin{array}{l} \text{Angular} \\ \text{momentum} \\ \text{operators} \end{array} \quad (8C.22)$$

The commutation relations among the three operators, which you are invited to derive in Problem 8C.11, are

$$[\hat{l}_x, \hat{l}_y] = i\hbar \hat{l}_z \quad [\hat{l}_y, \hat{l}_z] = i\hbar \hat{l}_x \quad [\hat{l}_z, \hat{l}_x] = i\hbar \hat{l}_y \quad \begin{array}{l} \text{Angular} \\ \text{momentum} \\ \text{commutators} \end{array} \quad (8C.23)$$

Therefore, we cannot specify more than one component (unless  $l=0$ ). In other words,  $l_x$ ,  $l_y$ , and  $l_z$  are complementary observables. On the other hand, the operator for the square of the magnitude of the angular momentum is

$$\hat{l}^2 = \hat{l}_x^2 + \hat{l}_y^2 + \hat{l}_z^2 \quad \begin{array}{l} \text{Operator for square of magnitude} \\ \text{of angular momentum} \end{array} \quad (8C.24)$$

This operator commutes with all three components (see Problem 8C.11):

$$[\hat{l}^2, \hat{l}_q] = 0 \quad q = x, y, \text{ and } z \quad \begin{array}{l} \text{Commutators of} \\ \text{angular momen-} \\ \text{tum operators} \end{array} \quad (8C.25)$$

Therefore, although we may specify the magnitude of the angular momentum and any of its components, if  $l_z$  is known, then it is impossible to ascribe values to the other two components. It follows that the illustration in Fig. 8C.9, which is summarized in Fig. 8C.11a, gives a false impression of the state of the system, because it suggests definite values for the  $x$ - and  $y$ -components. A better picture must reflect the impossibility of specifying  $l_x$  and  $l_y$  if  $l_z$  is known.

The **vector model** of angular momentum uses pictures like that in Fig. 8C.11b. The cones are drawn with side  $\{l(l+1)\}^{1/2}$  units, and represent the magnitude of the angular momentum. Each cone has a definite projection (of  $m_l$  units) on the  $z$ -axis, representing the system’s precise value of  $l_z$ . The  $l_x$  and  $l_y$  projections, however, are indefinite. The vector representing the state of angular momentum can be thought of as lying with its tip on any point on the mouth of the cone. At this stage it should not be thought of as sweeping round the cone; that aspect of the model will be added when we allow the picture to convey more information (Topics 9B and 9C).

**Figure 8C.11** (a) A summary of Fig. 8C.9. However, because the azimuthal angle of the vector around the  $z$ -axis is indeterminate, a better representation is as in (b), where each vector lies at an unspecified azimuthal angle on its cone.

#### Brief illustration 8C.4 The vector model of the angular momentum

If the wavefunction of a rotating molecule is given by the spherical harmonic  $Y_{3,+2}$  then the angular momentum can be represented by a cone

- with a side of length  $12^{1/2}$  (representing the magnitude of  $12^{1/2}\hbar$ ); and
- with a projection of  $+2$  on the  $z$ -axis (representing the  $z$ -component of  $+2\hbar$ ).

**Self-test 8C.6** Analyse the vector model of angular momentum if the wavefunction is given by the spherical harmonic  $Y_{3,-1}$ .

Answer: length is  $12^{1/2}$ , projection is  $-1$

## Checklist of concepts

1. The energy and angular momentum for a particle rotating in two- or three-dimensions are quantized; quantization results from the requirement that the wavefunction satisfies a **cyclic boundary condition**.
2. All energy levels of a particle rotating in two dimensions are doubly-degenerate except for the lowest level ( $m_l=0$ ).
3. There is no zero-point energy for a particle rotating in a plane or on a sphere.
4. It is impossible to specify the angular momentum and location of the particle rotating in two dimensions simultaneously with arbitrary precision.
5. For a particle rotating in three dimensions, the cyclic boundary conditions imply that the magnitude and  $z$ -component of the angular momentum are quantized.
6. **Space quantization** refers to the quantum mechanical result that a rotating body may not take up an arbitrary orientation with respect to some specified axis.
7. Angular momentum and orientation are complementary observables.
8. Because the components of angular momentum do not commute, only the magnitude of the angular momentum and one of its components can be specified simultaneously.
9. In the **vector model** of angular momentum, the angular momentum is represented by a cone with a side of length  $\{l(l+1)\}^{1/2}$  and a projection of  $m_l$  on the  $z$ -axis. The vector can be thought of as lying with its tip on an indeterminate point on the mouth of the cone.

## Checklist of equations

Property	Equation	Comment	Equation number
Wavefunction of particle on ring	$\psi_{m_l}(\phi) = e^{im_l\phi}/(2\pi)^{1/2}$	$m_l=0, \pm 1, \pm 2, \dots$	8C.6a
Energy levels of particle on ring	$E_{m_l} = m_l^2 \hbar^2 / 2I$	$m_l=0, \pm 1, \pm 2, \dots; I=mr^2$	8C.6b
$z$ -Component of angular momentum of particle on ring	$l_z = m_l \hbar$	$m_l=0, \pm 1, \pm 2, \dots$	8C.14
Wavefunction of particle on sphere	$\psi(\theta, \phi) = Y_{l,m_l}(\theta, \phi)$	$Y$ is a spherical harmonic	
Energy levels of particle on sphere	$E_{l,m_l} = l(l+1)\hbar^2 / 2I$	$l=0, 1, 2, \dots$	8C.20

# CHAPTER 8 The quantum theory of motion

## TOPIC 8A Translation

### Discussion questions

**8A.1** Discuss the physical origin of quantization energy for a particle confined to moving inside a one-dimensional box.

**8A.2** Describe the features of the solution of the particle in a one-dimensional box that appear in the solutions of the particle in two- and three-dimensional boxes. What concept applies to the latter but not to a one-dimensional box?

**8A.3** Discuss the physical origins of quantum mechanical tunnelling. Why is tunnelling more likely to contribute to the mechanisms of electron transfer and proton transfer processes than to mechanisms of group transfer reactions, such as  $AB + C \rightarrow A + BC$  (where A, B, and C are large molecular groups)?

### Exercises

**8A.1(a)** Determine the linear momentum and kinetic energy of a free electron described by the wavefunction  $e^{ikx}$  with  $k = 3 \text{ nm}^{-1}$ .

**8A.1(b)** Determine the linear momentum and kinetic energy of a free proton described by the wavefunction  $e^{-ikx}$  with  $k = 5 \text{ nm}^{-1}$ .

**8A.2(a)** Write the wavefunction for a particle of mass 2.0 g travelling to the left with a kinetic energy of 20 J.

**8A.2(b)** Write the wavefunction for a particle of mass 1.0 g travelling to the right at  $10 \text{ m s}^{-1}$ .

**8A.3(a)** Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (i)  $n=2$  and  $n=1$ , (ii)  $n=6$  and  $n=5$  of an electron in a box of length 1.0 nm.

**8A.3(b)** Calculate the energy separations in joules, kilojoules per mole, electronvolts, and reciprocal centimetres between the levels (i)  $n=3$  and  $n=1$ , (ii)  $n=7$  and  $n=6$  of an electron in a box of length 1.50 nm.

**8A.4(a)** Calculate the probability that a particle will be found between  $0.49L$  and  $0.51L$  in a box of length  $L$  when it has (i)  $n=1$ , (ii)  $n=2$ . Take the wavefunction to be a constant in this range.

**8A.4(b)** Calculate the probability that a particle will be found between  $0.65L$  and  $0.67L$  in a box of length  $L$  when it has (i)  $n=1$ , (ii)  $n=2$ . Take the wavefunction to be a constant in this range.

**8A.5(a)** Calculate the expectation values of  $\hat{p}$  and  $\hat{p}^2$  for a particle in the state  $n=1$  in a one-dimensional square-well potential.

**8A.5(b)** Calculate the expectation values of  $\hat{p}$  and  $\hat{p}^2$  for a particle in the state  $n=2$  in a one-dimensional square-well potential.

**8A.6(a)** Calculate the expectation values of  $\hat{x}$  and  $\hat{x}^2$  for a particle in the state  $n=1$  in a one-dimensional square-well potential.

**8A.6(b)** Calculate the expectation values of  $\hat{x}$  and  $\hat{x}^2$  for a particle in the state  $n=2$  in a one-dimensional square-well potential.

**8A.7(a)** An electron is confined to a square well of length  $L$ . What would be the length of the box such that the zero-point energy of the electron is equal to its rest mass energy,  $m_e c^2$ ? Express your answer in terms of the parameter  $\lambda_C = h/m_e c$ , the 'Compton wavelength' of the electron.

**8A.7(b)** Repeat Exercise 8A.7(a) for a general particle of mass  $m$  in a cubic box.

**8A.8(a)** What are the most likely locations of a particle in a box of length  $L$  in the state  $n=3$ ?

**8A.8(b)** What are the most likely locations of a particle in a box of length  $L$  in the state  $n=5$ ?

**8A.9(a)** Calculate the percentage change in a given energy level of a particle in a one-dimensional box when the length of the box is increased by 10 per cent.

**8A.9(b)** Calculate the percentage change in a given energy level of a particle in a cubic box when the length of the edge of the cube is decreased by 10 per cent in each direction.

**8A.10(a)** What is the value of  $n$  of a particle in a one-dimensional box such that the separation between neighbouring levels is equal to the mean energy of thermal motion ( $\frac{1}{2} kT$ ).

**8A.10(b)** A nitrogen molecule is confined in a cubic box of volume  $1.00 \text{ m}^3$ . (i) Assuming that the molecule has an energy equal to  $\frac{3}{2} kT$  at  $T = 300 \text{ K}$ , what is the value of  $n = (n_x^2 + n_y^2 + n_z^2)^{1/2}$  for this molecule? (ii) What is the energy separation between the levels  $n$  and  $n+1$ ? (iii) What is its de Broglie wavelength?

**8A.11(a)** For a particle in a rectangular box with sides of length  $L_1 = L$  and  $L_2 = 2L$ , find a state that is degenerate with the state  $n_1 = n_2 = 2$ . Degeneracy is normally associated with symmetry; why, then, are these two states degenerate?

**8A.11(b)** For a particle in a rectangular box with sides of length  $L_1 = L$  and  $L_2 = 2L$ , find a state that is degenerate with the state  $n_1 = 2, n_2 = 8$ . Degeneracy is normally associated with symmetry; why, then, are these two states degenerate?

**8A.12(a)** Consider a particle in a cubic box. What is the degeneracy of the level that has an energy three times that of the lowest level?

**8A.12(b)** Consider a particle in a cubic box. What is the degeneracy of the level that has an energy  $\frac{14}{3}$  times that of the lowest level?

**8A.13(a)** Suppose that the junction between two semiconductors can be represented by a barrier of height 2.0 eV and length 100 pm. Calculate the transmission probability of an electron with energy 1.5 eV.

**8A.13(b)** Suppose that a proton of an acidic hydrogen atom is confined to an acid that can be represented by a barrier of height 2.0 eV and length 100 pm. Calculate the probability that a proton with energy 1.5 eV can escape from the acid.

### Problems

**8A.1** Calculate the separation between the two lowest levels for an  $\text{O}_2$  molecule in a one-dimensional container of length 5.0 cm. At what value of  $n$  does the energy of the molecule reach  $\frac{1}{2} kT$  at 300 K, and what is the separation of this level from the one immediately below?

**8A.2** When  $\beta$ -carotene (1) is oxidized *in vivo*, it breaks in half and forms two molecules of retinal (vitamin A), which is a precursor to the pigment in the retina responsible for vision.

1  $\beta$ -Carotene

The conjugated system of retinal consists of 11 C atoms and one O atom. In the ground state of retinal, each level up to  $n=6$  is occupied by two electrons. Assuming an average internuclear distance of 140 pm, calculate (a) the separation in energy between the ground state and the first excited state in which one electron occupies the state with  $n=7$ , and (b) the frequency of the radiation required to produce a transition between these two states. (c) Using your results, choose among the words in parentheses to generate a rule for the prediction of frequency shifts in the absorption spectra of linear polyenes:

The absorption spectrum of a linear polyene shifts to (higher/lower) frequency as the number of conjugated atoms (increases/decreases).

**8A.3\*** A particle is confined to move in a one-dimensional box of length  $L$ . (a) If the particle is classical, show that the average value of  $x$  is  $\frac{1}{2}L$  and that the root-mean square value is  $L/3^{1/2}$ . (b) Show that for large values of  $n$ , a quantum particle approaches the classical values. This result is an example of the correspondence principle, which states that, for very large values of the quantum numbers, the predictions of quantum mechanics approach those of classical mechanics.

**8A.4** Here we explore further the idea introduced in *Impact* I8.1 that quantum mechanical effects need to be invoked in the description of the electronic properties of metallic nanocrystals, here modelled as three-dimensional boxes. (a) Set up the Schrödinger equation for a particle of mass  $m$  in a three-dimensional rectangular box with sides  $L_1$ ,  $L_2$ , and  $L_3$ . Show that the Schrödinger equation is separable. (b) Show that the wavefunction and the energy are defined by three quantum numbers. (c) Specialize the result from part (b) to an electron moving in a cubic box of side  $L=5$  nm and draw an energy diagram resembling Fig. 8A.2 and showing the first 15 energy levels. Note that each energy level may consist of degenerate energy states. (d) Compare the energy level diagram from part (c) with the energy level

diagram for an electron in a one-dimensional box of length  $L=5$  nm. Are the energy levels more or less sparsely distributed in the cubic box than in the one-dimensional box?

**8A.5** Many biological electron transfer reactions, such as those associated with biological energy conversion, may be visualized as arising from electron tunnelling between protein-bound cofactors, such as cytochromes, quinones, flavins, and chlorophylls. This tunnelling occurs over distances that are often greater than 1.0 nm, with sections of protein separating electron donor from acceptor. For a specific combination of donor and acceptor, the rate of electron tunnelling is proportional to the transmission probability, with  $\kappa \approx 7 \text{ nm}^{-1}$  (eqn 8A.23). By what factor does the rate of electron tunnelling between two cofactors increase as the distance between them changes from 2.0 nm to 1.0 nm?

**8A.6** Derive eqn 8A.23a, the expression for the transmission probability and show that then  $\kappa L \gg 1$  it reduces to eqn 8A.23b.

**8A.7\*** Consider the one-dimensional space in which a particle has one of three potential energies depending upon its position. They are:  $V=0$  for  $-\infty < x \leq 0$ ,  $V=V_2$  for  $0 \leq x \leq L$ , and  $V=V_3$  for  $L \leq x < \infty$ . The particle wavefunction has both a component  $e^{ik_1x}$  that is incident upon the barrier  $V_2$  and a reflected component  $e^{-ik_1x}$  in Zone 1 ( $-\infty < x \leq 0$ ). In Zone 2 ( $0 \leq x \leq L$ ) the wavefunction has components  $e^{k_2x}$  and  $e^{-k_2x}$ . In Zone 3 the wavefunction has only a forward component,  $e^{ik_3x}$ , which represents a particle that has traversed the barrier. The energy of the particle,  $E$ , is somewhere in the range  $V_2 > E > V_3$ . The transmission probability,  $T$ , is the ratio of the square modulus of Zone 3 amplitude to the square modulus of the incident amplitude. (a) Base your calculation on the continuity of the amplitude and slope of the wavefunction at the locations of the zone boundaries and derive a general equation for  $T$ . (b) Show that the general equation for  $T$  reduces to eqn 8A.23b in the high, wide barrier limit when  $V_1=V_3=0$ . (c) Draw a graph of the probability of proton tunnelling when  $V_3=0$ ,  $L=50$  pm, and  $E=10 \text{ kJ mol}^{-1}$  in the barrier range  $E < V_2 < 2E$ .

**8A.8** The wavefunction inside a long barrier of height  $V$  is  $\psi = Ne^{-\kappa x}$ . Calculate (a) the probability that the particle is inside the barrier and (b) the average penetration depth of the particle into the barrier.

## TOPIC 8B Vibrational motion

### Discussion questions

**8B.1** Describe the variation of the separation of the vibrational energy levels with the mass and force constant of the harmonic oscillator.

**8B.2** In what ways does the quantum mechanical description of a harmonic oscillator merge with its classical description at high quantum numbers?

**8B.3** What is the physical reason for the existence of a zero-point vibrational energy?

### Exercises

**8B.1(a)** Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass  $2.33 \times 10^{-26} \text{ kg}$  and force constant  $155 \text{ N m}^{-1}$ .

**8B.1(b)** Calculate the zero-point energy of a harmonic oscillator consisting of a particle of mass  $5.16 \times 10^{-26} \text{ kg}$  and force constant  $285 \text{ N m}^{-1}$ .

**8B.2(a)** For a certain harmonic oscillator of effective mass  $1.33 \times 10^{-25} \text{ kg}$ , the difference in adjacent energy levels is  $4.82 \text{ zJ}$ . Calculate the force constant of the oscillator.

**8B.2(b)** For a certain harmonic oscillator of effective mass  $2.88 \times 10^{-25} \text{ kg}$ , the difference in adjacent energy levels is  $3.17 \text{ zJ}$ . Calculate the force constant of the oscillator.

**8B.3(a)** Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of a proton ( $1.0078m_p$ ) and force constant  $855 \text{ N m}^{-1}$ .

**8B.3(b)** Calculate the wavelength of a photon needed to excite a transition between neighbouring energy levels of a harmonic oscillator of effective mass equal to that of an oxygen atom ( $15.9949m_p$ ) and force constant  $544 \text{ N m}^{-1}$ .

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**8B.4(a)** The vibrational frequency of  $\text{H}_2$  is 131.9 THz. What is the vibrational frequency of  $\text{D}_2$  ( $\text{D} = {}^2\text{H}$ )?

**8B.4(b)** The vibrational frequency of  $\text{H}_2$  is 131.9 THz. What is the vibrational frequency of  $\text{T}_2$  ( $\text{T} = {}^3\text{H}$ )?

**8B.5(a)** Calculate the minimum excitation energies of (i) a pendulum of length 1.0 m on the surface of the Earth, (ii) the balance-wheel of a clockwork watch ( $\nu = 5$  Hz).

**8B.5(b)** Calculate the minimum excitation energies of (i) the 33 kHz quartz crystal of a watch, (ii) the bond between two O atoms in  $\text{O}_2$ , for which  $k_f = 1177 \text{ N m}^{-1}$ .

**8B.6(a)** Assuming that the vibrations of a  ${}^{35}\text{Cl}_2$  molecule are equivalent to those of a harmonic oscillator with a force constant  $k_f = 329 \text{ N m}^{-1}$ , what is the zero-point energy of vibration of this molecule? The effective mass of a homonuclear diatomic molecule is half its total mass, and  $m({}^{35}\text{Cl}) = 34.9688 m_u$ .

**8B.6(b)** Assuming that the vibrations of a  ${}^{14}\text{N}_2$  molecule are equivalent to those of a harmonic oscillator with a force constant  $k_f = 2293.8 \text{ N m}^{-1}$ , what is the zero-point energy of vibration of this molecule? The effective mass of a homonuclear diatomic molecule is half its total mass, and  $m({}^{14}\text{N}) = 14.0031 m_u$ .

**8B.7(a)** Locate the nodes of the harmonic oscillator wavefunction with  $\nu = 4$ .

**8B.7(b)** Locate the nodes of the harmonic oscillator wavefunction with  $\nu = 5$ .

**8B.8(a)** What are the most probable displacements of a harmonic oscillator with  $\nu = 1$ ?

**8B.8(b)** What are the most probable displacements of a harmonic oscillator with  $\nu = 3$ ?

**8B.9(a)** Calculate the probability that an O–H bond treated as a harmonic oscillator will be found at a classically forbidden extension when  $\nu = 1$ .

**8B.9(b)** Calculate the probability that an O–H bond treated as a harmonic oscillator will be found at a classically forbidden extension when  $\nu = 2$ .

## Problems

**8B.1** The mass to use in the expression for the vibrational frequency of a diatomic molecule is the effective mass  $\mu = m_A m_B / (m_A + m_B)$ , where  $m_A$  and  $m_B$  are the masses of the individual atoms. The following data on the infrared absorption wavenumbers (wavenumbers in  $\text{cm}^{-1}$ ) of molecules are taken from *Spectra of diatomic molecules*, G. Herzberg, van Nostrand (1950):

$\text{H}^{35}\text{Cl}$	$\text{H}^{81}\text{Br}$	HI	CO	NO
2990	2650	2310	2170	1904

Calculate the force constants of the bonds and arrange them in order of increasing stiffness.

**8B.2** Carbon monoxide binds strongly to the  $\text{Fe}^{2+}$  ion of the haem group of the protein myoglobin. Estimate the vibrational frequency of CO bound to myoglobin by using the data in Problem 8B.1 and by making the following assumptions: the atom that binds to the haem group is immobilized, the protein is infinitely more massive than either the C or O atom, the C atom binds to the  $\text{Fe}^{2+}$  ion, and binding of CO to the protein does not alter the force constant of the C=O bond.

**8B.3** Of the four assumptions made in Problem 8B.2, the last two are questionable. Suppose that the first two assumptions are still reasonable and that you have at your disposal a supply of myoglobin, a suitable buffer in which to suspend the protein,  ${}^{12}\text{C}^{16}\text{O}$ ,  ${}^{13}\text{C}^{16}\text{O}$ ,  ${}^{12}\text{C}^{18}\text{O}$ ,  ${}^{13}\text{C}^{18}\text{O}$ , and an infrared spectrometer. Assuming that isotopic substitution does not affect the force constant of the C=O bond, describe a set of experiments that: (a) proves which atom, C or O, binds to the haem group of myoglobin, and (b) allows for the determination of the force constant of the C=O bond for myoglobin-bound carbon monoxide.

**8B.4** Confirm that a function of the form  $e^{-gx^2}$  is a solution of the Schrödinger equation for the ground state of a harmonic oscillator and find an expression for  $g$  in terms of the mass and force constant of the oscillator.

**8B.5** Calculate the mean kinetic energy of a harmonic oscillator by using the relations in Table 8B.1.

**8B.6** Calculate the values of  $\langle x^3 \rangle$  and  $\langle x^4 \rangle$  for a harmonic oscillator by using the relations in Table 8B.1.

**8B.7** Extend the calculation in *Example 8B.4* by using mathematical software to calculate the probability that a harmonic oscillator will be found outside the classically allowed displacements for general  $\nu$  and plot the probability as a function of  $\nu$ .

**8B.8** The intensities of spectroscopic transitions between the vibrational states of a molecule are proportional to the square of the integral  $\int \psi_{\nu'} x \psi_{\nu} dx$  over all space. Use the relations between Hermite polynomials given in Table 8B.1 to show that the only permitted transitions are those for which  $\nu' = \nu \pm 1$  and evaluate the integral in these cases.

**8B.9** Use mathematical software to construct a harmonic oscillator wavepacket of the form

$$\Psi(x, t) = \sum_{\nu=0}^N c_{\nu} \psi_{\nu}(x) e^{-iE_{\nu} t / \hbar}$$

where the wavefunctions and energies are those of a harmonic oscillator and with coefficients of your choice (for example, all equal). Explore how the wavepacket oscillates to and fro with time.

**8B.10** Show that, whatever superposition of harmonic oscillator states is used to construct a wavepacket (as in Problem 8B.9), it is localized at the same place at the times  $0, T, 2T, \dots$ , where  $T$  is the classical period of the oscillator.

**8B.11** The potential energy of the rotation of one  $\text{CH}_3$  group relative to its neighbour in ethane can be expressed as  $V(\phi) = V_0 \cos 3\phi$ . Show that for small displacements the motion of the group is quantized and calculate the energy of excitation from  $\nu = 0$  to  $\nu = 1$ . What do you expect to happen to the energy levels and wavefunctions as the excitation increases to high quantum numbers?

**8B.12** Use the virial theorem to obtain an expression for the relation between the mean kinetic and potential energies of an electron in a hydrogen atom.

## TOPIC 8C Rotational motion

### Discussion questions

**8C.1** Discuss the physical origin of quantization of energy for a particle confined to motion around a ring.

**8C.2** Describe the features of the solution of the particle on a ring that appear in the solution of the particle on a sphere. What concept applies to the latter but not to the former?

**8C.3** Describe the vector model of angular momentum in quantum mechanics. What features does it capture? What is its status as a model?

## Exercises

- 8C.1(a)** The rotation of a molecule can be represented by the motion of a point mass moving over the surface of a sphere. Calculate the magnitude of its angular momentum when  $l=1$  and the possible components of the angular momentum on an arbitrary axis. Express your results as multiples of  $\hbar$ .
- 8C.1(b)** The rotation of a molecule can be represented by the motion of a point mass moving over the surface of a sphere with angular momentum quantum number  $l=2$ . Calculate the magnitude of its angular momentum and the possible components of the angular momentum on an arbitrary axis. Express your results as multiples of  $\hbar$ .
- 8C.2(a)** The wavefunction,  $\psi(\phi)$ , for the motion of a particle in a ring is of the form  $\psi = Ne^{im\phi}$ . Determine the normalization constant,  $N$ .
- 8C.2(b)** Confirm that wavefunctions for a particle in a ring with different values of the quantum number  $m_l$  are mutually orthogonal.
- 8C.3(a)** Calculate the minimum excitation energy of a proton constrained to rotate in a circle of radius 100 pm around a fixed point.
- 8C.3(b)** Calculate the value of  $|m_l|$  for the system described in the preceding exercise corresponding to a rotational energy equal to the classical average energy at 25 °C (which is equal to  $\frac{1}{2}kT$ ).
- 8C.4(a)** The moment of inertia of a  $\text{CH}_4$  molecule is  $5.27 \times 10^{-47} \text{ kg m}^2$ . What is the minimum energy needed to start it rotating?

- 8C.4(b)** The moment of inertia of an  $\text{SF}_6$  molecule is  $3.07 \times 10^{-45} \text{ kg m}^2$ . What is the minimum energy needed to start it rotating?
- 8C.5(a)** Use the data in Exercise 8C.4(a) to calculate the energy needed to excite a  $\text{CH}_4$  molecule from a state with  $l=1$  to a state with  $l=2$ .
- 8C.5(b)** Use the data in Exercise 8C.4(b) to calculate the energy needed to excite an  $\text{SF}_6$  molecule from a state with  $l=2$  to a state with  $l=3$ .
- 8C.6(a)** What is the magnitude of the angular momentum of a  $\text{CH}_4$  molecule when it is rotating with its minimum energy?
- 8C.6(b)** What is the magnitude of the angular momentum of an  $\text{SF}_6$  molecule when it is rotating with its minimum energy?
- 8C.7(a)** Draw scale vector diagrams to represent the states (i)  $l=1, m_l=+1$ , (ii)  $l=2, m_l=0$ .
- 8C.7(b)** Draw the vector diagram for all the permitted states of a particle with  $l=6$ .
- 8C.8(a)** The number of states corresponding to a given energy plays a crucial role in atomic structure and thermodynamic properties. Determine the degeneracy of a body rotating with  $l=3$ .
- 8C.8(b)** The number of states corresponding to a given energy plays a crucial role in atomic structure and thermodynamic properties. Determine the degeneracy of a body rotating with  $l=4$ .

## Problems

**8C.1** The particle on a ring is a useful model for the motion of electrons around the porphine ring (2), the conjugated macrocycle that forms the structural basis of the haem group and the chlorophylls.

2 Porphine (porphin) ring

We may treat the group as a circular ring of radius 440 pm, with 22 electrons in the conjugated system moving along the perimeter of the ring. In the ground state of the molecule each state is occupied by two electrons. (a) Calculate the energy and angular momentum of an electron in the highest occupied level. (b) Calculate the frequency of radiation that can induce a transition between the highest occupied and lowest unoccupied levels.

**8C.2** Use mathematical software to construct a wavepacket for a particle moving on a circular ring of the form

$$\Psi(\phi, t) = \sum_{m_l=0}^{m_{l,\max}} c_{m_l} e^{i(m_l\phi - E_{m_l}t/\hbar)} \quad E_{m_l} = m_l^2 \hbar^2 / 2I$$

with coefficients  $c$  of your choice (for example, all equal). Explore how the wavepacket migrates on the ring but spreads with time.

**8C.3** Evaluate the  $z$ -component of the angular momentum and the kinetic energy of a particle on a ring that is described by the (unnormalized) wavefunctions (a)  $e^{i\phi}$ , (b)  $e^{-2i\phi}$ , (c)  $\cos \phi$ , and (d)  $(\cos \chi)e^{i\phi} + (\sin \chi)e^{-i\phi}$ .

**8C.4** Is the Schrödinger equation for a particle on an elliptical ring of semi-major axes  $a$  and  $b$  separable? *Hint:* Although  $r$  varies with angle  $\phi$ , the two are related by  $r^2 = a^2 \sin^2 \phi + b^2 \cos^2 \phi$ .

**8C.5** Calculate the energies of the first four rotational levels of  $^1\text{H}^{127}\text{I}$  free to rotate in three dimensions, using for its moment of inertia  $I = \mu R^2$ , with  $\mu = m_{\text{H}}m_{\text{I}}/(m_{\text{H}} + m_{\text{I}})$  and  $R = 160 \text{ pm}$ .

**8C.6** Confirm that the spherical harmonics (a)  $Y_{0,0}$ , (b)  $Y_{2,-1}$ , and (c)  $Y_{3,+3}$  satisfy the Schrödinger equation for a particle free to rotate in three dimensions, and find its energy and angular momentum in each case.

**8C.7** Confirm that  $Y_{3,+3}$  is normalized to 1. (The integration required is over the surface of a sphere.)

**8C.8** Show that the function  $f = \cos ax \cos by \cos cz$  is an eigenfunction of  $\nabla^2$ , and determine its eigenvalue.

**8C.9** Develop an expression (in Cartesian coordinates) for the quantum mechanical operators for the three components of angular momentum starting from the classical definition of angular momentum,  $l = r \times p$ . Show that any two of the components do not mutually commute, and find their commutator.

**8C.10** Starting from the operator  $\hat{L}_z = \hat{x}\hat{p}_y - \hat{y}\hat{p}_x$ , prove that in spherical polar coordinates  $\hat{L}_z = -i\hbar \partial/\partial \phi$ .

**8C.11** Show that  $[L^2, L_z] = 0$ , and then, without further calculation, justify the remark that  $\hat{L}^2, \hat{L}_q = 0$  for all  $q = x, y, \text{ and } z$ .

**8C.12** A particle confined to within a spherical cavity is a reasonable starting point for the discussion of the electronic properties of spherical metal nanoparticles (*Impact* I8.1). Here, you are invited to show in a series of steps that the  $l=0$  energy levels of an electron in a spherical cavity of radius  $R$  are quantized and given by

$$E_n = \frac{n^2 \hbar^2}{8m_e R^2}$$

(a) The hamiltonian for a particle free to move inside a sphere of radius  $a$  is

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla^2$$

Show that the Schrödinger equation is separable into radial and angular components. That is, begin by writing  $\psi(r, \theta, \phi) = R(r)Y(\theta, \phi)$ , where  $R(r)$  depends only on the distance of the particle from the centre of the sphere, and  $Y(\theta, \phi)$  is a spherical harmonic. Then show that the Schrödinger equation can be separated into two equations, one for  $R(r)$ , the radial equation, and the other for  $Y(\theta, \phi)$ , the angular equation. (b) Consider the case  $l=0$ . Show by differentiation that the solution of the radial equation has the form

$$R(r) = (2\pi a)^{-1/2} \frac{\sin(n\pi r/a)}{r}$$

(c) Now go on to show (by acknowledging the appropriate boundary conditions) that the allowed energies are given by  $E_n = n^2 h^2 / 8ma^2$ . With substitution of  $m_e$  for  $m$  and of  $R$  for  $a$ , this is the equation given above for the energy.

## Integrated activities

**8.1** Describe the features that stem from nanometre-scale dimensions that are not found in macroscopic objects.

**8.2** Explain why the particle in a box and the harmonic oscillator are useful models for quantum mechanical systems: what chemically significant systems can they be used to represent?

**8.3** Suppose that 1.0 mol perfect gas molecules all occupy the lowest energy level of a cubic box. (a) How much work must be done to change the volume of the box by  $\Delta V$ ? (b) Would the work be different if the molecules all occupied a state  $n \neq 1$ ? (c) What is the relevance of this discussion to the expression for the expansion work discussed in Topic 2A? (d) Can you identify a distinction between adiabatic and isothermal expansion?

**8.4** Determine the values of  $\Delta x = (\langle x^2 \rangle - \langle x \rangle^2)^{1/2}$  and  $\Delta p = (\langle p^2 \rangle - \langle p \rangle^2)^{1/2}$  for the ground state of (a) a particle in a box of length  $L$  and (b) an harmonic oscillator. Discuss these quantities with reference to the uncertainty principle.

**8.5** Repeat Problem 8.4 for (a) a particle in a box and (b) a harmonic oscillator in a general quantum state ( $n$  and  $\nu$ , respectively).

**8.6** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book for the following exercises:

(a) Plot the probability density for a particle in a box with  $n=1, 2, \dots, 5$  and  $n=50$ . How do your plots illustrate the correspondence principle?

(b) Plot the transmission probability  $T$  against  $E/V$  for passage by (i) a hydrogen molecule, (ii) a proton, and (iii) an electron through a barrier of height  $V$ .

(c) To gain some insight into the origins of the nodes in the harmonic oscillator wavefunctions, plot the Hermite polynomials  $H_\nu(y)$  for  $\nu=0$  through 5.

(d) Use mathematical software to generate three-dimensional plots of the wavefunctions for a particle confined to a rectangular surface with (i)  $n_1=1, n_2=1$ , the state of lowest energy, (ii)  $n_1=1, n_2=2$ , (iii)  $n_1=2, n_2=1$ , and (iv)  $n_1=2, n_2=2$ . Deduce a rule for the number of nodal lines in a wavefunction as a function of the values of  $n_1$  and  $n_2$ .

## Mathematical background 4 Differential equations

A **differential equation** is a relation between a function and its derivatives, as in

$$a \frac{d^2f}{dx^2} + b \frac{df}{dx} + cf = 0 \quad (\text{MB4.1})$$

where  $f$  is a function of the variable  $x$  and the factors  $a$ ,  $b$ ,  $c$  may be either constants or functions of  $x$ . If the unknown function depends on only one variable, as in this example, the equation is called an **ordinary differential equation**; if it depends on more than one variable, as in

$$a \frac{\partial^2 f}{\partial x^2} + b \frac{\partial^2 f}{\partial y^2} + cf = 0 \quad (\text{MB4.2})$$

it is called a **partial differential equation**. Here,  $f$  is a function of  $x$  and  $y$ , and the factors  $a$ ,  $b$ ,  $c$  may be either constants or functions of both variables. Note the change in symbol from  $d$  to  $\partial$  to signify a *partial derivative* (see *Mathematical background 2*).

### MB4.1 The structure of differential equations

The **order** of the differential equation is the order of the highest derivative that occurs in it: both examples above are second-order equations. Only rarely in science is a differential equation of order higher than two encountered.

A **linear differential equation** is one for which if  $f$  is a solution then so is  $\text{constant} \times f$ . Both examples above are linear. If the 0 on the right were replaced by a different number or a function other than  $f$ , then they would cease to be linear.

Solving a differential equation means something different from solving an algebraic equation. In the latter case, the solution is a value of the variable  $x$  (as in the solution  $x=2$  of the quadratic equation  $x^2-4=0$ ). The solution of a differential equation is the entire function that satisfies the equation, as in

$$\frac{d^2f}{dx^2} + f = 0, \quad f(x) = A \sin x + B \cos x \quad (\text{MB4.3})$$

with  $A$  and  $B$  constants. The process of finding a solution of a differential equation is called **integrating** the equation. The solution in eqn MB4.3 is an example of a **general solution** of a differential equation; that is, it is the most general solution of the equation and is expressed in terms of a number of constants ( $A$  and  $B$  in this case). When the constants are chosen to accord with certain specified **initial conditions** (if one variable is the time) or certain **boundary conditions** (to fulfil certain spatial restrictions on the solutions), we obtain the **particular solution** of the equation. The particular solution of a first-order differential equation requires one such condition; a second-order differential equation requires two.

### Brief illustration MB4.1 Particular solutions

If we are informed that  $f(0)=0$ , then because from eqn MB4.3 it follows that  $f(0)=B$ , we can conclude that  $B=0$ . That still leaves  $A$  undetermined. If we are also told that  $df/dx=2$  at  $x=0$  (that is,  $f'(0)=2$ , where the prime denotes a first derivative), then because the general solution (but with  $B=0$ ) implies that  $f'(x)=A \cos x$ , we know that  $f'(0)=A$ , and therefore  $A=2$ . The particular solution is therefore  $f(x)=2 \sin x$ . Figure MB4.1 shows a series of particular solutions corresponding to different boundary conditions.

Figure MB4.1 The solution of the differential equation in *Brief illustration MB4.1* with three different boundary conditions (as indicated by the resulting values of the constants  $A$  and  $B$ ).

### MB4.2 The solution of ordinary differential equations

The first-order linear differential equation

$$\frac{df}{dx} + af = 0 \quad (\text{MB4.4a})$$

with  $a$  a function of  $x$  or a constant can be solved by direct integration. To proceed, we use the fact that the quantities  $df$  and  $dx$  (called *differentials*) can be treated algebraically like any quantity and rearrange the equation into

$$\frac{df}{f} = -a dx \quad (\text{MB4.4b})$$

and integrate both sides. For the left-hand side, we use the familiar result  $\int dy/y = \ln y + \text{constant}$ . After pooling all the constants into a single constant  $C$ , we obtain:

$$\ln f(x) = -\int a dx + C \quad (\text{MB4.4c})$$

**Brief illustration MB4.2** The solution of a first-order equation

Suppose that in eqn MB4.4a the factor  $a=2x$ ; then the general solution, eqn MB4.4c, is

$$\ln f(x) = -2 \int x dx + C = -x^2 + C$$

(We have absorbed the constant of integration into the constant  $C$ .) Therefore

$$f(x) = Ne^{-x^2}, \quad N = e^C$$

If we are told that  $f(0) = 1$ , then we can infer that  $N = 1$  and therefore that  $f(x) = e^{-x^2}$ .

Even the solutions of first-order differential equations quickly become more complicated. A nonlinear first-order equation of the form

$$\frac{df}{dx} + af = b \quad (\text{MB4.5a})$$

with  $a$  and  $b$  functions of  $x$  (or constants) has a solution of the form

$$f(x)e^{\int a dx} = \int e^{\int a dx} b dx + C \quad (\text{MB4.5b})$$

as may be verified by differentiation. Mathematical software packages can often perform the required integrations.

Second-order differential equations are in general much more difficult to solve than first-order equations. One powerful approach commonly used to lay siege to second-order differential equations is to express the solution as a power series:

$$f(x) = \sum_{n=0}^{\infty} c_n x^n \quad (\text{MB4.6})$$

and then to use the differential equation to find a relation between the coefficients. This approach results, for instance, in the Hermite polynomials that form part of the solution of the Schrödinger equation for the harmonic oscillator (Topic 8B). Many of the second-order differential equations that occur in this text are tabulated in compilations of solutions or can be solved with mathematical software, and the specialized techniques that are needed to establish the form of the solutions may be found in mathematical texts.

**MB4.3 The solution of partial differential equations**

The only partial differential equations that we need to solve are those that can be separated into two or more ordinary differential equations by the technique known as **separation of variables**. To discover if the differential equation in eqn MB4.2 can be solved by this method we suppose that the full solution can be factored into functions that depend only on  $x$  or only on  $y$ , and write  $f(x,y) = X(x)Y(y)$ . At this stage there is no guarantee that the solution can be written in this way. Substituting this trial solution into the equation and recognizing that

$$\frac{\partial^2 XY}{\partial x^2} = Y \frac{d^2 X}{dx^2} \quad \frac{\partial^2 XY}{\partial y^2} = X \frac{d^2 Y}{dy^2}$$

we obtain

$$aY \frac{d^2 X}{dx^2} + bX \frac{d^2 Y}{dy^2} + cXY = 0$$

We are using  $d$  instead of  $\partial$  at this stage to denote differentials because each of the functions  $X$  and  $Y$  depends on one variable,  $x$  and  $y$ , respectively. Division through by  $XY$  turns this equation into

$$\frac{a}{X} \frac{d^2 X}{dx^2} + \frac{b}{Y} \frac{d^2 Y}{dy^2} + c = 0$$

Now suppose that  $a$  is a function only of  $x$ ,  $b$  a function of  $y$ , and  $c$  a constant. (There are various other possibilities that permit the argument to continue.) Then the first term depends only on  $x$  and the second only on  $y$ . If  $x$  is varied, only the first term can change. But as the other two terms do not change and the sum of the three terms is a constant (0), even that first term must be a constant. The same is true of the second term. Therefore because each term is equal to a constant, we can write

$$\frac{a}{X} \frac{d^2 X}{dx^2} = c_1 \quad \frac{b}{Y} \frac{d^2 Y}{dy^2} = c_2 \quad \text{with } c_1 + c_2 = -c$$

We now have two ordinary differential equations to solve by the techniques described in Section MB4.2. An example of this procedure is given in Topic 8A, for a particle in a two-dimensional region.

# CHAPTER 9

## Atomic structure and spectra

In this chapter we see how to use quantum mechanics to describe and investigate the electronic structure of an atom, the arrangement of electrons around a nucleus. The concepts we meet are of central importance for understanding the structures and reactions of atoms and molecules, and hence have extensive chemical applications.

### 9A Hydrogenic atoms

In this Topic we use the principles of quantum mechanics introduced in Chapters 7 and 8 to describe the internal structures of atoms. We start with the simplest type of atom. A 'hydrogenic atom' is a one-electron atom or ion of general atomic number  $Z$ ; examples are H, He<sup>+</sup>, Li<sup>2+</sup>, O<sup>7+</sup>, and even U<sup>91+</sup>. Hydrogenic atoms are important because their Schrödinger equations can be solved exactly. They also provide a set of concepts that are used to describe the structures of many-electron atoms and, as we see in the Topics of Chapter 10, the structures of molecules too. We see what experimental information is available from a study of the spectrum of atomic hydrogen. Then we set up the Schrödinger equation for an electron in an atom and separate it into angular and radial parts. The wavefunctions obtained are the hugely important 'atomic orbitals' of hydrogenic atoms.

### 9B Many-electron atoms

A 'many-electron atom' (or *polyelectronic atom*) is an atom or ion with more than one electron; examples include all neutral

atoms other than H. So even He, with only two electrons, is a many-electron atom. In this Topic we use hydrogenic atomic orbitals to describe the structures of many-electron atoms. Then, in conjunction with the concept of spin and the Pauli exclusion principle, we account for the periodicity of atomic properties and the structure of the periodic table.

### 9C Atomic spectra

The spectra of many-electron atoms are more complicated than those of hydrogen, but the same principles apply. In this Topic we see how such spectra are described by using term symbols, and the origin of their finer details.

### What is the impact of this material?

In *Impact* I9.1, we focus on the use of atomic spectroscopy to examine stars. By analysing their spectra we see that it is possible to determine the composition of their outer layers and the surrounding gases and to determine features of their physical state.

### ► Why do you need to know this material?

An understanding of the structure of the hydrogen atom is central to the understanding of all other atoms, the periodic table, and bonding. All accounts of the structures of molecules are based on the language and concepts it introduces.

### ► What is the key idea?

Atomic orbitals are labelled by three quantum numbers that specify the energy and angular momentum of an electron in a hydrogenic atom.

### ► What do you need to know already?

You need to be aware of the concept of wavefunction (Topic 7B) and its interpretation. You need to know how to set up a Schrödinger equation and how boundary conditions limit its solutions (Topic 8A).

When an electric discharge is passed through gaseous hydrogen, the  $\text{H}_2$  molecules are dissociated and the energetically excited H atoms that are produced emit light of discrete frequencies, producing a spectrum of a series of 'lines' (Fig. 9A.1). The Swedish spectroscopist Johannes Rydberg noted (in 1890) that all the lines are described by the expression

$$\tilde{\nu} = \tilde{R}_{\text{H}} \left( \frac{1}{n_1^2} - \frac{1}{n_2^2} \right) \quad \text{Spectral lines of a hydrogen atom} \quad (9A.1)$$

with  $n_1 = 1$  (the *Lyman series*), 2 (the *Balmer series*), and 3 (the *Paschen series*), and that in each case  $n_2 = n_1 + 1, n_1 + 2, \dots$ . The constant  $\tilde{R}_{\text{H}}$  is now called the **Rydberg constant** for the hydrogen atom and is found empirically to have the value  $109\,677\text{ cm}^{-1}$ .

As eqn 9A.1 suggests, each spectral line can be written as the difference of two terms, each of the form

$$T_n = \frac{\tilde{R}_{\text{H}}}{n^2} \quad (9A.2)$$

The **Ritz combination principle** states that *the wavenumber of any spectral line (of any atom, not just hydrogenic atoms) is the difference between two terms*. We say that two terms  $T_1$  and  $T_2$  'combine' to produce a spectral line of wavenumber

$$\tilde{\nu} = T_1 - T_2 \quad \text{Ritz combination principle} \quad (9A.3)$$

**Figure 9A.1** The spectrum of atomic hydrogen. Both the observed spectrum and its resolution into overlapping series are shown. Note that the Balmer series lies in the visible region.

Thus, if each spectroscopic term represents an energy  $hcT$ , the difference in energy when the atom undergoes a transition between two terms is  $\Delta E = hcT_1 - hcT_2$  and, according to the Bohr frequency condition ( $\Delta E = h\nu$ , Topic 7A), the frequency of the radiation emitted is given by  $\nu = cT_1 - cT_2$ . This expression rearranges into the Ritz formula when expressed in terms of wavenumbers (on division by  $c$ ;  $\tilde{\nu} = \nu/c$ ). The Ritz combination principle applies to all types of atoms and molecules, but only for hydrogenic atoms do the terms have the simple form (constant)/ $n^2$ .

Because spectroscopic observations show that electromagnetic radiation is absorbed and emitted by atoms only at certain wavenumbers, it follows that only certain energy states of atoms are permitted. Our tasks in this Topic are to determine the origin of this energy quantization, to find the permitted energy levels, and to account for the value of  $\tilde{R}_H$ . The spectra of more complex atoms are treated in Topic 9C.

## 9A.1 The structure of hydrogenic atoms

The Coulomb potential energy of an electron in a hydrogenic atom of atomic number  $Z$  and therefore nuclear charge  $Ze$  is

$$V(r) = -\frac{Ze^2}{4\pi\epsilon_0 r} \quad (9A.4)$$

where  $r$  is the distance of the electron from the nucleus and  $\epsilon_0$  is the vacuum permittivity. The hamiltonian for the electron and a nucleus of mass  $m_N$  is therefore

$$\begin{aligned} \hat{H} &= \hat{E}_{k,\text{electron}} + \hat{E}_{k,\text{nucleus}} + \hat{V}(r) \\ &= -\frac{\hbar^2}{2m_e} \nabla_e^2 - \frac{\hbar^2}{2m_N} \nabla_N^2 - \frac{Ze^2}{4\pi\epsilon_0 r} \end{aligned} \quad \text{Hamiltonian for a hydrogenic atom} \quad (9A.5)$$

The subscripts e and N on  $\nabla^2$  indicate differentiation with respect to the electron or nuclear coordinates, respectively.

### (a) The separation of variables

Physical intuition suggests that the full Schrödinger equation ought to separate into two equations, one for the motion of the atom as a whole through space and the other for the motion of the electron relative to the nucleus. We show in the following *Justification* how this separation is achieved, and that the Schrödinger equation for the internal motion of the electron relative to the nucleus is

$$\begin{aligned} -\frac{\hbar^2}{2\mu} \nabla^2 \psi - \frac{Ze^2}{4\pi\epsilon_0 r} \psi &= E\psi \\ \frac{1}{\mu} &= \frac{1}{m_e} + \frac{1}{m_N} \end{aligned} \quad \text{Schrödinger equation for a hydrogenic atom} \quad (9A.6)$$

where differentiation is now with respect to the coordinates of the electron relative to the nucleus. The quantity  $\mu$  is called the **reduced mass**. The reduced mass is very similar to the electron mass because  $m_N$ , the mass of the nucleus, is much larger than the mass of an electron, so  $1/\mu \approx 1/m_e$  and therefore  $\mu \approx m_e$ . In all except the most precise work, the reduced mass can be replaced by  $m_e$ .

### Justification 9A.1 The separation of internal and external motion

Consider a one-dimensional system in which the potential energy depends only on the separation of the two particles. The total energy is

$$E = \frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} + V(x_1 - x_2)$$

where  $p_1 = m_1(dx_1/dt)$  and  $p_2 = m_2(dx_2/dt)$ . The centre of mass (Fig. 9A.2) is located at

$$X = \frac{m_1}{m} x_1 + \frac{m_2}{m} x_2 \quad m = m_1 + m_2$$

and the separation of the particles is  $x = x_1 - x_2$ . It follows that

$$x_1 = X + \frac{m_2}{m} x \quad x_2 = X - \frac{m_1}{m} x$$

The linear momenta of the particles can now be expressed in terms of the rates of change of  $x$  and  $X$ :

$$\begin{aligned} p_1 &= m_1 \frac{dx_1}{dt} = m_1 \frac{dX}{dt} + \frac{m_1 m_2}{m} \frac{dx}{dt} \\ p_2 &= m_2 \frac{dx_2}{dt} = m_2 \frac{dX}{dt} - \frac{m_1 m_2}{m} \frac{dx}{dt} \end{aligned}$$

Then it follows that

$$\frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} = \frac{1}{2} m \left( \frac{dX}{dt} \right)^2 + \frac{1}{2} \mu \left( \frac{dx}{dt} \right)^2$$

where  $\mu$  is given in eqn 9A.6. By writing  $P = m(dX/dt)$  for the linear momentum of the system as a whole and  $p = \mu(dx/dt)$ , we find

$$E = \frac{P^2}{2m} + \frac{p^2}{2\mu} + V(x)$$

Figure 9A.2 The coordinates used for discussing the separation of the relative motion of two particles from the motion of the centre of mass.

The corresponding hamiltonian (generalized to three dimensions) is therefore

$$\hat{H} = -\frac{\hbar^2}{2m} \nabla_{\text{c.m.}}^2 - \frac{\hbar^2}{2\mu} \nabla^2$$

where the first term differentiates with respect to the centre of mass coordinates and the second with respect to the relative coordinates.

Now we write the overall wavefunction as the product  $\psi_{\text{total}}(X, x) = \psi_{\text{c.m.}}(X)\psi(x)$ , where the first factor is a function of only the centre of mass coordinates and the second is a function of only the relative coordinates. The overall Schrödinger equation,  $H\psi_{\text{total}} = E_{\text{total}}\psi_{\text{total}}$ , then separates by the argument that we have used in Topics 8A and 8C, with  $E_{\text{total}} = E_{\text{c.m.}} + E$ .

Because the potential energy is centrosymmetric (independent of angle), we can suspect that the equation for the wavefunction is separable into radial and angular components. Therefore, we write

$$\psi(r, \theta, \phi) = R(r)Y(\theta, \phi) \quad (9A.7)$$

and examine whether the Schrödinger equation can be separated into two equations, one for the **radial wavefunction**  $R(r)$  and the other for the **angular wavefunction**  $Y(\theta, \phi)$ . As shown in the following *Justification*, the equation does separate, and the equations we have to solve are

$$\Delta^2 Y = -l(l+1)Y \quad (9A.8a)$$

$$-\frac{\hbar^2}{2\mu} \frac{d^2 u}{dr^2} + V_{\text{eff}} u = Eu \quad (9A.8b)$$

where  $u(r) = rR(r)$  and

$$V_{\text{eff}}(r) = -\frac{Ze^2}{4\pi\epsilon_0 r} + \frac{l(l+1)\hbar^2}{2\mu r^2} \quad (9A.8c)$$

### Justification 9A.2 The separation of angular and radial motion

The laplacian in three dimensions is given in Table 7B.1. It follows that the Schrödinger equation in eqn 9A.6 is

$$-\frac{\hbar^2}{2\mu} \nabla^2 RY + VRY = -\frac{\hbar^2}{2\mu} \left( \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Delta^2 \right) RY + VRY = ERY$$

Because  $R$  depends only on  $r$  and  $Y$  depends only on the angular coordinates, this equation becomes

$$-\frac{\hbar^2}{2\mu} \left( Y \frac{d^2 R}{dr^2} + \frac{2Y}{r} \frac{dR}{dr} + \frac{R}{r^2} \Delta^2 Y \right) + VRY = ERY$$

where the partial derivatives with respect to  $r$  have been replaced by complete derivatives because  $R$  depends only on  $r$ . If we multiply through by  $r^2/R$ , we obtain

$$-\frac{\hbar^2}{2\mu R} \left( r^2 \frac{d^2 R}{dr^2} + 2r \frac{dR}{dr} \right) + Vr^2 - \frac{\hbar^2}{2\mu Y} \Delta^2 Y = Er^2$$

Depends on  $\theta, \phi$

At this point we employ the usual argument. The term in  $Y$  is the only one that depends on the angular variables, so it must be a constant. When we write this constant as  $\hbar^2 l(l+1)/2\mu$ , eqn 9A.8c follows immediately.

Equation 9A.8a is the same as the Schrödinger equation for a particle free to move round a central point, and is considered in Topic 8C. The solutions are the spherical harmonics (Table 8C.1), and are specified by the quantum numbers  $l$  and  $m_l$ . We consider them in more detail shortly. Equation 9A.8b is called the **radial wave equation**. The radial wave equation is the description of the motion of a particle of mass  $\mu$  in a one-dimensional region  $0 \leq r < \infty$  where the potential energy is  $V_{\text{eff}}(r)$ .

### (b) The radial solutions

We can anticipate some features of the shapes of the radial wavefunctions by analysing the form of  $V_{\text{eff}}$ . The first term in eqn 9A.8c is the Coulomb potential energy of the electron in the field of the nucleus. The second term stems from what in classical physics would be called the centrifugal force that arises from the angular momentum of the electron around the nucleus. When  $l=0$ , the electron has no angular momentum, and the effective potential energy is purely Coulombic and attractive at all radii (Fig. 9A.3). When  $l \neq 0$ , the centrifugal term gives a positive (repulsive) contribution to the effective potential energy. When the electron is close to the nucleus ( $r \approx 0$ ), this repulsive term, which is proportional to  $1/r^2$ , dominates the attractive Coulombic component, which is proportional to  $1/r$ , and the net result is an effective repulsion of the electron from the nucleus. The two effective potential energies, the one for  $l=0$  and the one for  $l \neq 0$ , are therefore qualitatively very different close to the nucleus. However, they are similar at large distances because the centrifugal contribution tends to zero more rapidly (as  $1/r^2$ ) than the Coulombic contribution (as  $1/r$ ). Therefore, we can expect the solutions with  $l=0$  and  $l \neq 0$  to be quite different near the nucleus but similar far away from it. There are two important features of the radial wavefunction:

- Close to the nucleus the radial wavefunction is proportional to  $r^l$ , and the higher the orbital angular momentum, the less likely it is that the electron will be found there (Fig. 9A.4).

Physical interpretation

**Figure 9A.3** The effective potential energy of an electron in the hydrogen atom. When the electron has zero orbital angular momentum, the effective potential energy is the Coulombic potential energy. When the electron has nonzero orbital angular momentum, the centrifugal effect gives rise to a positive contribution which is very large close to the nucleus. The  $l=0$  and  $l \neq 0$  wavefunctions are therefore very different near the nucleus.

- Far from the nucleus all radial wavefunctions approach zero exponentially.

We shall not go through the technical steps of solving the radial equation for the full range of radii and seeing how the form  $r^l$  close to the nucleus blends into the exponentially decaying form at great distances. For our purposes it is sufficient to know that the two limits can be bridged only for integral values of a quantum number  $n$ , and that the allowed energies corresponding to the allowed solutions are

$$E_n = -\frac{\mu e^4}{32\pi^2 \epsilon_0^2 \hbar^2} \times \frac{Z^2}{n^2} \quad \text{Bound state energies} \quad (9A.9)$$

**Figure 9A.4** Close to the nucleus, orbitals with  $l=1$  are proportional to  $r$ , orbitals with  $l=2$  are proportional to  $r^2$ , and orbitals with  $l=3$  are proportional to  $r^3$ . Electrons are progressively excluded from the neighbourhood of the nucleus as  $l$  increases. An orbital with  $l=0$  has a finite, nonzero value at the nucleus.

with  $n=1, 2, \dots$ . Likewise, the radial wavefunctions depend on the values of both  $n$  and  $l$  (but not on  $m_l$  because only  $l$  appears in the radial wave equation), and all of them have the form

$$R(r) = \underbrace{r^l}_{\text{Dominant close to the nucleus}} \times \underbrace{(\text{polynomial in } r)}_{\text{Bridges the two ends of the function}} \times \underbrace{(\text{decaying exponential in } r)}_{\text{Dominant far from the nucleus}} \quad (9A.10)$$

and therefore look like

$$R(r) = r^l L(r) e^{-r}$$

with various constants and where  $L(r)$  is the bridging polynomial. The specific forms of the functions are most simply written in terms of the dimensionless quantity  $\rho$  (rho), where

$$\rho = \frac{2Zr}{na} \quad a = \frac{m_e}{\mu} a_0 = \frac{m_e + m_N}{m_N} a_0 \quad a_0 = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2} \quad (9A.11)$$

The **Bohr radius**,  $a_0$ , has the value 52.9 pm; it is so called because the same quantity appeared in Bohr's early model of the hydrogen atom as the radius of the electron orbit of lowest energy. In practice, because  $m_e \ll m_N$  there is so little difference between  $a$  and  $a_0$  that it is safe to use  $a_0$  in the definition of  $\rho$  for all atoms (even for  $^1\text{H}$ ,  $a = 1.0005a_0$ ). Specifically, the radial wavefunctions for an electron with quantum numbers  $n$  and  $l$  are the (real) functions

$$R_{n,l}(r) = N_{n,l} \rho^l L_{n-l-1}^{2l+1}(\rho) e^{-\rho/2} \quad \text{Radial wavefunctions} \quad (9A.12)$$

where  $L(\rho)$  is an *associated Laguerre polynomial*. The notation might look fearsome, but the polynomials have quite simple forms, such as  $1$ ,  $\rho$ , and  $2-\rho$  (they can be picked out in Table 9A.1). The factor  $N$  ensures that the radial wavefunction is normalized to 1 in the sense that

$$\int_0^\infty R_{n,l}(r)^2 r^2 dr = 1 \quad (9A.13)$$

The  $r^2$  comes from the volume element in spherical polar coordinates (*The chemist's toolkit* 7B.1). Specifically, we can interpret the components of eqn 9A.12 as follows:

- The exponential factor ensures that the wavefunction approaches zero far from the nucleus.
- The factor  $\rho^l$  ensures that (provided  $l > 0$ ) the wavefunction vanishes at the nucleus. The zero at  $r=0$  is not a radial node because the radial wavefunction does not pass through zero at that point (because  $r$  cannot be negative). Nodes passing through the nucleus are all angular nodes.
- The associated Laguerre polynomial is a function that in general oscillates from positive to negative values and accounts for the presence of radial nodes.

Table 9A.1 Hydrogenic radial wavefunctions,  $R_{n,l}(r)$ 

$n$	$l$	$R_{n,l}(r)$
1	0	$2\left(\frac{Z}{a}\right)^{3/2} e^{-\rho/2}$
2	0	$\frac{1}{8^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (2-\rho)e^{-\rho/2}$
2	1	$\frac{1}{24^{1/2}}\left(\frac{Z}{a}\right)^{3/2} \rho e^{-\rho/2}$
3	0	$\frac{1}{243^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (6-6\rho+\rho^2)e^{-\rho/2}$
3	1	$\frac{1}{486^{1/2}}\left(\frac{Z}{a}\right)^{3/2} (4-\rho)\rho e^{-\rho/2}$
3	2	$\frac{1}{2430^{1/2}}\left(\frac{Z}{a}\right)^{3/2} \rho^2 e^{-\rho/2}$

$\rho = (2Z/na)r$  with  $a = 4\pi\epsilon_0\hbar^2/\mu e^2$ . For an infinitely heavy nucleus (or one that may be assumed to be),  $\mu = m_e$  and  $a = a_0$ , the Bohr radius.

Expressions for some radial wavefunctions are given in Table 9A.1 and illustrated in Fig. 9A.5.

#### Brief illustration 9A.1 Probability densities

To calculate the probability density at the nucleus for an electron with  $n=1$ ,  $l=0$ , and  $m_l=0$ , we evaluate  $\psi$  at  $r=0$ :

$$\psi_{1,0,0}(0, \theta, \phi) = R_{1,0}(0)Y_{0,0}(\theta, \phi) = 2\left(\frac{Z}{a_0}\right)^{3/2} \left(\frac{1}{4\pi}\right)^{1/2}$$

The probability density is therefore

$$\psi_{1,0,0}^2(0, \theta, \phi) = \frac{Z^3}{\pi a_0^3}$$

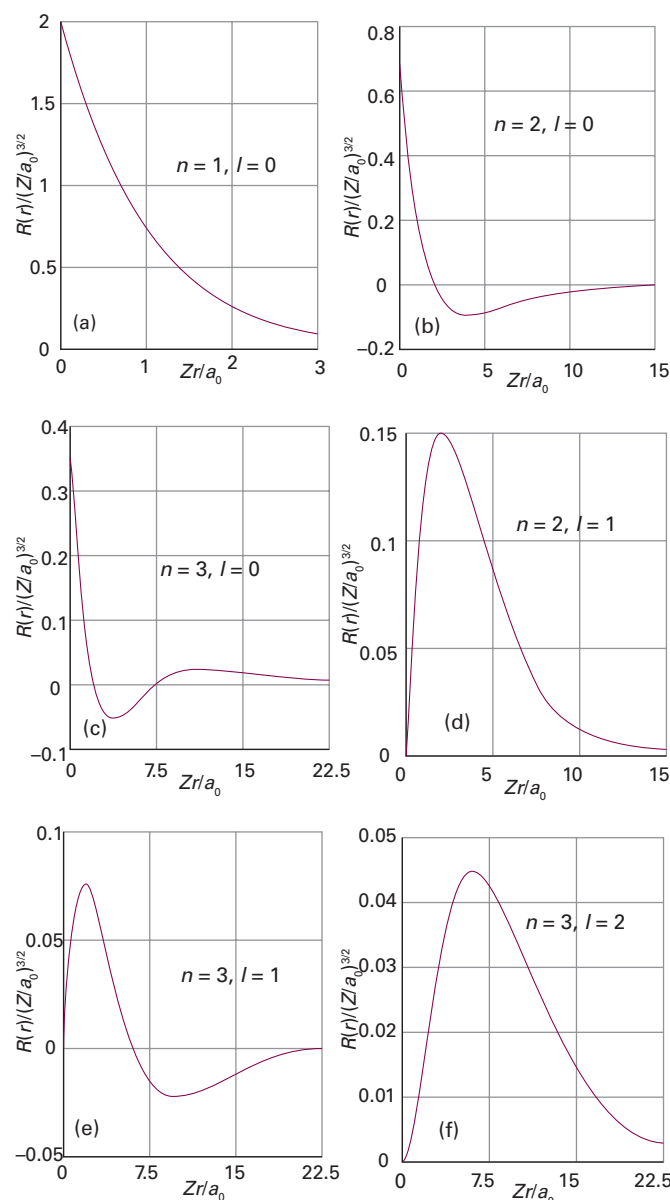

which evaluates to  $2.15 \times 10^{-6} \text{ pm}^{-3}$  when  $Z=1$ .

**Self-test 9A.1** Evaluate the probability density at the nucleus of the electron for an electron with  $n=2$ ,  $l=0$ ,  $m_l=0$ .

Answer:  $(Z/a_0)^3/8\pi$

## 9A.2 Atomic orbitals and their energies

An **atomic orbital** is a one-electron wavefunction for an electron in an atom. Each hydrogenic atomic orbital is defined by three quantum numbers, designated  $n$ ,  $l$ , and  $m_l$ . When an electron is described by one of these wavefunctions, we say that it 'occupies' that orbital. We could go on to say that the electron is in the state  $|n, l, m_l\rangle$ . For instance, an electron described by the wavefunction  $\psi_{1,0,0}$  and in the state  $|1,0,0\rangle$  is said to 'occupy' the orbital with  $n=0$ ,  $l=0$ , and  $m_l=0$ .

**Figure 9A.5** The radial wavefunctions of the first few states of hydrogenic atoms of atomic number  $Z$ . Note that the orbitals with  $l=0$  have a nonzero and finite value at the nucleus. The horizontal scales are different in each case: orbitals with high principal quantum numbers are relatively distant from the nucleus.

### (a) The specification of orbitals

The quantum number  $n$  is called the **principal quantum number**; it can take the value  $n=1, 2, 3, \dots$  and determines the energy of the electron:

- An electron in an orbital with quantum number  $n$  has an energy given by eqn 9A.9. The two other quantum numbers,  $l$  and  $m_l$ , come from the

Physical interpretation

angular solutions, and specify the angular momentum of the electron around the nucleus.

- An electron in an orbital with quantum number  $l$  has an angular momentum of magnitude  $\{l(l+1)\}^{1/2}\hbar$ , with  $l=0, 1, 2, \dots, n-1$ .
- An electron in an orbital with quantum number  $m_l$  has a  $z$ -component of angular momentum  $m_l\hbar$ , with  $m_l=0, \pm 1, \pm 2, \dots, \pm l$ .

Physical interpretation

Note how the value of the principal quantum number,  $n$ , controls the maximum value of  $l$  and  $l$  controls the range of values of  $m_l$ .

To define the state of an electron in a hydrogenic atom fully we need to specify not only the orbital it occupies but also its spin state. In Topic 8C it is mentioned that an electron possesses an intrinsic angular momentum, its ‘spin.’ We develop this property further in Topic 9B and show there that spin is described by the two quantum numbers  $s$  and  $m_s$  (the analogues of  $l$  and  $m_l$ ). The value of  $s$  is fixed at  $\frac{1}{2}$  for an electron, so we do not need to consider it further at this stage. However,  $m_s$  may be either  $+\frac{1}{2}$  or  $-\frac{1}{2}$ , and to specify the state of an electron in a hydrogenic atom we need to specify which of these values describes it. It follows that, to specify the state of an electron in a hydrogenic atom, we need to give the values of four quantum numbers, namely  $n, l, m_l$ , and  $m_s$ .

### (b) The energy levels

The energy levels predicted by eqn 9A.9 are depicted in Fig. 9A.6. The energies, and also the separation of neighbouring levels, are proportional to  $Z^2$ , so the levels are four times as wide apart (and the ground state four times lower in energy) in  $\text{He}^+$  ( $Z=2$ ) than in  $\text{H}$  ( $Z=1$ ). All the energies given by eqn 9A.9 are negative. They refer to the **bound states** of the atom, in which the energy of the atom is lower than that of the infinitely separated, stationary electron and nucleus (which corresponds to the zero of energy). There are also solutions of the Schrödinger equation with positive energies. These solutions correspond to **unbound states** of the electron, the states to which an electron is raised when it is ejected from the atom by a high-energy collision or photon. The energies of the unbound electron are not quantized and form the continuum states of the atom.

Equation 9A.9, which we can write as

$$E_n = -\frac{hcZ^2\tilde{R}_N}{n^2} \quad \tilde{R}_N = \frac{\mu e^4}{32\pi^2\epsilon_0^2\hbar^3c} \quad \text{Bound state energies} \quad (9A.14)$$

is consistent with the spectroscopic result summarized by eqn 9A.1, and we can identify the Rydberg constant for the atom as

$$\tilde{R}_N = \frac{\mu}{m_e} \times \tilde{R}_\infty \quad \tilde{R}_\infty = \frac{m_e e^4}{8\epsilon_0^2 h^3 c} \quad \text{Rydberg constant} \quad (9A.15)$$

**Figure 9A.6** The energy levels of a hydrogen atom. The values are relative to an infinitely separated, stationary electron and a proton.

where  $\mu$  is the reduced mass of the atom and  $\tilde{R}_\infty$  is the **Rydberg constant**. Insertion of the values of the fundamental constants into the expression for  $\tilde{R}_H$  gives very close agreement with the experimental value for hydrogen. The only discrepancies arise from the neglect of relativistic corrections (in simple terms, the increase of mass with speed), which the non-relativistic Schrödinger equation ignores.

#### Brief illustration 9A.2 The energy levels

The value of  $\tilde{R}_\infty$  is given inside the front cover and is  $109\,737\text{ cm}^{-1}$ . The reduced mass of a hydrogen atom with  $m_p = 1.672\,62 \times 10^{-27}\text{ kg}$  and  $m_e = 9.109\,38 \times 10^{-31}\text{ kg}$  is

$$\mu = \frac{m_e m_p}{m_e + m_p} = \frac{(9.109\,38 \times 10^{-31}\text{ kg}) \times (1.672\,62 \times 10^{-27}\text{ kg})}{(9.109\,38 \times 10^{-31}\text{ kg}) + (1.672\,62 \times 10^{-27}\text{ kg})} = 9.104\,42 \times 10^{-31}\text{ kg}$$

It then follows that

$$\tilde{R}_H = \frac{9.104\,42 \times 10^{-31}\text{ kg}}{9.109\,38 \times 10^{-31}\text{ kg}} \times 109\,737\text{ cm}^{-1} = 109\,677\text{ cm}^{-1}$$

and that the ground state of the electron ( $n=1$ ) lies at

$$E = -hc\tilde{R}_H = -(6.626\,08 \times 10^{-34}\text{ J s}) \times (2.997\,945 \times 10^{10}\text{ cm s}^{-1}) \times (109\,677\text{ cm}^{-1}) = -2.178\,69 \times 10^{-18}\text{ J} \quad (-2.178\,69\text{ aJ})$$

This energy corresponds to  $-13.598\text{ eV}$ .

**Self-test 9A.2** What is the corresponding value for a deuterium atom? Take  $m_D = 2.013\,55m_u$ .

Answer:  $-13.602\text{ eV}$

### (c) Ionization energies

The **ionization energy**,  $I$ , of an element is the minimum energy required to remove an electron from the ground state, the state of lowest energy, of one of its atoms in the gas phase. Because

the ground state of hydrogen is the state with  $n=1$ , with energy  $E_1 = -hc\tilde{R}_H$  and the atom is ionized when the electron has been excited to the level corresponding to  $n=\infty$  (see Fig. 9A.6), the energy that must be supplied is

$$I = hc\tilde{R}_H \quad (9A.16)$$

The value of  $I$  is 2.179 aJ ( $1 \text{ aJ} = 10^{-18} \text{ J}$ ), which corresponds to 13.60 eV.

*A note on good practice* Ionization energies are sometimes referred to as *ionization potentials*. That is incorrect, but not uncommon. If the term is used at all, it should denote the potential difference through which an electron must be moved for its potential energy to change by an amount equal to the ionization energy, and reported in volts.

### Example 9A.1 Measuring an ionization energy spectroscopically

The emission spectrum of atomic hydrogen shows lines at 82 259, 97 492, 102 824, 105 292, 106 632, and 107 440  $\text{cm}^{-1}$ , which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the value of the Rydberg constant for hydrogen.

**Method** The spectroscopic determination of ionization energies depends on the determination of the series limit, the wavenumber at which the series terminates and becomes a continuum. If the upper state lies at an energy  $-hc\tilde{R}_H/n^2$ , then, when the atom makes a transition to  $E_{\text{lower}} = -I$  a photon of wavenumber

$$\tilde{\nu} = -\frac{\tilde{R}_H}{n^2} - \frac{E_{\text{lower}}}{hc} = -\frac{\tilde{R}_H}{n^2} + \frac{I}{hc}$$

A plot of the wavenumbers against  $1/n^2$  should give a straight line of slope  $-\tilde{R}_H$  and intercept  $I/hc$ . Use a computer to make a least-squares fit of the data in order to obtain a result that reflects the precision of the data.

**Answer** The wavenumbers are plotted against  $1/n^2$  in Fig. 9A.7. (a) The (least-squares) intercept lies at 109 679  $\text{cm}^{-1}$ , so (b) the ionization energy is

$$I = hc\tilde{R}_H = (6.626\ 08 \times 10^{-34} \text{ J s}) \times (2.997\ 945 \times 10^{10} \text{ cm s}^{-1}) \times 109\ 679 \text{ cm}^{-1} = 2.1787 \times 10^{-18} \text{ J}$$

or 2.1787 aJ, corresponding to 1312.1  $\text{kJ mol}^{-1}$  (the negative of the value of  $E$  calculated in *Brief illustration* 9A.2).

**Self-test 9A.3** The emission spectrum of atomic deuterium shows lines at 15 238, 20 571, 23 039, and 24 380  $\text{cm}^{-1}$ , which correspond to transitions to the same lower state. Determine (a) the ionization energy of the lower state, (b) the ionization energy of the ground state, (c) the mass of the deuteron (by expressing the Rydberg constant in terms of the reduced mass

Figure 9A.7 The plot of the data in Example 9A.1 used to determine the ionization energy of an atom (in this case, of H).

of the electron and the deuteron, and solving for the mass of the deuteron).

Answer: (a) 328.1  $\text{kJ mol}^{-1}$ , (b) 1312.4  $\text{kJ mol}^{-1}$ , (c)  $2.8 \times 10^{-27} \text{ kg}$ , a result very sensitive to  $\tilde{R}_D$

### (d) Shells and subshells

All the orbitals of a given value of  $n$  are said to form a single **shell** of the atom. In a hydrogenic atom (and only in a hydrogenic atom), all orbitals of given  $n$ , and therefore belonging to the same shell, have the same energy. It is common to refer to successive shells by letters:

$$n = \begin{array}{cccc} 1 & 2 & 3 & 4 \dots \\ \text{K} & \text{L} & \text{M} & \text{N} \dots \end{array}$$

Specification of shells

Thus, all the orbitals of the shell with  $n=2$  form the L shell of the atom, and so on.

The orbitals with the same value of  $n$  but different values of  $l$  are said to form a **subshell** of a given shell. These subshells are generally referred to by letters:

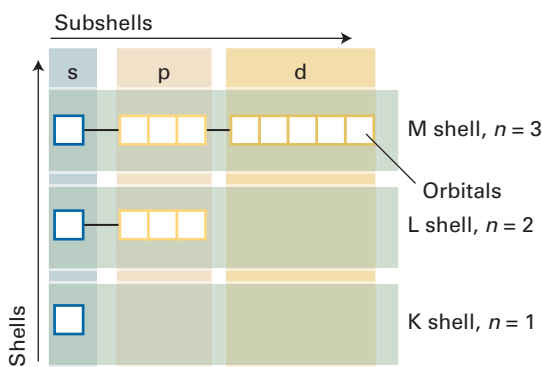

$$l = \begin{array}{cccccccc} 0 & 1 & 2 & 3 & 4 & 5 & 6 \dots \\ \text{s} & \text{p} & \text{d} & \text{f} & \text{g} & \text{h} & \text{i} \dots \end{array}$$

Specification of subshells

All orbitals of the same subshell have the same energy in both hydrogenic and many-electron atoms. The letters then run alphabetically (j is not used because in some languages i and j are not distinguished). Figure 9A.8 is a version of Fig. 9A.6 which shows the subshells explicitly. Because  $l$  can range from 0 to  $n-1$ , giving  $n$  values in all, it follows that there are  $n$  subshells of a shell with principal quantum number  $n$ . The organization of orbitals in the shells is summarized in Fig. 9A.9. In general, the number of orbitals in a shell of principal quantum number  $n$  is  $n^2$ , so in a hydrogenic atom each energy level is  $n^2$ -fold degenerate.

**Figure 9A.8** The energy levels of a hydrogenic atom showing the subshells and (in square brackets) the numbers of orbitals in each subshell. All orbitals of a given shell have the same energy.

**Figure 9A.9** The organization of orbitals (white squares) into subshells (characterized by  $l$ ) and shells (characterized by  $n$ ).

### Brief illustration 9A.3 Shells, subshells, and orbitals

When  $n=1$  there is only one subshell, that with  $l=0$ , and that subshell contains only one orbital, with  $m_l=0$  (the only value of  $m_l$  permitted). When  $n=2$ , there are four orbitals, one in the  $s$  subshell with  $l=0$  and  $m_l=0$ , and three in the  $l=1$  subshell with  $m_l=+1, 0, -1$ . When  $n=3$  there are nine orbitals (one with  $l=0$ , three with  $l=1$ , and five with  $l=2$ ).

**Self-test 9A.4** What subshells and orbitals are available in the  $N$  shell?

Answer:  $s$  (1),  $p$  (3),  $d$  (5),  $f$  (7)

### (e) $s$ Orbitals

The orbital occupied in the ground state is the one with  $n=1$  (and therefore with  $l=0$  and  $m_l=0$ , the only possible values of these quantum numbers when  $n=1$ ). From Table 9A.1 and  $Y_{0,0}=1/2\pi^{1/2}$  we can write (for  $Z=1$ ):

$$\psi = \frac{1}{(\pi a_0^3)^{1/2}} e^{-r/a_0} \quad (9A.17)$$

**Figure 9A.10** The balance of kinetic and potential energies that accounts for the structure of the ground state of hydrogenic atoms. (a) The sharply curved but localized orbital has high mean kinetic energy, but low mean potential energy; (b) the mean kinetic energy is low, but the potential energy is not very favourable; (c) the compromise of moderate kinetic energy and moderately favourable potential energy.

This wavefunction is independent of angle and has the same value at all points of constant radius; that is, the  $1s$  orbital is 'spherically symmetrical'. The wavefunction decays exponentially from a maximum value of  $1/(\pi a_0^3)^{1/2}$  at the nucleus (at  $r=0$ ). It follows that the probability density of the electron is greatest at the nucleus itself, where it has the value  $1/\pi a_0^3 = 2.15 \times 10^{-6} \text{ pm}^{-3}$ .

We can understand the general form of the ground-state wavefunction by considering the contributions of the potential and kinetic energies to the total energy of the atom. The closer the electron is to the nucleus on average, the lower its average potential energy. This dependence suggests that the lowest potential energy should be obtained with a sharply peaked wavefunction that has a large amplitude at the nucleus and is zero everywhere else (Fig. 9A.10). However, this shape implies a high kinetic energy, because such a wavefunction has a very high average curvature. The electron would have very low kinetic energy if its wavefunction had only a very low average curvature. However, such a wavefunction spreads to great distances from the nucleus and the average potential energy of the electron is correspondingly high. The actual ground-state wavefunction is a compromise between these two extremes: the wavefunction spreads away from the nucleus (so the expectation value of the potential energy is not as low as in the first example, but nor is it very high) and has a reasonably low average curvature (so the expectation of the kinetic energy is not very low, but nor is it as high as in the first example).

One way of depicting the probability density of the electron is to represent  $|\psi|^2$  by the density of shading (Fig. 9A.11). A simpler procedure is to show only the **boundary surface**, the surface that captures a high proportion (typically about 90 per cent) of the electron probability. For the  $1s$  orbital, the boundary surface is a sphere centred on the nucleus (Fig. 9A.12).

**Figure 9A.11** Representations of cross-sections through the (a) 1s and (b) 2s hydrogenic atomic orbitals in terms of their electron probability densities (as represented by the density of shading).

**Figure 9A.12** The boundary surface of a 1s orbital, within which there is a 90 per cent probability of finding the electron. All s orbitals have spherical boundary surfaces.

### Example 9A.2 Calculating the mean radius of an orbital

Use hydrogenic orbitals to calculate the mean radius of a 1s orbital.

**Method** The mean radius is the expectation value

$$\langle r \rangle = \int \psi^* r \psi \, d\tau = \int r |\psi|^2 \, d\tau$$

We therefore need to evaluate the integral using the wavefunctions given in Table 9A.1 and  $d\tau = r^2 dr \sin \theta \, d\theta \, d\phi$ . The angular parts of the wavefunction (Table 8C.1) are normalized in the sense that

$$\int_0^\pi \int_0^{2\pi} |Y_{l,m_l}|^2 \sin \theta \, d\theta \, d\phi = 1$$

The integral over  $r$  required is given in the *Resource section*.

**Answer** With the wavefunction written in the form  $\psi = RY$ , the integration (with the integral over the angular variables, which is equal to 1, in blue) is

$$\langle r \rangle = \int_0^\infty \int_0^\pi \int_0^{2\pi} r R_{n,l}^2 |Y_{l,m_l}|^2 r^2 dr \sin \theta \, d\theta \, d\phi = \int_0^\infty r^3 R_{n,l}^2 dr$$

For a 1s orbital

$$R_{1,0} = 2 \left( \frac{Z}{a_0} \right)^{3/2} e^{-Zr/a_0}$$

Hence

$$\langle r \rangle = \frac{4Z^3}{a_0^3} \int_0^\infty r^3 e^{-2Zr/a_0} dr \stackrel{\text{Integral E.1}}{=} \frac{4Z^3}{a_0^3} \times \frac{3!}{(2Z/a_0)^4} = \frac{3a_0}{2Z}$$

**Self-test 9A.5** Evaluate the mean radius of a 3s orbital by integration.

Answer:  $27a_0/2Z$

All s orbitals are spherically symmetric, but differ in the number of radial nodes. For example, the 1s, 2s, and 3s orbitals have 0, 1, and 2 radial nodes, respectively. In general, an  $ns$  orbital has  $n-1$  radial nodes. As  $n$  increases, the radius of the spherical boundary surface that captures a given fraction of the probability also increases.

### Brief illustration 9A.4 The location of radial nodes

The radial nodes of a 2s orbital lie at the locations where the Legendre polynomial factor (Table 9A.1) is equal to zero. In this case the factor is simply  $\rho-2$  so there is a node at  $\rho=2$ . For a 2s orbital,  $\rho=Zr/a_0$ , so the radial node occurs at  $r=2a_0/Z$  (see Fig. 9A.5).

**Self-test 9A.6** Locate the two nodes of a 3s orbital.

Answer:  $1.90a_0/Z$  and  $7.10a_0/Z$

## (f) Radial distribution functions

The wavefunction tells us, through the value of  $|\psi|^2$ , the probability of finding an electron in any region. As we have stressed,  $|\psi|^2$  is a probability *density* (dimensions: 1/volume) and can be interpreted as a (dimensionless) probability when multiplied by the (infinitesimal) volume of interest. Thus, we can imagine a probe with a fixed volume  $d\tau$  and sensitive to electrons, and which we can move around near the nucleus of a hydrogen atom. Because the probability density in the ground state of the atom is proportional to  $e^{-2Zr/a_0}$ , the reading from the detector decreases exponentially as the probe is moved out along any radius but is constant if the probe is moved on a circle of constant radius (Fig. 9A.13).

Now consider the total probability of finding the electron *anywhere* between the two walls of a spherical shell of thickness

**Figure 9A.13** A constant-volume electron-sensitive detector (the small cube) gives its greatest reading at the nucleus, and a smaller reading elsewhere. The same reading is obtained anywhere on a circle of given radius: the s orbital is spherically symmetrical.

$dr$  at a radius  $r$ . The sensitive volume of the probe is now the volume of the shell (Fig. 9A.14), which is  $4\pi r^2 dr$  (the product of its surface area,  $4\pi r^2$ , and its thickness,  $dr$ ). Note that the volume probed increases with distance from the nucleus and is zero at the nucleus itself, when  $r=0$ . The probability that the electron will be found between the inner and outer surfaces of this shell is the probability density at the radius  $r$  multiplied by the volume of the probe, or  $|\psi|^2 \times 4\pi r^2 dr$ . This expression has the form  $P(r)dr$ , where

$$P(r) = 4\pi r^2 |\psi|^2 \quad (9A.18a)$$

The more general expression, which also applies to orbitals that are not spherically symmetrical is derived in the following *Justification*, and is

$$P(r) = r^2 R(r)^2 \quad \text{Radial distribution function} \quad (9A.18b)$$

where  $R(r)$  is the radial wavefunction for the orbital in question.

### Justification 9A.3 The general form of the radial distribution function

The probability of finding an electron in a volume element  $d\tau$  when its wavefunction is  $\psi = RY$  is  $|RY|^2 d\tau$  with  $d\tau = r^2 dr \sin\theta d\theta d\phi$ . The total probability of finding the electron at any angle at a constant radius is the integral of this probability over the surface of a sphere of radius  $r$ , and is written  $P(r)dr$ ; so

$$P(r)dr = \int_0^\pi \int_0^{2\pi} R(r)^2 |Y_{l,m}|^2 r^2 dr \sin\theta d\theta d\phi = r^2 R(r)^2$$

The last equality follows from the fact that the spherical harmonics are normalized to 1 (the blue integration, as in *Example 9A.1*).

**Figure 9A.14** The radial distribution function  $P(r)$  is the probability density that the electron will be found anywhere in a shell of radius  $r$ ; the probability itself is  $P(r)dr$ , where  $dr$  is the thickness of the shell. For a 1s electron in hydrogen,  $P(r)$  is a maximum when  $r$  is equal to the Bohr radius  $a_0$ . The value of  $P(r)dr$  is equivalent to the reading that a detector shaped like a spherical shell of thickness  $dr$  would give as its radius is varied.

The **radial distribution function**,  $P(r)$ , is a probability density in the sense that, when it is multiplied by  $dr$ , it gives the probability of finding the electron anywhere between the two walls of a spherical shell of thickness  $dr$  at the radius  $r$ . For a 1s orbital,

$$P(r) = \frac{4Z^3}{a_0^3} r^2 e^{-2Zr/a_0} \quad (9A.19)$$

Let's interpret this expression:

- Because  $r^2=0$  at the nucleus,  $P(0)=0$ . The volume of the shell of inspection is zero when  $r=0$ .
- As  $r \rightarrow \infty$ ,  $P(r) \rightarrow 0$  on account of the exponential term. The wavefunction has fallen to zero at great distances from the nucleus.
- The increase in  $r^2$  and the decrease in the exponential factor means that  $P$  passes through a maximum at an intermediate radius (see Fig. 9A.14).

Physical interpretation

The maximum of  $P(r)$ , which can be found by differentiation, marks the most probable radius at which the electron will be found, and for a 1s orbital in hydrogen occurs at  $r=a_0$ , the Bohr radius. When we carry through the same calculation for the radial distribution function of the 2s orbital in hydrogen, we find that the most probable radius is  $5.2a_0=275$  pm. This larger value reflects the expansion of the atom as its energy increases.

### Example 9A.3 Calculating the most probable radius

Calculate the most probable radius,  $r^*$ , at which an electron will be found when it occupies a 1s orbital of a hydrogenic atom of atomic number  $Z$ , and tabulate the values for the one-electron species from H to  $\text{Ne}^{9+}$ .

**Method** We find the radius at which the radial distribution function of the hydrogenic 1s orbital has a maximum value by solving  $dP/dr=0$ . If there are several maxima, then we choose the one corresponding to the greatest amplitude.

**Answer** The radial distribution function is given in eqn 9A.19A. It follows that

$$\frac{dP}{dr} = \frac{4Z^3}{a_0^3} \left( 2r - \frac{2Zr^2}{a_0} \right) e^{-2Zr/a_0}$$

This function is zero where the term in parentheses is zero, which (other than at  $r=0$ ) is at

$$r^* = \frac{a_0}{Z}$$

Then, with  $a_0 = 52.9$  pm, the most probable radius is

	H	He <sup>+</sup>	Li <sup>2+</sup>	Be <sup>3+</sup>	B <sup>4+</sup>	C <sup>5+</sup>	N <sup>6+</sup>	O <sup>7+</sup>	F <sup>8+</sup>	Ne <sup>9+</sup>
$r^*/\text{pm}$	52.9	26.5	17.6	13.2	10.6	8.82	7.56	6.61	5.88	5.29

Notice how the 1s orbital is drawn towards the nucleus as the nuclear charge increases. At uranium the most probable radius is only 0.58 pm, almost 100 times closer than for hydrogen. (On a scale where  $r^* = 10$  cm for H,  $r^* = 1$  mm for U.) We need to be cautious, though, in extending this result to very heavy atoms because relativistic effects are then important and complicate the calculation.

**Self-test 9A.7** Find the most probable distance of a 2s electron from the nucleus in a hydrogenic atom.

Answer:  $(3 + 5^{1/2})a_0/Z = 5.24a_0/Z$

## (g) p Orbitals

The three 2p orbitals are distinguished by the three different values that  $m_l$  can take when  $l=1$ . Because the quantum number  $m_l$  tells us the orbital angular momentum around an axis, these different values of  $m_l$  denote orbitals in which the electron has different orbital angular momenta around an arbitrary  $z$ -axis but the same magnitude of that momentum (because  $l$  is the same for all three). The orbital with  $m_l=0$ , for instance, has zero angular momentum around the  $z$ -axis. Its angular variation is given by the spherical harmonic  $Y_{1,0}$ , which is proportional to  $\cos \theta$  (see Table 8C.1). Therefore, the probability density, which is proportional to  $\cos^2 \theta$ , has its maximum value on either side of the nucleus along the  $z$ -axis (at  $\theta=0$  and  $180^\circ$ ). Specifically, the wavefunction of a 2p orbital with  $m_l=0$  is

$$\begin{aligned} \psi_{2,1,0} &= R_{2,1}(r)Y_{1,0}(\theta, \phi) = \frac{1}{4(2\pi)^{1/2}} \left( \frac{Z}{a_0} \right)^{5/2} r \cos \theta e^{-Zr/2a_0} \\ &= r \cos \theta f(r) \end{aligned} \quad (9A.20a)$$

**Figure 9A.15** The boundary surfaces of 2p orbitals.

A nodal plane passes through the nucleus and separates the two lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction. The angles of the spherical polar coordinate system are also shown. All p orbitals have boundary surfaces like those shown here.

where  $f(r)$  is a function only of  $r$ . Because in spherical polar coordinates  $z=r \cos \theta$ , this wavefunction may also be written

$$\psi_{2,1,0} = zf(r) \quad (9A.20b)$$

All p orbitals with  $m_l=0$  have wavefunctions of this form, but  $f(r)$  depends on the value of  $n$ . This way of writing the orbital is the origin of the name 'p<sub>z</sub> orbital': its boundary surface is shown in Fig. 9A.15. The wavefunction is zero everywhere in the  $xy$ -plane, where  $z=0$ , so the  $xy$ -plane is a **nodal plane** of the orbital: the wavefunction changes sign on going from one side of the plane to the other.

The wavefunctions of 2p orbitals with  $m_l=\pm 1$  have the following form:

$$\begin{aligned} \psi_{2,1,\pm 1} &= R_{2,1}(r)Y_{1,\pm 1}(\theta, \phi) \\ &= \mp \frac{1}{8\pi^{1/2}} \left( \frac{Z}{a_0} \right)^{5/2} r \sin \theta e^{\pm i\phi} e^{-Zr/2a_0} \\ &= \mp \frac{1}{2^{1/2}} r \sin \theta e^{\pm i\phi} f(r) \end{aligned} \quad (9A.21)$$

In Topic 8A it is shown that a particle that has net motion is described by a complex wavefunction. In the present case, the functions correspond to non-zero angular momentum about the  $z$ -axis:  $e^{+i\phi}$  corresponds to clockwise rotation when viewed from below, and  $e^{-i\phi}$  corresponds to anticlockwise rotation (from the same viewpoint). They have zero amplitude where  $\theta=0$  and  $180^\circ$  (along the  $z$ -axis) and maximum amplitude at  $90^\circ$ , which is in the  $xy$ -plane. To draw the functions it is usual

to represent them as standing waves. To do so, we take the real linear combinations

$$\begin{aligned}\psi_{2p_x} &= \frac{1}{2^{1/2}}(\psi_{2,1,+1} - \psi_{2,1,-1}) = r \sin \theta \cos \phi f(r) = xf(r) \\ \psi_{2p_y} &= \frac{i}{2^{1/2}}(\psi_{2,1,+1} + \psi_{2,1,-1}) = r \sin \theta \sin \phi f(r) = yf(r)\end{aligned}\quad (9A.22)$$

(See the following *Justification*.) These linear combinations are indeed standing waves with no net orbital angular momentum around the  $z$ -axis, as they are superpositions of states with equal and opposite values of  $m_l$ . The  $p_x$  orbital has the same shape as a  $p_z$  orbital, but it is directed along the  $x$ -axis (see Fig. 9A.15); the  $p_y$  orbital is similarly directed along the  $y$ -axis. The wavefunction of any  $p$  orbital of a given shell can be written as a product of  $x$ ,  $y$ , or  $z$  and the same function  $f$  (which depends on the value of  $n$ ).

#### Justification 9A.4 The linear combination of degenerate wavefunctions

We justify here the step of taking linear combinations of degenerate orbitals when we want to indicate a particular point. The freedom to do so rests on the fact, as we show below, that whenever two or more wavefunctions correspond to the same energy, then any linear combination of them is an equally valid solution of the Schrödinger equation.

Suppose  $\psi_1$  and  $\psi_2$  are both solutions of the Schrödinger equation with energy  $E$ ; then we know that  $\hat{H}\psi_1 = E\psi_1$  and  $\hat{H}\psi_2 = E\psi_2$ . Now consider the linear combination  $\psi = c_1\psi_1 + c_2\psi_2$  where  $c_1$  and  $c_2$  are arbitrary coefficients. Then it follows that

$$\hat{H}\psi = \hat{H}(c_1\psi_1 + c_2\psi_2) = c_1\hat{H}\psi_1 + c_2\hat{H}\psi_2 = c_1E\psi_1 + c_2E\psi_2 = E\psi$$

Hence, the linear combination is also a solution corresponding to the same energy  $E$ .

#### (h) d Orbitals

When  $n=3$ ,  $l$  can be 0, 1, or 2. As a result, this shell consists of one  $3s$  orbital, three  $3p$  orbitals, and five  $3d$  orbitals. Each value of the quantum number  $m_l = +2, +1, 0, -1, -2$  corresponds to a different value for the component of the angular momentum about the  $z$ -axis. As for the  $p$  orbitals,  $d$  orbitals with opposite values of  $m_l$  (and hence opposite senses of motion around the  $z$ -axis) may be combined in pairs to give real standing waves, and the boundary surfaces of the resulting shapes are shown in Fig. 9A.16. The real linear combinations have the following forms, with the function  $f$  depending on the value of  $n$ :

$$\begin{aligned}\psi_{d_{xy}} &= xyf(r) & \psi_{d_{yz}} &= yzf(r) & \psi_{d_{zx}} &= zxf(r) \\ \psi_{d_{x^2-y^2}} &= \frac{1}{2}(x^2 - y^2)f(r) & \psi_{d_{z^2}} &= \frac{3^{1/2}}{2}(3z^2 - r^2)f(r)\end{aligned}\quad (9A.23)$$

Figure 9A.16 The boundary surfaces of  $3d$  orbitals. Two nodal planes in each orbital intersect at the nucleus and separate the lobes of each orbital. The dark and light areas denote regions of opposite sign of the wavefunction. All  $d$  orbitals have boundary surfaces like those shown here.

## Checklist of concepts

- 1. The **Ritz combination principle** states that the wave-number of any spectral line is the difference between two terms.
- 2. The Schrödinger equation for hydrogenic atoms separates into two equations: the solutions of one give the angular variation of the wavefunction and the solution of the other gives its radial dependence.
- 3. Close to the nucleus the radial wavefunction is proportional to  $r^l$ ; far from the nucleus all wavefunctions approach zero exponentially.
- 4. An **atomic orbital** is a one-electron wavefunction for an electron in an atom.
- 5. Atomic orbitals are specified by the **quantum numbers**  $n$ ,  $l$ , and  $m_l$ .
- 6. The energies of the bound states of hydrogenic atoms are proportional to  $Z^2/n^2$ .
- 7. The **ionization energy** of an element is the minimum energy required to remove an electron from the ground state of one of its atoms.

- 8. Orbitals of a given value of  $n$  form a **shell** of an atom, and within that shell orbitals of the same value of  $l$  form **subshells**.
- 9. Orbitals of the same shell all have the same energy in hydrogenic atoms; orbitals of the same subshell of a shell are degenerate in all types of atoms.
- 10. **s Orbitals** are spherically symmetrical and have nonzero probability density at the nucleus.
- 11. A **radial distribution function** is the probability density for the distribution of the electron as a function of distance from the nucleus.
- 12. There are three **p orbitals** in a given subshell; each one has an angular node.
- 13. There are five **d orbitals** in a given subshell; each one has two angular nodes.

## Checklist of equations

Property	Equation	Comment	Equation number
Wavenumbers of the spectral lines of a hydrogen atom	$\tilde{\nu} = \tilde{R}_H (1/n_1^2 - 1/n_2^2)$	$\tilde{R}_H$ is the Rydberg constant for hydrogen (expressed as a wavenumber)	9A.1
Wavefunctions of hydrogenic atoms	$\psi(r, \theta, \phi) = R(r)Y(\theta, \phi)$	$Y$ are spherical harmonics	9A.7
Bohr radius	$a_0 = 4\pi\epsilon_0\hbar^2/m_e e^2$	$a_0 = 52.9$ pm; the most probable radius for a 1s electron in hydrogen	9A.11
Rydberg constant for an atom N	$\tilde{R}_N = \mu e^4 / 32\pi^2 \epsilon_0^2 \hbar^2$	$\tilde{R}_N \approx \tilde{R}_\infty$ , the Rydberg constant; $\mu = m_e m_N / (m_e + m_N)$	9A.14
Energies of hydrogenic atoms	$E_n = -hcZ^2 \tilde{R}_N / n^2$	$\tilde{R}_N$ is the for the atom N	9A.14
Radial distribution function	$P(r) = r^2 R(r)^2$	$P(r) = 4\pi r^2 \psi^2$ for s orbitals	9A.18b

### ► Why do you need to know this material?

Many-electron atoms are the building blocks of all compounds, and to understand their properties, including their ability to participate in chemical bonding, it is essential to understand their electronic structure. Moreover, a knowledge of that structure explains the structure of the periodic table and all that it summarizes.

### ► What is the key idea?

Electrons occupy the lowest energy available orbital subject to the requirements of the Pauli exclusion principle.

### ► What do you need to know already?

This Topic builds on the account of the structure of hydrogenic atoms (Topic 9A), especially their shell structure. In the discussion of ionization energies and electron affinities it makes use of the properties of standard reaction enthalpy (Topic 2C).

The Schrödinger equation for a many-electron atom is highly complicated because all the electrons interact with one another. One very important consequence of these interactions is that orbitals of the same value of  $n$  but different values of  $l$  are no longer degenerate in a many-electron atom. Moreover, even for a helium atom, with its two electrons, no analytical expression for the orbitals and energies can be given, and we are forced to make approximations. We adopt a simple approach based on the structure of hydrogenic atoms (Topic 9A). In the final section we see the kind of numerical computations that are currently used to obtain accurate wavefunctions and energies.

## 9B.1 The orbital approximation

The wavefunction of a many-electron atom is a very complicated function of the coordinates of all the electrons, and we should write it  $\Psi(r_1, r_2, \dots)$ , where  $r_i$  is the vector from the nucleus to electron  $i$  (uppercase psi,  $\Psi$ , is commonly used to denote a many-electron wavefunction). However, in the **orbital approximation** we suppose that a reasonable first approximation to this exact wavefunction is obtained by thinking of each electron as occupying its 'own' orbital, and write

$$\Psi(r_1, r_2, \dots) = \psi(r_1)\psi(r_2)\dots \quad \text{Orbital approximation} \quad (9B.1)$$

We can think of the individual orbitals as resembling the hydrogenic orbitals, but corresponding to nuclear charges modified by the presence of all the other electrons in the atom. This description is only approximate, as the following *Justification* reveals, but it is a useful model for discussing the chemical properties of atoms, and is the starting point for more sophisticated descriptions of atomic structure.

### Justification 9B.1 The orbital approximation

The orbital approximation would be exact if there were no interactions between electrons. To demonstrate the validity of this remark, we need to consider a system in which the hamiltonian for the energy is the sum of two contributions, one for electron 1 and the other for electron 2:  $\hat{H} = \hat{H}_1 + \hat{H}_2$ . In an actual atom (such as helium atom), there is an additional term

(proportional to  $1/r_{12}$ ) corresponding to the interaction of the two electrons:

$$\hat{H} = -\frac{\hbar^2}{2m_e} \nabla_1^2 - \frac{2e^2}{4\pi\epsilon_0 r_1} - \frac{\hbar^2}{2m_e} \nabla_2^2 - \frac{2e^2}{4\pi\epsilon_0 r_2} + \frac{e^2}{4\pi\epsilon_0 r_{12}}$$

but we are ignoring that term. We shall now show that if  $\psi(r_1)$  is an eigenfunction of  $\hat{H}_1$  with energy  $E_1$ , and  $\psi(r_2)$  is an eigenfunction of  $\hat{H}_2$  with energy  $E_2$ , then the product  $\Psi(r_1, r_2) = \psi(r_1)\psi(r_2)$  is an eigenfunction of the combined hamiltonian  $\hat{H}$ . To do so we write

$$\begin{aligned} \hat{H}\Psi(r_1, r_2) &= (\hat{H}_1 + \hat{H}_2)\psi(r_1)\psi(r_2) = \hat{H}_1\psi(r_1)\psi(r_2) + \psi(r_1)\hat{H}_2\psi(r_2) \\ &= E_1\psi(r_1)\psi(r_2) + \psi(r_1)E_2\psi(r_2) = (E_1 + E_2)\psi(r_1)\psi(r_2) \\ &= E\Psi(r_1, r_2) \end{aligned}$$

where  $E = E_1 + E_2$ . This is the result we need to prove. However, if the electrons interact (as they do in fact), then the proof fails.

### (a) The helium atom

The orbital approximation allows us to express the electronic structure of an atom by reporting its **configuration**, a statement of its occupied orbitals (usually, but not necessarily, in its ground state). Thus, as the ground state of a hydrogenic atom consists of the single electron in a 1s orbital, we report its configuration as  $1s^1$  (read ‘one-ess-one’).

A He atom has two electrons. We can imagine forming the atom by adding the electrons in succession to the orbitals of the bare nucleus (of charge  $2e$ ). The first electron occupies a 1s hydrogenic orbital, but because  $Z=2$  that orbital is more compact than in H itself. The second electron joins the first in the 1s orbital, so the electron configuration of the ground state of He is  $1s^2$ .

#### Brief illustration 9B.1 Helium wavefunctions

According to the orbital approximation, each electron occupies a hydrogenic 1s orbital of the kind given in Topic 9A. If we anticipate (see below) that the electrons experience an effective nuclear charge  $Z_{\text{eff}}$  rather than its actual charge  $Ze$  (specifically, as we shall see,  $1.69e$  rather than  $2e$ ), then the two-electron wavefunction of the atom is

$$\begin{aligned} \Psi(r_1, r_2) &= \frac{Z_{\text{eff}}^{3/2}}{(\pi a_0^3)^{1/2}} e^{-Z_{\text{eff}} r_1/a_0} \times \frac{Z_{\text{eff}}^{3/2}}{(\pi a_0^3)^{1/2}} e^{-Z_{\text{eff}} r_2/a_0} \\ &= \frac{Z_{\text{eff}}^3}{\pi a_0^3} e^{-Z_{\text{eff}}(r_1+r_2)/a_0} \end{aligned}$$

As can be seen, there is nothing particularly mysterious about a two-electron wavefunction: in this case it is a simple

exponential function of the distances of the two electrons from the nucleus.

**Self-test 9B.1** Construct the wavefunction for an excited state of the He atom with configuration  $1s^1 2s^1$ . Use  $Z_{\text{eff}}=2$  for the 1s electron and  $Z_{\text{eff}}=1$  for the 2s electron. Why those values should become clear shortly.

$$\text{Answer: } \Psi(r_1, r_2) = (1/2\pi a_0^3)(2 - r_2/a_0)e^{-(2r_1+r_2/2)/a_0}$$

It is tempting to suppose that the electronic configurations of the atoms of successive elements with atomic numbers  $Z=3, 4, \dots$ , and therefore with  $Z$  electrons, are simply  $1s^Z$ . That, however, is not the case. The reason lies in two aspects of nature: that electrons possess ‘spin’ and must obey the very fundamental ‘Pauli principle’.

### (b) Spin

The quantum mechanical property of electron **spin**, the possession of an intrinsic angular momentum, was identified by the experiment performed by Otto Stern and Walther Gerlach in 1921, who shot a beam of silver atoms through an inhomogeneous magnetic field, as explained in Topic 8C. Stern and Gerlach observed *two* bands of Ag atoms in their experiment. This observation seems to conflict with one of the predictions of quantum mechanics, because an angular momentum  $l$  gives rise to  $2l+1$  orientations, which is equal to 2 only if  $l = \frac{1}{2}$ , contrary to the conclusion that  $l$  must be an integer. The conflict was resolved by the suggestion that the angular momentum they were observing was not due to orbital angular momentum (the motion of an electron around the atomic nucleus) but arose instead from the motion of the electron about its own axis. This intrinsic angular momentum of the electron, or ‘spin’, also emerged when Dirac combined quantum mechanics with special relativity and established the theory of relativistic quantum mechanics.

The spin of an electron about its own axis does not have to satisfy the same boundary conditions as those for a particle circulating around a central point, so the quantum number for spin angular momentum is subject to different restrictions. To distinguish this spin angular momentum from orbital angular momentum we use the **spin quantum number**  $s$  (in place of the  $l$  in Topic 9A; like  $l$ ,  $s$  is a non-negative number) and  $m_s$ , the **spin magnetic quantum number**, for the projection on the  $z$ -axis. The magnitude of the spin angular momentum is  $\{s(s+1)\}^{1/2}\hbar$  and the component  $m_s\hbar$  is restricted to the  $2s+1$  values  $m_s = s, s-1, \dots, -s$ . To account for Stern and Gerlach’s observation,  $s = \frac{1}{2}$  and  $m_s = \pm \frac{1}{2}$ .

*A note on good practice* You will sometimes see the quantum number  $s$  used in place of  $m_s$ , and written  $s = \pm \frac{1}{2}$ . That is wrong: like  $l$ ,  $s$  is never negative and denotes the magnitude of the spin angular momentum. For the  $z$ -component, use  $m_s$ .

**Figure 9B.1** The vector representation of the spin of an electron. The length of the side of the cone is  $3^{1/2}/2$  units and the projections are  $\pm \frac{1}{2}$  units.

The detailed analysis of the spin of a particle is sophisticated and shows that the property should not be taken to be an actual spinning motion. It is better to regard ‘spin’ as an intrinsic property like mass and charge: every electron has exactly the same value and the magnitude of the spin angular momentum of an electron cannot be changed. However, the picture of an actual spinning motion can be very useful when used with care. On the vector model of angular momentum (Topic 8C), the spin may lie in two different orientations (Fig. 9B.1). One orientation corresponds to  $m_s = +\frac{1}{2}$  (this state is often denoted  $\alpha$  or  $\uparrow$ ); the other orientation corresponds to  $m_s = -\frac{1}{2}$  (this state is denoted  $\beta$  or  $\downarrow$ ).

Other elementary particles have characteristic spin. For example, protons and neutrons are spin- $\frac{1}{2}$  particles (that is,  $s = \frac{1}{2}$ ) and invariably spin with the same angular momentum. Because the masses of a proton and a neutron are so much greater than the mass of an electron, yet they all have the same spin angular momentum, the classical picture would be of these two particles spinning much more slowly than an electron. Some mesons, another variety of fundamental particle, are spin-1 particles (that is,  $s = 1$ ), as are some atomic nuclei, but for our purposes the most important spin-1 particle is the photon. The importance of photon spin in spectroscopy is explained in Topic 12A; proton spin is the basis of Topic 14A (magnetic resonance).

### Brief illustration 9B.2 Spin

The magnitude of the spin angular momentum, like any angular momentum, is  $\{s(s+1)\}^{1/2}\hbar$ . For any spin- $\frac{1}{2}$  particle, not only electrons, this angular momentum is  $(\frac{3}{4})^{1/2}\hbar = 0.866\hbar$ , or  $9.13 \times 10^{-35}$  J s. The component on the  $z$ -axis is  $m_s\hbar$ , which for a spin- $\frac{1}{2}$  particle is  $\pm \frac{1}{2}\hbar$ , or  $\pm 5.27 \times 10^{-35}$  J s.

**Self-test 9B.2** Evaluate the spin angular momentum of a photon.

Answer:  $2^{1/2}\hbar = 1.49 \times 10^{-34}$  J s

Particles with half-integral spin are called **fermions** and those with integral spin (including 0) are called **bosons**. Thus, electrons and protons are fermions and photons are bosons. It is a very deep feature of nature that all the elementary particles that constitute matter are fermions whereas the elementary

particles that transmit the forces that bind fermions together are all bosons. Photons, for example, transmit the electromagnetic force that binds together electrically charged particles. Matter, therefore, is an assembly of fermions held together by forces conveyed by bosons.

### (c) The Pauli principle

With the concept of spin established, we can resume our discussion of the electronic structures of atoms. Lithium, with  $Z=3$ , has three electrons. The first two occupy a 1s orbital drawn even more closely than in He around the more highly charged nucleus. The third electron, however, does not join the first two in the 1s orbital because that configuration is forbidden by the **Pauli exclusion principle**:

No more than two electrons may occupy any given orbital, and if two do occupy one orbital, then their spins must be paired.

Pauli exclusion principle

Electrons with paired spins, denoted  $\uparrow\downarrow$ , have zero net spin angular momentum because the spin of one electron is cancelled by the spin of the other. Specifically, one electron has  $m_s = +\frac{1}{2}$  the other has  $m_s = -\frac{1}{2}$  and in the vector model they are orientated on their respective cones so that the resultant spin is zero (Fig. 9B.2). The exclusion principle is the key to the structure of complex atoms, to chemical periodicity, and to molecular structure. It was proposed by Wolfgang Pauli in 1924 when he was trying to account for the absence of some lines in the spectrum of helium. Later he was able to derive a very general form of the principle from theoretical considerations.

The Pauli exclusion principle in fact applies to any pair of identical fermions. Thus it applies to protons, neutrons, and  $^{13}\text{C}$  nuclei (all of which have  $s = \frac{1}{2}$ ) and to  $^{35}\text{Cl}$  nuclei (which have  $s = \frac{3}{2}$ ). It does not apply to identical bosons, which include photons ( $s = 1$ ) and  $^{12}\text{C}$  nuclei ( $s = 0$ ). Any number of identical bosons may occupy the same state (that is, be described by the same wavefunction).

**Figure 9B.2** Electrons with paired spins have zero resultant spin angular momentum. They can be represented by two vectors that lie at an indeterminate position on the cones shown here, but wherever one lies on its cone, the other points in the opposite direction; their resultant is zero.

The Pauli *exclusion* principle is a special case of a general statement called the **Pauli principle**:

When the labels of any two identical fermions are exchanged, the total wavefunction changes sign; when the labels of any two identical bosons are exchanged, the sign of the total wavefunction remains the same.

Pauli principle

By ‘total wavefunction’ is meant the entire wavefunction, including the spin of the particles.

To see that the Pauli principle implies the Pauli exclusion principle, we consider the wavefunction for two electrons  $\Psi(1,2)$ . The Pauli principle implies that it is a fact of nature (which has its roots in the theory of relativity) that the wavefunction must change sign if we interchange the labels 1 and 2 wherever they occur in the function:

$$\Psi(1,2) = -\Psi(2,1) \quad (9B.2)$$

Suppose the two electrons in an atom occupy an orbital  $\psi$ , then in the orbital approximation the overall wavefunction is  $\psi(1)\psi(2)$ . To apply the Pauli principle, we must deal with the *total* wavefunction, the wavefunction including spin. There are several possibilities for two spins: both  $\alpha$ , denoted  $\alpha(1)\alpha(2)$ , both  $\beta$ , denoted  $\beta(1)\beta(2)$ , and one  $\alpha$  the other  $\beta$ , denoted either  $\alpha(1)\beta(2)$  or  $\alpha(2)\beta(1)$ . Because we cannot tell which electron is  $\alpha$  and which is  $\beta$ , in the last case it is appropriate to express the spin states as the (normalized) linear combinations

$$\begin{aligned} \sigma_+(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \\ \sigma_-(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} \end{aligned} \quad (9B.3)$$

(A stronger justification for taking these linear combinations is that they correspond to eigenfunctions of the total spin operators  $S^2$  and  $S_z$ , with  $M_S=0$  and, respectively,  $S=1$  and  $0$ .) These combinations allow one spin to be  $\alpha$  and the other  $\beta$  with equal probability. The total wavefunction of the system is therefore the product of the orbital part and one of the four spin states:

$$\begin{aligned} \psi(1)\psi(2)\alpha(1)\alpha(2) \quad \psi(1)\psi(2)\beta(1)\beta(2) \\ \psi(1)\psi(2)\sigma_+(1,2) \quad \psi(1)\psi(2)\sigma_-(1,2) \end{aligned} \quad (9B.4)$$

The Pauli principle says that for a wavefunction to be acceptable (for electrons), it must change sign when the electrons are exchanged. In each case, exchanging the labels 1 and 2 converts the factor  $\psi(1)\psi(2)$  into  $\psi(2)\psi(1)$ , which is the same, because the order of multiplying the functions does not change the value of the product. The same is true of  $\alpha(1)\alpha(2)$  and  $\beta(1)\beta(2)$ . Therefore, the first two overall products are not allowed, because they do not change sign. The combination  $\sigma_+(1,2)$  changes to

$$\sigma_+(2,1) = (1/2^{1/2})\{\alpha(2)\beta(1) + \beta(2)\alpha(1)\} = \sigma_+(1,2)$$

because it is simply the original function written in a different order. The third overall product is therefore also disallowed. Finally, consider  $\sigma_-(1,2)$ :

$$\begin{aligned} \sigma_-(2,1) &= (1/2^{1/2})\{\alpha(2)\beta(1) - \beta(2)\alpha(1)\} \\ &= -(1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\} = -\sigma_-(1,2) \end{aligned}$$

This combination does change sign (it is ‘antisymmetric’). The product  $\psi(1)\psi(2)\sigma_-(1,2)$  also changes sign under particle exchange, and therefore it is acceptable.

Now we see that only one of the four possible states is allowed by the Pauli principle, and the one that survives has paired  $\alpha$  and  $\beta$  spins. This is the content of the Pauli exclusion principle. The exclusion principle (but not the more general Pauli principle) is irrelevant when the orbitals occupied by the electrons are different, and both electrons may then have, but need not have, the same spin state. In each case the overall wavefunction must still be antisymmetric overall and must satisfy the Pauli principle itself.

A final point in this connection is that the acceptable product wavefunction  $\psi(1)\psi(2)\sigma_-(1,2)$  can be expressed as a determinant (see *The chemist’s toolkit* 9B.1):

$$\begin{aligned} & \frac{1}{2^{1/2}} \begin{vmatrix} \psi(1)\alpha(1) & \psi(2)\alpha(2) \\ \psi(1)\beta(1) & \psi(2)\beta(2) \end{vmatrix} \\ &= \frac{1}{2^{1/2}} \{\psi(1)\alpha(1)\psi(2)\beta(2) - \psi(2)\alpha(2)\psi(1)\beta(1)\} \\ &= \psi(1)\psi(2)\sigma_-(1,2) \end{aligned}$$

Any acceptable wavefunction for a closed-shell species can be expressed as a **Slater determinant**, as such determinants are known. In general, for  $N$  electrons in orbitals  $\psi_a, \psi_b, \dots$

$$\begin{aligned} & \Psi(1,2,\dots,N) \\ &= \frac{1}{(N!)^{1/2}} \begin{vmatrix} \psi_a(1)\alpha(1) & \psi_a(2)\alpha(2) & \psi_a(3)\alpha(3) & \dots & \psi_a(N)\alpha(N) \\ \psi_a(1)\beta(1) & \psi_a(2)\beta(2) & \psi_a(3)\beta(3) & \dots & \psi_a(N)\beta(N) \\ \psi_b(1)\alpha(1) & \psi_b(2)\alpha(2) & \psi_b(3)\alpha(3) & \dots & \psi_b(N)\alpha(N) \\ \vdots & \vdots & \vdots & \dots & \vdots \\ \psi_z(1)\beta(1) & \psi_z(2)\beta(2) & \psi_z(3)\beta(3) & \dots & \psi_z(N)\beta(N) \end{vmatrix} \end{aligned} \quad (9B.5a)$$

Writing a many-electron wavefunction in this way ensures that it is antisymmetric under the interchange of any pair of electrons (see Problem 9B.2). Because a Slater determinant takes up a lot of space, it is normally reported by writing only its diagonal elements, as in

$$\Psi(1,2,\dots,N) = (1/N!)^{1/2} \det \left| \psi_a^\alpha(1)\psi_a^\beta(2)\psi_b^\alpha(3)\dots\psi_z^\beta(N) \right| \quad (9B.5b)$$

Notation for a Slater determinant

### The chemist's toolkit 9B.1 Determinants

A  $2 \times 2$  determinant is the quantity

$$\begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc \quad \text{2} \times \text{2 Determinant}$$

A  $3 \times 3$  determinant is evaluated by expanding it as a sum of  $2 \times 2$  determinants:

$$\begin{vmatrix} a & b & c \\ d & e & f \\ g & h & i \end{vmatrix} = a \begin{vmatrix} e & f \\ h & i \end{vmatrix} - b \begin{vmatrix} d & f \\ g & i \end{vmatrix} + c \begin{vmatrix} d & e \\ g & h \end{vmatrix} \quad \text{3} \times \text{3 Determinant}$$

$$= a(ei - fh) - b(di - fg) + c(dh - eg)$$

Note the sign change in alternate columns ( $b$  occurs with a negative sign in the expansion). An important property of a determinant is that if any two rows or any two columns are interchanged, then the determinant changes sign:

$$\text{Exchange columns: } \begin{vmatrix} b & a \\ d & c \end{vmatrix} = bc - ad = -(ad - bc) = - \begin{vmatrix} a & b \\ c & d \end{vmatrix}$$

$$\text{Exchange rows: } \begin{vmatrix} c & d \\ a & b \end{vmatrix} = cd - da = -(ad - bc) = - \begin{vmatrix} a & b \\ c & d \end{vmatrix}$$

Now we can return to lithium. In Li ( $Z=3$ ), the third electron cannot enter the 1s orbital because that orbital is already full: we say the K shell (the orbital with  $n=1$ , Topic 9A) is *complete* and that the two electrons form a **closed shell**. Because a similar closed shell is characteristic of the He atom, we denote it [He]. The third electron is excluded from the K shell and must occupy the next available orbital, which is one with  $n=2$  and hence belonging to the L shell (which consists of the four orbitals with  $n=2$ ). However, we now have to decide whether the next available orbital is the 2s orbital or a 2p orbital, and therefore whether the lowest energy configuration of the atom is [He]2s<sup>1</sup> or [He]2p<sup>1</sup>.

#### (d) Penetration and shielding

Unlike in hydrogenic atoms, the 2s and 2p orbitals (and, in general, all subshells of a given shell) are not degenerate in many-electron atoms. An electron in a many-electron atom experiences a Coulombic repulsion from all the other electrons present. If it is at a distance  $r$  from the nucleus, it experiences an average repulsion that can be represented by a point negative charge located at the nucleus and equal in magnitude to the total charge of the electrons within a sphere of radius  $r$  (Fig. 9B.3). The effect of this point negative charge, when averaged over all the locations of the electron, is to reduce the full charge

**Figure 9B.3** An electron at a distance  $r$  from the nucleus experiences a Coulombic repulsion from all the electrons within a sphere of radius  $r$  and which is equivalent to a point negative charge located on the nucleus. The negative charge reduces the effective nuclear charge of the nucleus from  $Ze$  to  $Z_{\text{eff}}e$ .

of the nucleus from  $Ze$  to  $Z_{\text{eff}}e$ , the **effective nuclear charge**. In everyday parlance,  $Z_{\text{eff}}$  itself is commonly referred to as the ‘effective nuclear charge’. We say that the electron experiences a **shielded** nuclear charge, and the difference between  $Z$  and  $Z_{\text{eff}}$  is called the **shielding constant**,  $\sigma$ :

$$Z_{\text{eff}} = Z - \sigma \quad \text{Effective nuclear charge} \quad (9B.6)$$

The electrons do not actually ‘block’ the full Coulombic attraction of the nucleus: the shielding constant is simply a way of expressing the net outcome of the nuclear attraction and the electronic repulsions in terms of a single equivalent charge at the centre of the atom.

The shielding constant is different for s and p electrons because they have different radial distributions (Fig. 9B.4). An

**Figure 9B.4** An electron in an s orbital (here a 3s orbital) is more likely to be found close to the nucleus than an electron in a p orbital of the same shell (note the closeness of the innermost peak of the 3s orbital to the nucleus at  $r=0$ ). Hence an s electron experiences less shielding and is more tightly bound than a p electron.

s electron has a greater **penetration** through inner shells than a p electron, in the sense that it is more likely to be found close to the nucleus than a p electron of the same shell (the wavefunction of a p orbital, remember, is zero at the nucleus). Because only electrons inside the sphere defined by the location of the electron contribute to shielding, an s electron experiences less shielding than a p electron. Consequently, by the combined effects of penetration and shielding, an s electron is more tightly bound than a p electron of the same shell. Similarly, a d electron penetrates less than a p electron of the same shell (recall that the wavefunction of a d orbital varies as  $r^2$  close to the nucleus, whereas a p orbital varies as  $r$ ), and therefore experiences more shielding.

Shielding constants for different types of electrons in atoms have been calculated from their wavefunctions obtained by numerical solution of the Schrödinger equation for the atom (Table 9B.1). We see that, in general, valence-shell s electrons do experience higher effective nuclear charges than p electrons, although there are some discrepancies. We return to this point shortly.

**Table 9B.1\*** Effective nuclear charge,  $Z_{\text{eff}} = Z - \sigma$

Element	$Z$	Orbital	$Z_{\text{eff}}$
He	2	1s	1.6875
C	6	1s	5.6727
		2s	3.2166
		2p	3.1358

\* More values are given in the *Resource section*.

### Brief illustration 9B.3 Penetration and shielding

The effective nuclear charge for 1s, 2s, and 2p electrons in a carbon atom are 5.6727, 3.2166, and 3.1358, respectively. The radial distribution functions for these orbitals (Topic 9A) are generated by forming  $P(r) = r^2 R(r)^2$ , where  $R(r)$  is the radial wavefunction, which are given in Table 9A.1. The three radial

**Figure 9B.5** The radial distribution functions for electrons in a carbon atom, as calculated in *Brief illustration 9B.3*.

distribution functions are plotted in Fig. 9B.5. As can be seen, the s orbital has greater penetration than the p orbital. The average radii of the 2s and 2p orbitals are 99 pm and 84 pm, respectively, which shows that the average distance of a 2s electron from the nucleus is greater than that of a 2p orbital. To account for the lower energy of the 2s orbital we see that the extent of penetration is more important than the average distance.

**Self-test 9B.3** Confirm the values for the average radii. Instead of carrying out the integrations, you might prefer to use the general formula  $\langle r \rangle_{n,l} = (n^2 a_0 / Z) \{1 + \frac{1}{2} [1 - l(l+1)/n^2]\}$ .

Answer: 2s:  $1.865a_0$ ; 2p:  $1.595a_0$

The consequence of penetration and shielding is that the energies of subshells of a shell in a many-electron atom (those with the same values of  $n$  but different values of  $l$ ) in general lie in the order  $s < p < d < f$ . The individual orbitals of a given subshell (those with the same value of  $l$  but different values of  $m_l$ ) remain degenerate because they all have the same radial characteristics and so experience the same effective nuclear charge.

We can now complete the Li story. Because the shell with  $n=2$  consists of two non-degenerate subshells, with the 2s orbital lower in energy than the three 2p orbitals, the third electron occupies the 2s orbital. This occupation results in the ground-state configuration  $1s^2 2s^1$ , with the central nucleus surrounded by a complete helium-like shell of two 1s electrons, and around that a more diffuse 2s electron. The electrons in the outermost shell of an atom in its ground state are called the **valence electrons** because they are largely responsible for the chemical bonds that the atom forms. Thus, the valence electron in Li is a 2s electron and its other two electrons belong to its core.

## 9B.2 The building-up principle

The extension of the argument used to account for the structures of H, He, and Li is called the **building-up principle**, or the *Aufbau principle*, from the German word for building up, which will be familiar from introductory courses. In brief, we imagine the bare nucleus of atomic number  $Z$ , and then feed into the orbitals  $Z$  electrons in succession. The order of occupation is

1s 2s 2p 3s 3p 4s 3d 4p 5s 4d 5p 6s

Each orbital may accommodate up to two electrons.

**Brief illustration 9B.4** The building-up principle

Consider the carbon atom, for which  $Z=6$  and there are six electrons to accommodate. Two electrons enter and fill the 1s orbital, two enter and fill the 2s orbital, leaving two electrons to occupy the orbitals of the 2p subshell. Hence the ground-state configuration of C is  $1s^2 2s^2 2p^2$ , or more succinctly  $[\text{He}]2s^2 2p^2$ , with  $[\text{He}]$  the helium-like  $1s^2$  core.

**Self-test 9B.4** What is the ground-state configuration of a Mg atom?

Answer:  $[\text{Ne}]3s^2$

**(a) Hund's rules**

We can be more precise about the configuration of a carbon atom than in *Brief illustration 9B.4*: we can expect the last two electrons to occupy different 2p orbitals because they will then be further apart on average and repel each other less than if they were in the same orbital. Thus, one electron can be thought of as occupying the  $2p_x$  orbital and the other the  $2p_y$  orbital (the  $x, y, z$  designation is arbitrary, and it would be equally valid to use the complex forms of these orbitals), and the lowest energy configuration of the atom is  $[\text{He}]2s^2 2p_x^1 2p_y^1$ . The same rule applies whenever degenerate orbitals of a subshell are available for occupation. Thus, another rule of the building-up principle is:

Electrons occupy different orbitals of a given subshell before doubly occupying any one of them.

For instance, nitrogen ( $Z=7$ ) has the ground-state configuration  $[\text{He}]2s^2 2p_x^1 2p_y^1 2p_z^1$ , and only when we get to oxygen ( $Z=8$ ) is a 2p orbital doubly occupied, giving  $[\text{He}]2s^2 2p_x^2 2p_y^1 2p_z^1$ .

When electrons occupy orbitals singly we invoke **Hund's maximum multiplicity rule**:

An atom in its ground state adopts a configuration with the greatest number of unpaired electrons.

Hund's  
maximum  
multiplicity  
rule

The explanation of Hund's rule is subtle, but it reflects the quantum mechanical property of **spin correlation**, that, as we demonstrate in the following *Justification*, electrons with parallel spins behave as if they have a tendency to stay well apart, and hence repel each other less. In essence, the effect of spin correlation is to allow the atom to shrink slightly, so the electron–nucleus interaction is improved when the spins are parallel. We can now conclude that, in the ground state of the carbon atom, the two 2p electrons have the same spin, that all three 2p electrons in the N atoms have the same spin (that is, they are parallel), and that the two 2p electrons in different orbitals in the O atom have the same spin (the two in the  $2p_x$  orbital are necessarily paired).

**Justification 9B.2** Spin correlation

Suppose electron 1 is described by a wavefunction  $\psi_a(r_1)$  and electron 2 is described by a wavefunction  $\psi_b(r_2)$ ; then, in the orbital approximation, the joint wavefunction of the electrons is the product  $\Psi = \psi_a(r_1)\psi_b(r_2)$ . However, this wavefunction is not acceptable, because it suggests that we know which electron is in which orbital, whereas we cannot keep track of electrons. According to quantum mechanics, the correct description is either of the two following wavefunctions:

$$\Psi_{\pm} = (1/2^{1/2})\{\psi_a(r_1)\psi_b(r_2) \pm \psi_b(r_1)\psi_a(r_2)\}$$

According to the Pauli principle, because  $\Psi_+$  is symmetrical under particle interchange, it must be multiplied by an antisymmetric spin function (the one denoted  $\sigma_-$ ). That combination corresponds to a spin-paired state. Conversely,  $\Psi_-$  is antisymmetric, so it must be multiplied by one of the three symmetric spin states. These three symmetric states correspond to electrons with parallel spins (see Section 9C.2 for an explanation of this point).

Now consider the values of the two combinations when one electron approaches another, and  $r_1 = r_2$ . We see that  $\Psi_-$  vanishes, which means that there is zero probability of finding the two electrons at the same point in space when they have parallel spins. The other combination does not vanish when the two electrons are at the same point in space. Because the two electrons have different relative spatial distributions depending on whether their spins are parallel or not, it follows that their Coulombic interaction is different, and hence that the two states have different energies.

Neon, with  $Z=10$ , has the configuration  $[\text{He}]2s^2 2p^6$ , which completes the L shell. This closed-shell configuration is denoted  $[\text{Ne}]$ , and acts as a core for subsequent elements. The next electron must enter the 3s orbital and begin a new shell, so an Na atom, with  $Z=11$ , has the configuration  $[\text{Ne}]3s^1$ . Like lithium with the configuration  $[\text{He}]2s^1$ , sodium has a single s electron outside a complete core. This analysis has brought us to the origin of chemical periodicity. The L shell is completed by eight electrons, so the element with  $Z=3$  (Li) should have similar properties to the element with  $Z=11$  (Na). Likewise, Be ( $Z=4$ ) should be similar to  $Z=12$  (Mg), and so on, up to the noble gases He ( $Z=2$ ), Ne ( $Z=10$ ), and Ar ( $Z=18$ ).

Ten electrons can be accommodated in the five 3d orbitals, which accounts for the electron configurations of scandium to zinc. Calculations of the type discussed in Section 9B.3 show that for these atoms the energies of the 3d orbitals are always lower than the energy of the 4s orbital. However, spectroscopic results show that Sc has the configuration  $[\text{Ar}]3d^1 4s^2$ , instead of  $[\text{Ar}]3d^3$  or  $[\text{Ar}]3d^2 4s^1$ . To understand this observation, we have to consider the nature of electron–electron repulsions in 3d and 4s orbitals. The most probable

distance of a 3d electron from the nucleus is less than that for a 4s electron, so two 3d electrons repel each other more strongly than two 4s electrons. As a result, Sc has the configuration  $[\text{Ar}]3d^14s^2$  rather than the two alternatives, for then the strong electron–electron repulsions in the 3d orbitals are minimized. The total energy of the atom is least despite the cost of allowing electrons to populate the high energy 4s orbital (Fig. 9B.6). The effect just described is generally true for scandium through zinc, so their electron configurations are of the form  $[\text{Ar}]3d^n4s^2$ , where  $n=1$  for scandium and  $n=10$  for zinc. Two notable exceptions, which are observed experimentally, are Cr, with electron configuration  $[\text{Ar}]3d^54s^1$ , and Cu, with electron configuration  $[\text{Ar}]3d^{10}4s^1$ .

At gallium, the building-up principle is used in the same way as in preceding periods. Now the 4s and 4p subshells constitute the valence shell, and the period terminates with krypton. Because 18 electrons have intervened since argon, this row is the first ‘long period’ of the periodic table. The existence of the d-block elements (the ‘transition metals’) reflects the stepwise occupation of the 3d orbitals, and the subtle shades of energy differences and effects of electron–electron repulsion along this series gives rise to the rich complexity of inorganic d-metal chemistry. A similar intrusion of the f orbitals in Periods 6 and 7 accounts for the existence of the f block of the periodic table (the lanthanoids and actinoids).

We derive the configurations of cations of elements in the s, p, and d blocks of the periodic table by removing electrons from the ground-state configuration of the neutral atom in a specific order. First, we remove valence p electrons, then valence s electrons, and then as many d electrons as are necessary to achieve the specified charge. The configurations of anions of the p-block elements are derived by continuing the building-up procedure and adding electrons to the neutral atom until the configuration of the next noble gas has been reached.

**Figure 9B.6** Strong electron–electron repulsions in the 3d orbitals are minimized in the ground state of Sc if the atom has the configuration  $[\text{Ar}]3d^14s^2$  (shown on the left) instead of  $[\text{Ar}]3d^24s^1$  (shown on the right). The total energy of the atom is lower when it has the  $[\text{Ar}]3d^14s^2$  configuration despite the cost of populating the high energy 4s orbital.

### Brief illustration 9B.5 Ion configurations

Because the configuration of vanadium is  $[\text{Ar}]3d^34s^2$ , the  $\text{V}^{2+}$  cation has the configuration  $[\text{Ar}]3d^3$ . It is reasonable that we remove the more energetic 4s electrons in order to form the cation, but it is not obvious why the  $[\text{Ar}]3d^3$  configuration is preferred in  $\text{V}^{2+}$  over the  $[\text{Ar}]3d^14s^2$  configuration, which is found in the isoelectronic Sc atom. Calculations show that the energy difference between  $[\text{Ar}]3d^3$  and  $[\text{Ar}]3d^14s^2$  depends on  $Z_{\text{eff}}$ . As  $Z_{\text{eff}}$  increases, transfer of a 4s electron to a 3d orbital becomes more favourable because the electron–electron repulsions are compensated by attractive interactions between the nucleus and the electrons in the spatially compact 3d orbital. Indeed, calculations reveal that, for a sufficiently large  $Z_{\text{eff}}$ ,  $[\text{Ar}]3d^3$  is lower in energy than  $[\text{Ar}]3d^14s^2$ . This conclusion explains why  $\text{V}^{2+}$  has a  $[\text{Ar}]3d^3$  configuration and also accounts for the observed  $[\text{Ar}]4s^03d^n$  configurations of the  $\text{M}^{2+}$  cations of Sc through Zn.

**Self-test 9B.5** Write the ground state configuration of the  $\text{O}^{2-}$  ion.

Answer:  $[\text{He}]2s^22p^6$

### (b) Ionization energies and electron affinities

The minimum energy necessary to remove an electron from a many-electron atom in the gas phase is the **first ionization energy**,  $I_1$ , of the element. The **second ionization energy**,  $I_2$ , is the minimum energy needed to remove a second electron (from the singly charged cation). The variation of the first ionization energy through the periodic table is shown in Fig. 9B.7 and some numerical values are given in Table 9B.2. In thermodynamic calculations we often need the **standard enthalpy of ionization**,  $\Delta_{\text{ion}}H^\ominus$ . As shown in the following *Justification*, the two are related by

$$\Delta_{\text{ion}}H^\ominus(T) = I + \frac{5}{2}RT \quad \text{Enthalpy of ionization} \quad (9B.7a)$$

**Figure 9B.7** The first ionization energies of the elements plotted against atomic number.

**Table 9B.2\*** First and second ionization energies,  $I/(kJ\ mol^{-1})$ 

Element	$I_1/(kJ\ mol^{-1})$	$I_2/(kJ\ mol^{-1})$
H	1312	
He	2372	5251
Mg	738	1451
Na	496	4562

\* More values are given in the *Resource section*.

At 298 K, the difference between the ionization enthalpy and the corresponding ionization energy is  $6.20\ kJ\ mol^{-1}$ . The same expression applies to each successive ionization step, so the overall ionization enthalpy for the formation of  $M^{2+}$  is

$$\Delta_{\text{ion}}H^\ominus(T) = I_1 + I_2 + 5RT \quad (9B.7b)$$

### Justification 9B.3 The ionization enthalpy and the ionization energy

It follows from Kirchhoff's law (Topic 2C, eqn 2C.7a) that the reaction enthalpy, the enthalpy of ionization, for

at a temperature  $T$  is related to the value at  $T=0$  by

$$\Delta_{\text{ion}}H^\ominus(T) = \overbrace{\Delta_{\text{ion}}H^\ominus(0)} + \int_0^T \Delta_{\text{ion}}C_p^\ominus dT$$

The molar constant pressure heat capacity of each species in the reaction is  $\frac{5}{2}R$ , so  $\Delta_{\text{ion}}C_p^\ominus = +\frac{5}{2}R$ . The integral in this expression therefore evaluates to  $\frac{5}{2}RT$ . The reaction enthalpy at  $T=0$  is the same as the (molar) ionization energy,  $I$ . Equation 9B.7a then follows.

The **electron affinity**,  $E_{\text{ea}}$ , is the energy released when an electron attaches to a gas-phase atom (Table 9B.3). In a common, logical (given its name), but not universal convention (which we adopt), the electron affinity is positive if energy is released when the electron attaches to the atom (that is,  $E_{\text{ea}} > 0$  implies that electron attachment is exothermic). It follows from a similar argument to that given in the *Justification* above that the **standard enthalpy of electron gain**,  $\Delta_{\text{eg}}H^\ominus$ , at a temperature  $T$  is related to the electron affinity by

**Table 9B.3\*** Electron affinities,  $E_a/(kJ\ mol^{-1})$ 

Cl	349		
F	322		
H	73		
O	141	O <sup>-</sup>	-844

\* More values are given in the *Resource section*.

$$\Delta_{\text{eg}}H^\ominus(T) = -E_{\text{ea}} - \frac{5}{2}RT \quad \text{Enthalpy of electron gain} \quad (9B.8)$$

Note the change of sign. In typical thermodynamic cycles the  $\frac{5}{2}RT$  that appears in eqn 9B.7 cancels that in eqn 9B.8, so ionization energies and electron affinities can be used directly. A final preliminary point is that the electron-gain enthalpy of a species  $X$  is the negative of the ionization enthalpy of its negative ion:

$$\Delta_{\text{eg}}H^\ominus(X) = -\Delta_{\text{ion}}H^\ominus(X^-) \quad (9B.9)$$

As ionization energy is often easier to measure than electron affinity, this relation can be used to determine numerical values of the latter.

### Brief illustration 9B.6 Ionization energy and electron affinity

Tables of thermodynamic data give the standard enthalpies of formation of Na(g) and Na<sup>+</sup>(g) at 298.15 K as  $+107.32\ kJ\ mol^{-1}$  and  $+609.358\ kJ\ mol^{-1}$ , respectively. Therefore, the standard enthalpy of ionization is the difference,  $+502.04\ kJ\ mol^{-1}$ . The ionization energy is therefore

$$\begin{aligned} I &= \Delta_{\text{ion}}H^\ominus(298.15\ K) - \frac{5}{2}R \times (298.15\ K) \\ &= 502.04\ kJ\ mol^{-1} - 6.197\ kJ\ mol^{-1} \\ &= 495.84\ kJ\ mol^{-1} \quad (\text{or } 5.139\ eV) \end{aligned}$$

as in Table 9B.2.

**Self-test 9B.6** The standard enthalpies of formation of Cl(g) and Cl<sup>-</sup>(g) at 298.15 K are  $+121.679\ kJ\ mol^{-1}$  and  $-233.13\ kJ\ mol^{-1}$ , respectively. What is the electron affinity of chlorine atoms?

Answer:  $+348.61\ kJ\ mol^{-1}$ ,  $+3.613\ eV$

As will be familiar from introductory chemistry, ionization energies and electron affinities show periodicities. The former is more regular and we concentrate on it. Lithium has a low first ionization energy because its outermost electron is well shielded from the nucleus by the core ( $Z_{\text{eff}} = 1.3$ , compared with  $Z = 3$ ). The ionization energy of beryllium ( $Z = 4$ ) is greater but that of boron is lower because in the latter the outermost electron occupies a 2p orbital and is less strongly bound than if it had been a 2s electron. The ionization energy increases from boron to nitrogen on account of the increasing nuclear charge. However, the ionization energy of oxygen is less than would be expected by simple extrapolation. The explanation is that at oxygen a 2p orbital must become doubly occupied, and the electron–electron repulsions are increased above what would be expected by simple extrapolation along the row. In addition, the loss of a 2p electron results in a configuration with

a half-filled subshell (like that of N), which is an arrangement of low energy, so the energy of  $O^+ + e^-$  is lower than might be expected, and the ionization energy is correspondingly low too. (The kink is less pronounced in the next row, between phosphorus and sulfur because their orbitals are more diffuse.) The values for oxygen, fluorine, and neon fall roughly on the same line, the increase of their ionization energies reflecting the increasing attraction of the more highly charged nuclei for the outermost electrons.

The outermost electron in sodium ( $Z=11$ ) is 3s. It is far from the nucleus, and the latter's charge is shielded by the compact, complete neon-like core, with the result that  $Z_{\text{eff}} \approx 2.5$ . As a result, the ionization energy of sodium is substantially lower than that of neon ( $Z=10$ ,  $Z_{\text{eff}} \approx 5.8$ ). The periodic cycle starts again along this row, and the variation of the ionization energy can be traced to similar reasons.

Electron affinities are greatest close to fluorine, for the incoming electron enters a vacancy in a compact valence shell and can interact strongly with the nucleus. The attachment of an electron to an anion (as in the formation of  $O^{2-}$  from  $O^-$ ) is invariably endothermic, so  $E_{\text{ea}}$  is negative. The incoming electron is repelled by the charge already present. Electron affinities are also small, and may be negative, when an electron enters an orbital that is far from the nucleus (as in the heavier alkali metal atoms) or is forced by the Pauli principle to occupy a new shell (as in the noble gas atoms).

### 9B.3 Self-consistent field orbitals

The central difficulty of the Schrödinger equation is the presence of the electron–electron interaction terms. The potential energy of all the electrons in an  $N$ -electron atom is

$$V = - \underbrace{\sum_{i=1}^N \frac{Ze^2}{4\pi\epsilon_0 r_i}}_{\text{Attraction to the nucleus}} + \frac{1}{2} \underbrace{\sum_{i,j=1}^N \frac{e^2}{4\pi\epsilon_0 r_{ij}}}_{\text{Repulsion between electrons}} \quad (9B.10)$$

The first term on the right is the total attractive interaction between the electrons and the nucleus. The second term is the total repulsive interaction between the electrons;  $r_{ij}$  is the distance between electrons  $i$  and  $j$ . The prime on the second sum indicates that contributions with  $i=j$  are excluded, and the factor of one-half prevents double-counting of electron pair repulsions (1 interacting with 2 is the same as 2 interacting with 1). It is hopeless to expect to find analytical solutions of a Schrödinger equation with such a complicated potential energy term, but computational techniques are available that give very detailed and reliable numerical solutions for the wavefunctions and energies. The techniques were originally introduced by D.R. Hartree (before computers were available) and

then modified by V. Fock to take into account the Pauli principle. In broad outline, the **Hartree–Fock self-consistent field (HF-SCF) procedure** is as follows.

Imagine that we have a rough idea of the structure of the atom. In the Ne atom, for instance, the orbital approximation suggests the configuration  $1s^2 2s^2 2p^6$  with the orbitals approximated by hydrogenic atomic orbitals. Now consider one of the 2p electrons. A Schrödinger equation can be written for this electron by ascribing to it a potential energy due to the nuclear attraction and the repulsion from the other electrons. This equation has the form

$$\begin{aligned} \hat{H}(1)\psi_{2p}(1) + V(\text{other electrons})\psi_{2p}(1) \\ - V(\text{exchange correction})\psi_{2p}(1) \\ = E_{2p}\psi_{2p}(1) \end{aligned} \quad (9B.11)$$

Although the equation is for an electron in the 2p orbital, it depends on the wavefunctions of all the other occupied orbitals in the atom, and similar equations can be written for them too. The various terms are as follows:

- The first term on the left is the contribution of the kinetic energy and the attraction of the electron to the nucleus, just as in a hydrogenic atom
- The second term takes into account the potential energy of the electron of interest due to the electrons in the other occupied orbitals.
- The third term is an *exchange correction* that takes into account the spin correlation effects discussed earlier.

Physical interpretation

There is no hope of solving eqn 9B.11 analytically. However, it can be solved numerically if we guess an approximate form of

**Figure 9B.8** The radial distribution functions for the orbitals of Na based on SCF calculations. Note the shell-like structure, with the 3s orbital outside the inner K and L shells.

the wavefunctions of all the orbitals except 2p. The procedure is then repeated for the other orbitals in the atom, the 1s and 2s orbitals. This sequence of calculations gives the form of the 2p, 2s, and 1s orbitals, and in general they will differ from the set used initially to start the calculation. These improved orbitals can be used in another cycle of calculation, and a second improved set of orbitals is obtained. The recycling continues until the orbitals and energies obtained are insignificantly different from those used at the start of the current cycle. The solutions are then 'self-consistent' and accepted as solutions of the problem.

Figure 9B.8 shows plots of some of the HF-SCF radial distribution functions for sodium. They show the grouping of electron density into shells, as was anticipated by the early chemists, and the differences of penetration as discussed above. These SCF calculations therefore support the qualitative discussions that are used to explain chemical periodicity. They also considerably extend that discussion by providing detailed wavefunctions and precise energies.

## Checklist of concepts

- 1. In the **orbital approximation**, each electron is regarded as occupying its own orbital.
- 2. A **configuration** is a statement of the occupied orbitals.
- 3. The **Pauli exclusion principle**, a special case of the Pauli principle, limits to two the number of electrons that can occupy a given orbital.
- 4. In many-electron atoms, s orbitals lie at a lower energy than p orbitals of the same shell due to the combined effects of **penetration** and **shielding**.
- 5. The **building-up principle** is a procedure for predicting the ground state electron configuration of an atom.
- 6. Electrons occupy different orbitals of a given subshell before doubly occupying any one of them.
- 7. An atom in its ground state adopts a configuration with the greatest number of unpaired electrons.
- 8. The **ionization energy** and **electron affinity** vary periodically through the periodic table.
- 9. The Schrödinger equation for many-electron atoms is solved numerically and iteratively until the solutions are self-consistent.

## Checklist of equations

### ► Why do you need to know this material?

A knowledge of the energies of electrons in atoms is essential for understanding many chemical properties and concepts, such as chemical bonding and the structure of the periodic table.

### ► What is the key idea?

The frequency and wavenumber of radiation emitted when transitions take place provide information on the electronic energy states of atoms.

### ► What do you need to know already?

This Topic draws on knowledge of the energy levels of hydrogenic atoms (Topic 9A) and the configurations of many-electron atoms (Topic 9B). In places, it uses the properties of angular momentum (Topic 8C).

The general idea behind atomic spectroscopy is straightforward: lines in the spectrum (in either emission or absorption)

occur when the electron distribution in an atom undergoes a transition with a change of energy  $|\Delta E|$ , and emits or absorbs a photon of frequency  $\nu = |\Delta E|/h$  and wavenumber  $\tilde{\nu} = |\Delta E|/hc$ . Hence, we can expect the spectrum to give information about the energies of electrons in atoms.

## 9C.1 The spectra of hydrogenic atoms

The energies of the hydrogenic atoms are given in Topic 9A ( $E_n = -hcZ^2\tilde{R}_N/n^2$ ). When the electron undergoes a **transition**, a change of state, from an orbital with quantum numbers  $n_1, l_1, m_{l1}$  to another (lower energy) orbital with quantum numbers  $n_2, l_2, m_{l2}$ , it undergoes a change of energy  $\Delta E$  and discards the excess energy as a photon of electromagnetic radiation with a frequency  $\nu$  given by the Bohr frequency condition (Topic 7A, eqn 7A.12;  $\Delta E = h\nu$ ).

Not all transitions are observed. A photon has an intrinsic spin angular momentum corresponding to  $s=1$  (Topic 9B). Because total angular momentum is conserved, the change in angular momentum of the electron must compensate for the angular momentum carried away by the photon. Thus, an electron in a d orbital ( $l=2$ ) cannot make a transition into an s orbital ( $l=0$ ) because the photon cannot carry away enough angular momentum. Similarly, an s electron cannot make a transition to another s orbital, because there would then be no change in the angular momentum of the electron to make up for the angular momentum carried away by the photon. It follows that some spectroscopic transitions are **allowed**, meaning that they can occur, whereas others are **forbidden**, meaning that they cannot occur.

A **selection rule** is a statement about which transitions are allowed. They are derived (for atoms) by identifying the transitions that conserve angular momentum when a photon is emitted or absorbed. We show in the following *Justification* that the selection rules for hydrogenic atoms are

$$\Delta l = \pm 1 \quad \Delta m_l = 0, \pm 1 \quad \text{Selection rules for hydrogenic atoms} \quad (9C.1)$$

The principal quantum number  $n$  can change by any amount consistent with the  $\Delta l$  for the transition, because it does not relate directly to the angular momentum.

**Brief illustration 9C.1** Selection rules

To identify the orbitals to which a 4d electron may make radiative transitions, we first identify the value of  $l$  and then apply the selection rule for this quantum number. Because  $l=2$ , the final orbital must have  $l=1$  or 3. Thus, an electron may make a transition from a 4d orbital to any  $np$  orbital (subject to  $\Delta m_l=0, \pm 1$ ) and to any  $nf$  orbital (subject to the same rule). However, it cannot undergo a transition to any other orbital, so a transition to any  $ns$  orbital or to another  $nd$  orbital is forbidden.

**Self-test 9C.1** To what orbitals may a 4s electron make electric-dipole allowed radiative transitions?

Answer: to  $np$  orbitals only

**Justification 9C.1** The identification of selection rules

The underlying classical idea behind a spectroscopic transition is that, for an atom or molecule to be able to interact with the electromagnetic field and absorb or create a photon of frequency  $\nu$ , it must possess, at least transiently, a dipole oscillating at that frequency. This transient dipole is expressed quantum mechanically in terms of the **transition dipole moment**,  $\mu_{fi}$ , between the initial and final states, where<sup>1</sup>

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau \quad (9C.2)$$

and  $\hat{\mu}$  is the electric dipole moment operator. For a one-electron atom  $\hat{\mu}$  is multiplication by  $-er$  with components  $\mu_x = -ex$ ,  $\mu_y = -ey$ , and  $\mu_z = -ez$ . If the transition dipole moment is zero, then the transition is forbidden; the transition is allowed if the transition moment is non-zero.

To evaluate a transition dipole moment, we consider each component in turn. For example, for the  $z$ -component,

$$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau$$

To evaluate the integral, we note from Table 8C.1 that  $z = r \cos \theta = (4\pi/3)^{1/2} r Y_{1,0}$ , so

$$\int \psi_f^* z \psi_i d\tau = \int_0^\infty \int_0^{2\pi} \int_0^\pi R_{n_f, l_f}^* Y_{l_f, m_f}^* \left( \frac{4\pi}{3} \right)^{1/2} r Y_{1,0} R_{n_i, l_i} Y_{l_i, m_i} r^2 dr \sin \theta d\theta d\phi$$

This multiple integral is the product of three factors, an integral over  $r$  and two integrals (in blue) over the angles, so the factors on the right can be grouped as follows:

$$\int \psi_f^* z \psi_i d\tau = \left( \frac{4\pi}{3} \right)^{1/2} \int_0^\infty R_{n_f, l_f}^* r^3 R_{n_i, l_i} dr \int_0^{2\pi} \int_0^\pi Y_{l_f, m_f}^* Y_{1,0} Y_{l_i, m_i} \sin \theta d\theta d\phi$$

It follows from the properties of the spherical harmonics that the integral

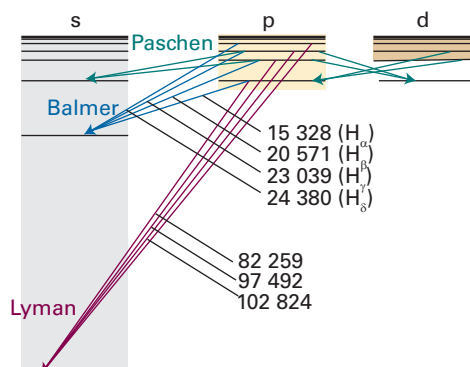

$$I = \int_0^{2\pi} \int_0^\pi Y_{l_f, m_f}^* Y_{1,0} Y_{l_i, m_i} \sin \theta d\theta d\phi$$

is zero unless  $l_f = l_i \pm 1$  and  $m_{l_f} = m_{l_i} + m$ . Because  $m=0$  in the present case, the angular integral, and hence the  $z$ -component of the transition dipole moment, is zero unless  $\Delta l = \pm 1$  and  $\Delta m_l = 0$ , which is a part of the set of selection rules. The same procedure, but considering the  $x$ - and  $y$ -components, results in the complete set of rules.

The selection rules and the atomic energy levels jointly account for the structure of a **Grotrian diagram** (Fig. 9C.1), which summarizes the energies of the states and the transitions between them. The thicknesses of the transition lines in the diagram denote their relative intensities in the spectrum.

**9C.2 The spectra of complex atoms**

The spectra of atoms rapidly become very complicated as the number of electrons increases, but there are some important and moderately simple features that make atomic spectroscopy useful in the study of the composition of samples as large and as complex as stars. However, the actual energy levels are not given solely by the energies of the orbitals, because the electrons interact with one another in various ways.

**Figure 9C.1** A Grotrian diagram that summarizes the appearance and analysis of the spectrum of atomic hydrogen. The wavenumbers of the transitions (in  $\text{cm}^{-1}$ ) are indicated.

<sup>1</sup> See our *Physical chemistry: Quanta, matter, and change* (2014) for a detailed development of the form of eqn 9C.2.

### (a) Singlet and triplet states

Suppose we were interested in the energy levels of a He atom, with its two electrons. We know that the ground-state configuration is  $1s^2$ , and can anticipate that an excited configuration will be one in which one of the electrons has been promoted into a  $2s$  orbital, giving the configuration  $1s^1 2s^1$ . The two electrons need not be paired because they occupy different orbitals. According to Hund's maximum multiplicity rule (Topic 9B), the state of the atom with the spins parallel lies lower in energy than the state in which they are paired. Both states are permissible, and can contribute to the spectrum of the atom.

Parallel and antiparallel (paired) spins differ in their overall spin angular momentum. In the paired case, the two spin momenta cancel each other, and there is zero net spin (as depicted in Fig. 9B.2). The paired-spin arrangement is called a **singlet**. Its spin state is the one denoted  $\sigma_-$  in the discussion of the Pauli principle:

$$\sigma_-(2,1) = (1/2^{1/2})\{\alpha(2)\beta(1) - \beta(2)\alpha(1)\} \quad \text{Singlet spin function} \quad (9C.3a)$$

The angular momenta of two parallel spins add together to give a nonzero total spin, and the resulting state is called a **triplet**. As illustrated in Fig. 9C.2, there are three ways of achieving a nonzero total spin, but only one way to achieve zero spin. The three spin states are the symmetric combinations introduced in Topic 9B:

$$\begin{aligned} &\alpha(1)\alpha(2) \\ \sigma_+(1,2) &= (1/2^{1/2})\{\alpha(1)\beta(2) + \beta(1)\alpha(2)\} \quad \text{Triplet spin functions} \quad (9C.3b) \\ &\beta(1)\beta(2) \end{aligned}$$

**Figure 9C.2** (a) Electrons with paired spins have zero resultant spin angular momentum ( $S=0$ ). They can be represented by two vectors that lie at an indeterminate position on the cones shown here, but wherever one lies on its cone, the other points in the opposite direction; their resultant is zero. (b) When two electrons have parallel spins, they have a nonzero total spin angular momentum ( $S=1$ ). There are three ways of achieving this resultant, which are shown by these vector representations. Note that, whereas two paired spins are precisely antiparallel, two 'parallel' spins are not strictly parallel.

The fact that the parallel arrangement of spins in the  $1s^1 2s^1$  configuration of the He atom lies lower in energy than the antiparallel arrangement can now be expressed by saying that the triplet state of the  $1s^1 2s^1$  configuration of He lies lower in energy than the singlet state. This is a general conclusion that applies to other atoms (and molecules) and, *for states arising from the same configuration, the triplet state generally lies lower than the singlet state*. The origin of the energy difference lies in the effect of spin correlation on the Coulombic interactions between electrons, as in the case of Hund's maximum multiplicity rule for ground-state configurations (Topic 9B). Because the Coulombic interaction between electrons in an atom is strong, the difference in energies between singlet and triplet states of the same configuration can be large. The two states of  $1s^1 2s^1$  He, for instance, differ by  $6421 \text{ cm}^{-1}$  (corresponding to  $0.80 \text{ eV}$ ).

The spectrum of atomic helium is more complicated than that of atomic hydrogen, but there are two simplifying features. One is that the only excited configurations it is necessary to consider are of the form  $1s^1 n l^1$ ; that is, only one electron is excited. Excitation of two electrons requires an energy greater than the ionization energy of the atom, so the  $\text{He}^+$  ion is formed instead of the doubly excited atom. Second, no radiative transitions take place between singlet and triplet states because the relative orientation of the two electron spins cannot change during a transition. Thus, there is a spectrum arising from transitions between singlet states (including the ground state) and between triplet states, but not between the two. Spectroscopically, helium behaves like two distinct species, and the early spectroscopists actually thought of helium as consisting of 'parahelium' and 'orthohelium'. The Grotrian diagram for helium in Fig. 9C.3 shows the two sets of transitions.

### (b) Spin-orbit coupling

An electron has a magnetic moment that arises from its spin. Similarly, an electron with orbital angular momentum (that is, an electron in an orbital with  $l > 0$ ) is in effect a circulating current, and possesses a magnetic moment that arises from its orbital momentum. The interaction of the spin magnetic

**Figure 9C.3** The transitions responsible for the spectrum of atomic helium.

**Figure 9C.4** Spin-orbit coupling is a magnetic interaction between spin and orbital magnetic moments. When the angular momenta are parallel, as in (a), the magnetic moments are aligned unfavourably; when they are opposed, as in (b), the interaction is favourable. This magnetic coupling is the cause of the splitting of a configuration into levels.

moment with the magnetic field arising from the orbital angular momentum is called **spin-orbit coupling**. The strength of the coupling, and its effect on the energy levels of the atom, depend on the relative orientations of the spin and orbital magnetic moments, and therefore on the relative orientations of the two angular momenta (Fig. 9C.4).

One way of expressing the dependence of the spin-orbit interaction on the relative orientation of the spin and orbital momenta is to say that it depends on the total angular momentum of the electron, the vector sum of its spin and orbital momenta. Thus, when the spin and orbital angular momenta are nearly parallel, the total angular momentum is high; when the two angular momenta are opposed, the total angular momentum is low.

The total angular momentum of an electron is described by the quantum numbers  $j$  and  $m_j$ , with  $j = l + \frac{1}{2}$  (when the two angular momenta are in the same direction) or  $j = l - \frac{1}{2}$  (when they are opposed, as in Fig. 9C.5). The different values of  $j$  that can arise for a given value of  $l$  label levels of a term. For  $l=0$ , the only permitted value is  $j = \frac{1}{2}$  (the total angular momentum is the same as the spin angular momentum because there is no other source of angular momentum in the atom). When  $l=1$ ,  $j$  may be either  $\frac{3}{2}$  (the spin and orbital angular momenta are in the same sense) or  $\frac{1}{2}$  (the spin and angular momenta are in opposite senses).

**Figure 9C.5** The coupling of the spin and orbital angular momenta of a d electron ( $l=2$ ) gives two possible values of  $j$  depending on the relative orientations of the spin and orbital angular momenta of the electron.

### Brief illustration 9C.2 The levels of a configuration

To identify the levels that may arise from the configurations (a)  $d^1$ , (b)  $s^1$  we need to identify the value of  $l$  and then the possible values of  $j$ . (a) For a d electron,  $l=2$  and there are two levels in the configuration, one with  $j=2+\frac{1}{2}=\frac{5}{2}$  and the other with  $j=2-\frac{1}{2}=\frac{3}{2}$ . (b) For an s electron  $l=0$ , so only one level is possible, and  $j=\frac{1}{2}$ .

**Self-test 9C.2** Identify the levels of the configurations (a)  $p^1$  and (b)  $f^1$ .

Answer: (a)  $\frac{3}{2}, \frac{1}{2}$ ; (b)  $\frac{7}{2}, \frac{5}{2}$

The dependence of the spin-orbit interaction on the value of  $j$  is expressed in terms of the **spin-orbit coupling constant**,  $\tilde{A}$  (which is typically expressed as a wavenumber). The calculation in the following *Justification* leads to the result that the energies of the levels with quantum numbers  $s$ ,  $l$ , and  $j$  are given by

$$E_{l,s,j} = \frac{1}{2} hc\tilde{A} \{j(j+1) - l(l+1) - s(s+1)\} \quad (9C.4)$$

### Brief illustration 9C.3 Spin-orbit coupling

The unpaired electron in the ground state of an alkali metal atom has  $l=0$ , so  $j=\frac{1}{2}$ . Because the orbital angular momentum is zero in this state, the spin-orbit coupling energy is zero (as is confirmed by setting  $j=s$  and  $l=0$  in eqn 9C.4). When the electron is excited to an orbital with  $l=1$ , it has orbital angular momentum and can give rise to a magnetic field that interacts with its spin. In this configuration the electron can have  $j=\frac{3}{2}$  or  $j=\frac{1}{2}$ , and the energies of these levels are

$$E_{1,1/2,3/2} = \frac{1}{2} hc\tilde{A} \left\{ \frac{3}{2} \times \frac{5}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2} \right\} = \frac{1}{2} hc\tilde{A}$$

$$E_{1,1/2,1/2} = \frac{1}{2} hc\tilde{A} \left\{ \frac{1}{2} \times \frac{3}{2} - 1 \times 2 - \frac{1}{2} \times \frac{3}{2} \right\} = -hc\tilde{A}$$

The corresponding energies are shown in Fig. 9C.6. Note that the barycentre (the 'centre of gravity') of the levels is

**Figure 9C.6** The levels of a  $2p^1$  term arising from spin-orbit coupling. Note that the low- $j$  level lies below the high- $j$  level in energy.

unchanged, because there are four states of energy  $\frac{1}{2}hc\tilde{A}$  and two of energy  $-hc\tilde{A}$ .

**Self-test 9C.3** What are the energies of the two terms that can arise from a  $d^1$  configuration?

Answer:  $E_{2,1/2,5/2} = 2hc\tilde{A}$ ,  $E_{2,1/2,3/2} = -3hc\tilde{A}$

### Justification 9C.2 The energy of spin-orbit interaction

The energy of a magnetic moment  $\mu$  in a magnetic field  $\mathcal{B}$  is equal to their scalar product  $-\mu \cdot \mathcal{B}$ . If the magnetic field arises from the orbital angular momentum of the electron, it is proportional to  $l$ ; if the magnetic moment  $\mu$  is that of the electron spin, then it is proportional to  $s$ . It then follows that the energy of interaction is proportional to the scalar product  $s \cdot l$ :

$$\text{Energy of interaction} = -\mu \cdot \mathcal{B} \propto s \cdot l$$

(For the various vector manipulations used in this section, see *Mathematical background 5*.) Next, we note that the total angular momentum is the vector sum of the spin and orbital momenta:  $j = l + s$ . The magnitude of the vector  $j$  is calculated by evaluating

$$\mathbf{j} \cdot \mathbf{j} = (\mathbf{l} + \mathbf{s}) \cdot (\mathbf{l} + \mathbf{s}) = \mathbf{l} \cdot \mathbf{l} + \mathbf{s} \cdot \mathbf{s} + 2\mathbf{s} \cdot \mathbf{l}$$

so that

$$j^2 = l^2 + s^2 + 2\mathbf{s} \cdot \mathbf{l}$$

That is,

$$\mathbf{s} \cdot \mathbf{l} = \frac{1}{2}\{j^2 - l^2 - s^2\}$$

This equation is a classical result. To make the transition to quantum mechanics, we replace all the quantities on the right with their quantum-mechanical values (Topic 8C):

$$\mathbf{s} \cdot \mathbf{l} = \frac{1}{2}\{j(j+1) - l(l+1) - s(s+1)\}\hbar^2$$

Then, by inserting this expression into the formula for the energy of interaction ( $E \propto \mathbf{s} \cdot \mathbf{l}$ ) and writing the constant of proportionality as  $hc\tilde{A}/\hbar^2$ , we obtain eqn 9C.4.

The strength of the spin-orbit coupling depends on the nuclear charge. To understand why this is so, imagine riding on the orbiting electron and seeing a charged nucleus apparently orbiting around us (like the Sun rising and setting). As a result, we find ourselves at the centre of a ring of current. The greater the nuclear charge, the greater this current, and therefore the stronger the magnetic field we detect. Because the spin magnetic moment of the electron interacts with this orbital magnetic field, it follows that the greater the nuclear charge, the stronger the spin-orbit interaction. The coupling increases sharply with atomic number (as  $Z^4$ ). Whereas it is

**Figure 9C.7** The energy-level diagram for the formation of the sodium D lines. The splitting of the spectral lines (by  $17\text{ cm}^{-1}$ ) reflects the splitting of the levels of the  $2P$  term.

only small in H (giving rise to shifts of energy levels of no more than about  $0.4\text{ cm}^{-1}$ ), in heavy atoms like Pb it is very large (giving shifts of the order of thousands of reciprocal centimetres).

Two spectral lines are observed when the p electron of an electronically excited alkali metal atom undergoes a transition and falls into a lower s orbital. One line is due to a transition starting in a  $j = \frac{3}{2}$  level and the other line is due to a transition starting in the  $j = \frac{1}{2}$  level of the same configuration. The two lines are jointly an example of the **fine structure** of a spectrum, the structure in a spectrum due to spin-orbit coupling. Fine structure can be clearly seen in the emission spectrum from sodium vapour excited by an electric discharge (for example, in one kind of street lighting). The yellow line at 589 nm (close to  $17000\text{ cm}^{-1}$ ) is actually a doublet composed of one line at 589.76 nm ( $16956.2\text{ cm}^{-1}$ ) and another at 589.16 nm ( $16973.4\text{ cm}^{-1}$ ); the components of this doublet are the 'D lines' of the spectrum (Fig. 9C.7). Therefore, in Na, the spin-orbit coupling affects the energies by about  $17\text{ cm}^{-1}$ .

### Example 9C.1 Analysing a spectrum for the spin-orbit coupling constant

The origin of the D lines in the spectrum of atomic sodium is shown in Fig. 9C.7. Calculate the spin-orbit coupling constant for the upper configuration of the Na atom.

**Method** We see from Fig. 9C.7 that the splitting of the lines is equal to the energy separation of the  $j = \frac{3}{2}$  and  $\frac{1}{2}$  levels of the excited configuration. This separation can be expressed in terms of  $\tilde{A}$  by using eqn 9C.4. Therefore, set the observed splitting equal to the energy separation calculated from eqn 9C.4 and solve the equation for  $\tilde{A}$ .

**Answer** The two levels are split by

$$\Delta\tilde{\nu} = (E_{0, \frac{3}{2}, \frac{3}{2}} - E_{0, \frac{1}{2}, \frac{1}{2}}) / hc = \frac{1}{2} \tilde{A} \left\{ \frac{3}{2} \left( \frac{3}{2} + 1 \right) - \frac{1}{2} \left( \frac{1}{2} + 1 \right) \right\} = \frac{3}{2} \tilde{A}$$

The experimental value of  $\Delta\tilde{\nu}$  is  $17.2 \text{ cm}^{-1}$ ; therefore

$$\tilde{A} = \frac{2}{3} \times (17.2 \text{ cm}^{-1}) = 11.5 \text{ cm}^{-1}$$

The same calculation repeated for the other alkali metal atoms gives Li:  $0.23 \text{ cm}^{-1}$ , K:  $38.5 \text{ cm}^{-1}$ , Rb:  $158 \text{ cm}^{-1}$ , Cs:  $370 \text{ cm}^{-1}$ . Note the increase of  $A$  with atomic number (but more slowly than  $Z^4$  for these many-electron atoms).

**Self-test 9C.4** The configuration  $\dots 4p^6 5d^1$  of rubidium has two levels at  $25700.56 \text{ cm}^{-1}$  and  $25703.52 \text{ cm}^{-1}$  above the ground state. What is the spin-orbit coupling constant in this excited state?

*Answer:*  $1.18 \text{ cm}^{-1}$

### (c) Term symbols

We have used expressions such as ‘the  $j = \frac{3}{2}$  level of a doublet term with  $L=1$ ’. A **term symbol**, which is a symbol looking like  ${}^2P_{3/2}$  or  ${}^3D_2$ , conveys this information, specifically the total spin, total orbital angular momentum, and total overall angular momentum, very succinctly.

A term symbol gives three pieces of information:

- The letter (P or D in the examples) indicates the total orbital angular momentum quantum number,  $L$ .
- The left superscript in the term symbol (the 2 in  ${}^2P_{3/2}$ ) gives the multiplicity of the term.
- The right subscript on the term symbol (the  $\frac{3}{2}$  in  ${}^2P_{3/2}$ ) is the value of the total angular momentum quantum number,  $J$ .

We shall now say what each of these statements means; the contributions to the energies which we are about to discuss are summarized in Fig. 9C.8.

When several electrons are present, it is necessary to judge how their individual orbital angular momenta add together to augment or oppose each other. The **total orbital angular momentum quantum number**,  $L$ , tells us the magnitude of the angular momentum through  $\{L(L+1)\}^{1/2}\hbar$ . It has  $2L+1$  orientations distinguished by the quantum number  $M_L$ , which can take the values  $L, L-1, \dots, -L$ . Similar remarks apply to the **total spin quantum number**,  $S$ , and the quantum number  $M_S$ , and the **total angular momentum quantum number**,  $J$ , and the quantum number  $M_J$ .

The value of  $L$  (a non-negative integer) is obtained by coupling the individual orbital angular momenta by using the Clebsch–Gordan series:

**Figure 9C.8** A summary of the types of interaction that are responsible for the various kinds of splitting of energy levels in atoms. For light atoms, magnetic interactions are small, but in heavy atoms they may dominate the electrostatic (charge-charge) interactions.

$$L = l_1 + l_2, l_1 + l_2 - 1, \dots, |l_1 - l_2| \quad \text{Clebsch–Gordan series} \quad (9C.5)$$

The modulus signs are attached to  $l_1 - l_2$  because  $L$  is non-negative. The maximum value,  $L = l_1 + l_2$ , is obtained when the two orbital angular momenta are in the same direction; the lowest value,  $|l_1 - l_2|$ , is obtained when they are in opposite directions. The intermediate values represent possible intermediate relative orientations of the two momenta (Fig. 9C.9). For two p electrons (for which  $l_1 = l_2 = 1$ ),  $L = 2, 1, 0$ . The code for converting the value of  $L$  into a letter is the same as for the s, p, d, f, ... designation of orbitals, but uses uppercase Roman letters (the convention of using lowercase letters to label orbitals and uppercase letters to label overall states applies throughout spectroscopy, not just to atoms):

$L:$	0	1	2	3	4	5	6 ...
	S	P	D	F	G	H	I ...

Thus, a  $p^2$  configuration for which  $L = 2, 1, 0$  can give rise to D, P, and S terms. The terms differ in energy on account of the

**Figure 9C.9** The total angular orbital momenta of a p electron and a d electron correspond to  $L = 3, 2$ , and  $1$  and reflect the different relative orientations of the two momenta.

different spatial distribution of the electrons and the consequent differences in repulsion between them.

A closed shell has zero orbital angular momentum because all the individual orbital angular momenta sum to zero. Therefore, when working out term symbols, we need consider only the electrons of the unfilled shell. In the case of a single electron outside a closed shell, the value of  $L$  is the same as the value of  $l$ ; so the configuration  $[\text{Ne}]3s^1$  has only an S term.

### Example 9C.2 Deriving the total orbital angular momentum of a configuration

Find the terms that can arise from the configurations (a)  $d^2$ , (b)  $p^3$ .

**Method** Use the Clebsch–Gordan series and begin by finding the minimum value of  $L$  (so that we know where the series terminates). When there are more than two electrons to couple together, use two series in succession: first couple two electrons, and then couple the third to each combined state, and so on.

**Answer** (a) The minimum value is  $|l_1 - l_2| = |2 - 2| = 0$ . Therefore,

$$L = 2+2, 2+2-1, \dots, 0 = 4, 3, 2, 1, 0$$

corresponding to G, F, D, P, S terms, respectively. (b) Coupling two electrons gives a minimum value of  $|1 - 1| = 0$ . Therefore,

$$L' = 1+1, 1+1-1, \dots, 0 = 2, 1, 0$$

Now couple  $l_3$  with  $L' = 2$ , to give  $L = 3, 2, 1$ ; with  $L' = 1$ , to give  $L = 2, 1, 0$ ; and with  $L' = 0$ , to give  $L = 1$ . The overall result is

$$L = 3, 2, 2, 1, 1, 1, 0$$

giving one F, two D, three P, and one S term.

**Self-test 9C.5** Repeat the question for the configurations (a)  $f^1d^1$  and (b)  $d^3$ .

Answer: (a) H, G, F, D, P; (b) I, 2H, 3G, 4F, 5D, 3P, S

*A note on good practice* Throughout our discussion of atomic spectroscopy, distinguish italic  $S$ , the total spin quantum number, from Roman  $S$ , the term label.

When there are several electrons to be taken into account, we must assess their total spin angular momentum quantum number,  $S$  (a non-negative integer or half integer). Once again, we use the Clebsch–Gordan series in the form

$$S = s_1 + s_2, s_1 + s_2 - 1, \dots, |s_1 - s_2| \quad (9C.6)$$

to decide on the value of  $S$ , noting that each electron has  $s = \frac{1}{2}$ , which gives  $S = 1, 0$  for two electrons (Fig. 9C.10). If there are

**Figure 9C.10** For two electrons (each of which has  $s = \frac{1}{2}$ ), only two total spin states are permitted ( $S = 0, 1$ ). (a) The state with  $S = 0$  can have only one value of  $M_S$  ( $M_S = 0$ ) and is a singlet; (b) the state with  $S = 1$  can have any of three values of  $M_S$  ( $+1, 0, -1$ ) and is a triplet. The vector representations of the singlet and triplet states are shown in Figs. 9C.2.

three electrons, the total spin angular momentum is obtained by coupling the third spin to each of the values of  $S$  for the first two spins, which results in  $S = \frac{3}{2}$  and  $\frac{1}{2}$ .

The **multiplicity** of a term is the value of  $2S + 1$ . When  $S = 0$  (as for a closed shell, like  $1s^2$ ) the electrons are all paired and there is no net spin: this arrangement gives a singlet term,  $^1S$ . A single electron has  $S = s = \frac{1}{2}$ , so a configuration such as  $[\text{Ne}]3s^1$  can give rise to a doublet term,  $^2S$ . Likewise, the configuration  $[\text{Ne}]3p^1$  is a doublet,  $^2P$ . When there are two unpaired electrons  $S = 1$ , so  $2S + 1 = 3$ , giving a triplet term, such as  $^3D$ . We discussed the relative energies of singlets and triplets earlier in the Topic and saw that their energies differ on account of the different effects of spin correlation.

As we have seen, the quantum number  $j$  tells us the relative orientation of the spin and orbital angular momenta of a single electron. The **total angular momentum quantum number**,  $J$  (a non-negative integer or half integer), does the same for several electrons. If there is a single electron outside a closed shell,  $J = j$ , with  $j$  either  $l = \frac{1}{2}$  or  $|l - \frac{1}{2}|$ . The  $[\text{Ne}]3s^1$  configuration has  $j = \frac{1}{2}$  (because  $l = 0$  and  $s = \frac{1}{2}$ ), so the  $^2S$  term has a single level, which we denote  $^2S_{1/2}$ . The  $[\text{Ne}]3p^1$  configuration has  $l = 1$ ; therefore  $j = \frac{3}{2}$  and  $\frac{1}{2}$ ; the  $^2P$  term therefore has two levels,  $^2P_{3/2}$  and  $^2P_{1/2}$ . These levels lie at different energies on account of the magnetic spin–orbit interaction.

If there are several electrons outside a closed shell we have to consider the coupling of all the spins and all the orbital angular momenta. This complicated problem can be simplified when the spin–orbit coupling is weak (for atoms of low atomic number), for then we can use the **Russell–Saunders coupling scheme**. This scheme is based on the view that, if spin–orbit coupling is weak, then it is effective only when all the orbital momenta are operating cooperatively. We therefore imagine that all the orbital angular momenta of the electrons couple to give a total  $L$ , and that all the spins are similarly coupled to give a total  $S$ . Only at this stage do we imagine the two kinds of momenta coupling through the spin–orbit interaction to give a total  $J$ . The permitted values of  $J$  are given by the Clebsch–Gordan series

$$J = L+S, L+S-1, \dots, |L-S| \quad (9C.7)$$

For example, in the case of the  ${}^3D$  term of the configuration  $[\text{Ne}]2p^13p^1$ , the permitted values of  $J$  are 3, 2, 1 (because  ${}^3D$  has  $L=2$  and  $S=1$ ), so the term has three levels,  ${}^3D_3$ ,  ${}^3D_2$ , and  ${}^3D_1$ .

When  $L \geq S$ , the multiplicity is equal to the number of levels. For example, a  ${}^2P$  term ( $L=1 > S=\frac{1}{2}$ ) has the two levels  ${}^2P_{3/2}$  and  ${}^2P_{1/2}$ , and  ${}^3D$  ( $L=2 > S=1$ ) has the three levels  ${}^3D_3$ ,  ${}^3D_2$ , and  ${}^3D_1$ . However, this is not the case when  $L < S$ : the term  ${}^2S$  ( $L=0 < S=\frac{1}{2}$ ), for example, has only the one level  ${}^2S_{1/2}$ .

### Example 9C.3 Deriving term symbols

Write the term symbols arising from the ground-state configurations of (a) Na and (b) F, and (c) the excited configuration  $1s^22s^22p^13p^1$  of C.

**Method** Begin by writing the configurations, but ignore inner closed shells. Then couple the orbital momenta to find  $L$  and the spins to find  $S$ . Next, couple  $L$  and  $S$  to find  $J$ . Finally, express the term as  ${}^{2S+1}\{L\}_J$ , where  $\{L\}$  is the appropriate letter. For F, for which the valence configuration is  $2p^5$ , treat the single gap in the closed-shell  $2p^6$  configuration as a single spin- $\frac{1}{2}$  particle.

**Answer** (a) For Na, the configuration is  $[\text{Ne}]3s^1$ , and we consider the single  $3s$  electron. Because  $L=l=0$  and  $S=s=\frac{1}{2}$ , it is possible for  $J=j=s=\frac{1}{2}$  only. Hence the term symbol is  ${}^2S_{1/2}$ . (b) For F, the configuration is  $[\text{He}]2s^22p^5$ , which we can treat as  $[\text{Ne}]2p^{-1}$  (where the notation  $2p^{-1}$  signifies the absence of a  $2p$  electron). Hence  $L=1$ , and  $S=s=\frac{1}{2}$ . Two values of  $J=j$  are allowed:  $J=\frac{3}{2}, \frac{1}{2}$ . Hence, the term symbols for the two levels are  ${}^2P_{3/2}, {}^2P_{1/2}$ . (c) We are treating an excited configuration of carbon because, in the ground configuration,  $2p^2$ , the Pauli principle forbids some terms, and deciding which survive ( ${}^1D$ ,  ${}^3P$ ,  ${}^1S$ , in fact) is quite complicated. That is, there is a distinction between ‘equivalent electrons’, which are electrons that occupy the same orbitals, and ‘inequivalent electrons’, which are electrons that occupy different orbitals. The excited configuration of C under consideration is effectively  $2p^13p^1$ . This is a two-electron problem, and  $l_1=l_2=1$ ,  $s_1=s_2=\frac{1}{2}$ . It follows that  $L=2, 1, 0$  and  $S=1, 0$ . The terms are therefore  ${}^3D$  and  ${}^1D$ ,  ${}^3P$  and  ${}^1P$ , and  ${}^3S$  and  ${}^1S$ . For  ${}^3D$ ,  $L=2$  and  $S=1$ ; hence  $J=3, 2, 1$  and the levels are  ${}^3D_3, {}^3D_2$ , and  ${}^3D_1$ . For  ${}^1D$ ,  $L=2$  and  $S=0$ , so the single level is  ${}^1D_2$ . The triplet of levels of  ${}^3P$  is  ${}^3P_2, {}^3P_1$ , and  ${}^3P_0$ , and the singlet is  ${}^1P_1$ . For the  ${}^3S$  term there is only one level,  ${}^3S_1$  (because  $J=1$  only), and the singlet term is  ${}^1S_0$ .

**Self-test 9C.6** Write down the terms arising from the configurations (a)  $2s^12p^1$ , (b)  $2p^13d^1$ .

Answer: (a)  ${}^3P_2, {}^3P_1, {}^3P_0, {}^1P_1$ ; (b)  ${}^3F_4, {}^3F_3, {}^3F_2, {}^1F_3, {}^3D_3, {}^3D_2, {}^3D_1, {}^1D_2, {}^3P_1, {}^3P_0, {}^1P_1$

Russell–Saunders coupling fails when the spin–orbit coupling is large (in heavy atoms, those with high  $Z$ ). In that case,

the individual spin and orbital momenta of the electrons are coupled into individual  $j$  values; then these momenta are combined into a grand total,  $J$ . This scheme is called ***jj-coupling***. For example, in a  $p^2$  configuration, the individual values of  $j$  are  $\frac{3}{2}$  and  $\frac{1}{2}$  for each electron. If the spin and the orbital angular momentum of each electron are coupled together strongly, it is best to consider each electron as a particle with angular momentum  $j=\frac{3}{2}$  or  $\frac{1}{2}$ . These individual total momenta then couple as follows:

$j_1$	$j_2$	$J$
$\frac{3}{2}$	$\frac{3}{2}$	3, 2, 1, 0
$\frac{3}{2}$	$\frac{1}{2}$	2, 1
$\frac{1}{2}$	$\frac{3}{2}$	2, 1
$\frac{3}{2}$	$\frac{3}{2}$	1, 0

For heavy atoms, in which *jj*-coupling is appropriate, it is best to discuss their energies using these quantum numbers.

Although *jj*-coupling should be used for assessing the energies of heavy atoms, the term symbols derived from Russell–Saunders coupling can still be used as labels. To see why this procedure is valid, we need to examine how the energies of the atomic states change as the spin–orbit coupling increases in strength. Such a **correlation diagram** is shown in Fig. 9C.11. It shows that there is a correspondence between the low spin–orbit coupling (Russell–Saunders coupling) and high spin–orbit coupling (*jj*-coupling) schemes, so the labels derived by using the Russell–Saunders scheme can be used to label the states of the *jj*-coupling scheme.

**Figure 9C.11** The correlation diagram for some of the states of a two-electron system. All atoms lie between the two extremes, but the heavier the atom, the closer it lies to the pure *jj*-coupling case.

### (d) Hund's rules

As we have remarked, the terms arising from a given configuration differ in energy because they represent different relative orientations of the angular momenta of the electrons and therefore different spatial distributions. The terms arising from the ground-state configuration of an atom (and less reliably from other configurations) can be put into the order of increasing energy by using **Hund's rules**, which summarize the preceding discussion:

1. For a given configuration, the term of greatest multiplicity lies lowest in energy.

As discussed in Topic 9B, this rule is a consequence of electron spin correlation, the quantum-mechanical tendency of electrons of the same spin orientation to stay apart from one another.

2. For a given multiplicity, the term with the highest value of  $L$  lies lowest in energy.

This rule can be explained classically by noting that two electrons have a high orbital angular momentum if they circulate in the same direction, in which case they can stay apart. If they circulate in opposite directions, they meet. Thus, a D term is expected to lie lower in energy than an S term of the same multiplicity.

3. For atoms with less than half-filled shells, the level with the lowest value of  $J$  lies lowest in energy; for more than half-filled shells, the highest value of  $J$ .

This rule stems from considerations of spin-orbit coupling. Thus, for a state of low  $J$ , the orbital and spin angular momenta lie in opposite directions, and so too do the corresponding magnetic moments. In classical terms the magnetic moments are then antiparallel, with the N pole of one close to the S pole of the other, which is a low-energy arrangement.

### (e) Selection rules

Any state of the atom, and any spectral transition, can be specified by using term symbols. For example, the transitions giving

rise to the yellow sodium doublet (which were shown in Fig. 9C.7) are

By convention, the upper term precedes the lower. The corresponding absorptions are therefore denoted  ${}^2P_{3/2} \leftarrow {}^2S_{1/2}$  and  ${}^2P_{1/2} \leftarrow {}^2S_{1/2}$ . (The configurations have been omitted.)

We have seen (in Section 9C.1) that selection rules arise from the conservation of angular momentum during a transition and from the fact that a photon has a spin of 1. They can therefore be expressed in terms of the term symbols, because the latter carry information about angular momentum. A detailed analysis leads to the following rules:

$$\Delta S = 0 \quad \Delta L = 0, \pm 1 \quad \Delta J = 0, \pm 1 \quad \text{but } J = 0 \leftarrow | \rightarrow J = 0$$

Selection rules for atoms (9C.8)

where the symbol  $\leftarrow | \rightarrow$  denotes a forbidden transition. The rule about  $\Delta S$  (no change of overall spin) stems from the fact that the light does not affect the spin directly. The rules about  $\Delta L$  and  $\Delta J$  express the fact that the orbital angular momentum of an individual electron must change (so  $\Delta l = \pm 1$ ), but whether or not this results in an overall change of orbital momentum depends on the coupling.

The selection rules given above apply when Russell-Saunders coupling is valid (in light atoms, those of low  $Z$ ). If we insist on labelling the terms of heavy atoms with symbols like  ${}^3D$ , then we shall find that the selection rules progressively fail as the atomic number increases because the quantum numbers  $S$  and  $L$  become ill defined as  $jj$ -coupling becomes more appropriate. As explained above, Russell-Saunders term symbols are only a convenient way of labelling the terms of heavy atoms: they do not bear any direct relation to the actual angular momenta of the electrons in a heavy atom. For this reason, transitions between singlet and triplet states (for which  $\Delta S = \pm 1$ ), while forbidden in light atoms, are allowed in heavy atoms.

## Checklist of concepts

- 1. Two electrons with paired spins form a singlet state; if their spins are parallel, they form a **triplet state**.
- 2. The orbital and spin angular momenta interact magnetically.
- 3. **Spin-orbit coupling** results in the levels of a term having different energies.
- 4. Fine structure in a spectrum is due to transitions to different levels of a term.
- 5. A **term symbol** specifies the angular momentum states of an atom.
- 6. Angular momenta are combined into a resultant by using the **Clebsch-Gordan series**.
- 7. The **multiplicity** of a term is the value of  $2S + 1$ .
- 8. The total angular momentum in light atoms is obtained on the basis of **Russell-Saunders coupling**; in heavy atoms,  **$jj$ -coupling** is used.

- 9. Selection rules for light atoms include the fact that changes of total spin do not occur.
- 10. **Hund's rules** can be expressed as:
  - The term with the maximum multiplicity lies lowest in energy.
  - For a given multiplicity, the term with the highest value of  $L$  lies lowest in energy.
  - For atoms with less than half-filled shells, the level with the lowest value of  $J$  lies lowest in energy; for more than half-filled shells, the highest value of  $J$ .

## Checklist of equations

Property	Equation	Comment	Equation number
Spin-orbit coupling energies	$E_{l,s,j} = \frac{1}{2} hc\tilde{A}\{j(j+1) - l(l+1) - s(s+1)\}$		9C.4
Clebsch-Gordan series	$J = j_1 + j_2, j_1 + j_2 - 1, \dots,  j_1 - j_2 $	$J, j$ denote any kind of angular momentum	9C.5
Selection rules	$\Delta S = 0, \Delta L = 0, \pm 1, \Delta I = \pm 1, \Delta J = 0, \pm 1$ , but $J = 0 \nleftrightarrow J = 0$	Light atoms	9C.8

# CHAPTER 9 Atomic structure and atomic spectra

## TOPIC 9A Hydrogenic atoms

### Discussion questions

**9A.1** Describe the separation of variables procedure as it is applied to simplify the description of a hydrogenic atom free to move through space.

**9A.2** List and describe the significance of the quantum numbers needed to specify the internal state of a hydrogenic atom.

**9A.3** Explain the significance of (a) a boundary surface and (b) the radial distribution function for hydrogenic orbitals.

### Exercises

**9A.1(a)** State the orbital degeneracy of the levels in a hydrogen atom that have energy (i)  $-hc\tilde{R}_H$ ; (ii)  $-\frac{1}{9}hc\tilde{R}_H$ ; (iii)  $-\frac{1}{25}hc\tilde{R}_H$ .

**9A.1(b)** State the orbital degeneracy of the levels in a hydrogenic atom ( $Z$  in parentheses) that have energy (i)  $-4hc\tilde{R}_N$ , (2); (ii)  $-\frac{1}{4}hc\tilde{R}_N$  (4), and (iii)  $-hc\tilde{R}_N$  (5).

**9A.2(a)** The wavefunction for the ground state of a hydrogen atom is  $Ne^{-r/a_0}$ . Determine the normalization constant  $N$ .

**9A.2(b)** The wavefunction for the 2s orbital of a hydrogen atom is  $N(2-r/a_0)e^{-r/2a_0}$ . Determine the normalization constant  $N$ .

**9A.3(a)** By differentiation of the 2s radial wavefunction, show that it has two extrema in its amplitude, and locate them.

**9A.3(b)** By differentiation of the 3s radial wavefunction, show that it has three extrema in its amplitude, and locate them.

**9A.4(a)** At what radius does the probability of finding an electron at a point in the H atom fall to 50 per cent of its maximum value?

**9A.4(b)** At what radius in the H atom does the radial distribution function of the ground state have (i) 50 per cent, (ii) 75 per cent of its maximum value.

**9A.5(a)** Locate the radial nodes in the 3s orbital of an H atom.

**9A.5(b)** Locate the radial nodes in the 4p orbital of an H atom. A 4p orbital is proportional to  $(20-10\rho+\rho^2)\rho e^{-\rho/2}$ .

**9A.6(a)** Calculate the average kinetic and potential energies of an electron in the ground state of a hydrogen atom.

**9A.6(b)** Calculate the average kinetic and potential energies of a 2s electron in a hydrogenic atom of atomic number  $Z$ .

**9A.7(a)** Write down the expression for the radial distribution function of a 2s electron in a hydrogenic atom of atomic number  $Z$  and determine the radius at which the electron is most likely to be found.

**9A.7(b)** Write down the expression for the radial distribution function of a 3s electron in a hydrogenic atom of atomic number  $Z$  and determine the radius at which the electron is most likely to be found.

**9A.8(a)** Write down the expression for the radial distribution function of a 2p electron in a hydrogenic atom of atomic number  $Z$  and determine the radius at which the electron is most likely to be found.

**9A.8(b)** Write down the expression for the radial distribution function of a 3p electron in a hydrogenic atom of atomic number  $Z$  and determine the radius at which the electron is most likely to be found.

**9A.9(a)** What is the orbital angular momentum of an electron in the orbitals (i) 1s, (ii) 3s, (iii) 3d? Give the numbers of angular and radial nodes in each case.

**9A.9(b)** What is the orbital angular momentum of an electron in the orbitals (i) 4d, (ii) 2p, (iii) 3p? Give the numbers of angular and radial nodes in each case.

**9A.10(a)** Locate the radial nodes and nodal planes of each of the 3p orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane makes with the  $z$ -axis.

**9A.10(b)** Locate the radial nodes and nodal planes of each of the 4d orbitals of a hydrogenic atom of atomic number  $Z$ . To locate the angular nodes, give the angle that the plane or cone makes with the  $z$ -axis. A 4d wavefunction is proportional to  $(6-\rho)^2 e^{-\rho/2}$ .

### Problems

**9A.1** What is the most probable point (not radius) that a 2p electron will be found in the hydrogen atom?

**9A.2** Show by explicit integration that (a) hydrogenic 1s and 2s orbitals, (b)  $2p_x$  and  $2p_y$  orbitals are mutually orthogonal.

**9A.3** Explicit expressions for hydrogenic orbitals are given in Tables 8C.1 (for the angular component) and 9A.1 (for the radial component). (a) Verify both that the  $3p_x$  orbital is normalized (to 1) and that  $3p_x$  and  $3d_{xy}$  are mutually orthogonal. (b) Determine the positions of both the radial nodes and nodal planes of the 3s,  $3p_x$ , and  $3d_{xy}$  orbitals. (c) Determine the mean radius of the 3s orbital. (d) Draw a graph of the radial distribution function for the three orbitals (of part (b)) and discuss the significance of the graphs for interpreting the properties of many-electron atoms. (e) Create both  $xy$ -plane polar plots and boundary surface plots for these orbitals. Construct the boundary plots so that the distance from the origin to the surface is the absolute value of the angular part of the wavefunction. Compare the s, p, and d boundary surface plots with that of an f orbital; e.g.,  $\psi_f \propto x(5z^2-r^2) \propto \sin\theta(5\cos^2\theta-1)\cos\phi$ .

**9A.4** Determine whether the  $p_x$  and  $p_y$  orbitals are eigenfunctions of  $l_z$ . If not, does a linear combination exist that is an eigenfunction of  $l_z$ ?

**9A.5** Show that  $l_z$  and  $l^2$  both commute with the hamiltonian for a hydrogen atom. What is the significance of this result?

**9A.6** The 'size' of an atom is sometimes considered to be measured by the radius of a sphere that contains 90 per cent of the charge density of the electrons in the outermost occupied orbital. Calculate the 'size' of a hydrogen atom in its ground state according to this definition. Go on to explore how the 'size' varies as the definition is changed to other percentages, and plot your conclusion.

**9A.7** Some atomic properties depend on the average value of  $1/r$  rather than the average value of  $r$  itself. Evaluate the expectation value of  $1/r$  for (a) a hydrogen 1s orbital, (b) a hydrogenic 2s orbital, (c) a hydrogenic 2p orbital. (d) Does  $\langle 1/r \rangle = 1/\langle r \rangle$ ?

**9A.8** One of the most famous of the obsolete theories of the hydrogen atom was proposed by Bohr. It has been replaced by quantum mechanics, but by

a remarkable coincidence (not the only one where the Coulomb potential is concerned), the energies it predicts agree exactly with those obtained from the Schrödinger equation. In the Bohr atom, an electron travels in a circle around the nucleus. The Coulombic force of attraction ( $Ze^2/4\pi\epsilon_0r^2$ ) is balanced by the centrifugal effect of the orbital motion. Bohr proposed that the angular momentum is limited to integral values of  $\hbar$ . When the two forces are balanced, the atom remains in a stationary state until it makes a spectral transition. Calculate the energies of a hydrogenic atom using the Bohr model.

**9A.9** The Bohr model of the atom is specified in Problem 9A.8. (a) What features of it are untenable according to quantum mechanics? (b) How does the Bohr ground state differ from the actual ground state? (c) Is there an experimental distinction between the Bohr and quantum mechanical models of the ground state?

**9A.10** Atomic units of length and energy may be based on the properties of a particular atom. The usual choice is that of a hydrogen atom, with the unit of length being the Bohr radius,  $a_0$ , and the unit of energy being the 'hartree',  $E_h$ , which is equal to twice the (negative of the) energy of the 1s orbital (specifically, and more precisely,  $E_h = 2hcR_\infty$ ). If the positronium atom ( $e^+, e^-$ ) were used instead, with analogous definitions of units of length and energy, what would be the relation between these two sets of atomic units?

**9A.11** The distribution of isotopes of an element may yield clues about the nuclear reactions that occur in the interior of a star. Show that it is possible to use spectroscopy to confirm the presence of both  $^4\text{He}^+$  and  $^3\text{He}^+$  in a star by calculating the wavenumbers of the  $n=3 \rightarrow n=2$  and of the  $n=2 \rightarrow n=1$  transitions for each isotope.

## TOPIC 9B Many-electron atoms

### Discussion questions

**9B.1** Outline the electron configurations of many-electron atoms in terms of their location in the periodic table.

**9B.2** Describe and account for the variation of first ionization energies along Period 2 of the periodic table. Would you expect the same variation in Period 3?

**9B.3** Describe the orbital approximation for the wavefunction of a many-electron atom. What are the limitations of the approximation?

### Exercises

**9B.1(a)** Write the ground-state electron configurations of the d-metals from scandium to zinc.

**9B.1(b)** Write the ground-state electron configurations of the d-metals from yttrium to cadmium.

**9B.2(a)** (i) Write the electronic configuration of the  $\text{Ni}^{2+}$  ion. (ii) What are the possible values of the total spin quantum numbers  $S$  and  $M_S$  for this ion?

**9B.2(b)** (i) Write the electronic configuration of the  $\text{V}^{2+}$  ion. (ii) What are the possible values of the total spin quantum numbers  $S$  and  $M_S$  for this ion?

### Problems

**9B.1** In 1976 it was mistakenly believed that the first of the 'superheavy' elements had been discovered in a sample of mica. Its atomic number was believed to be 126. Without taking relativistic effects into account, calculate the most probable distance of the innermost electrons from the nucleus of an atom of this element? Does your result suggest that relativistic effects should be included in the calculation?

**9B.2** The wavefunction of a many-electron closed-shell atom can be expressed as a Slater determinant. A useful property of determinants is that interchanging any two rows or columns changes their sign and therefore that if any two rows or columns are identical, then the determinant vanishes. Use this property to show that (a) the wavefunction is antisymmetric under particle exchange, (b) no two electrons can occupy the same orbital with the same spin.

**9B.3** The d-metals iron, copper, and manganese form cations with different oxidation states. For this reason, they are found in many oxidoreductases and

in several proteins of oxidative phosphorylation and photosynthesis. Explain why many d-metals form cations with different oxidation states.

**9B.4** Thallium, a neurotoxin, is the heaviest member of Group 13 of the periodic table and is found most usually in the +1 oxidation state. Aluminium, which causes anaemia and dementia, is also a member of the group but its chemical properties are dominated by the +3 oxidation state. Examine this issue by plotting the first, second, and third ionization energies for the Group 13 elements against atomic number. Explain the trends you observe. *Hints:* The third ionization energy,  $I_3$ , is the minimum energy needed to remove an electron from the doubly charged cation:  $\text{E}^{2+}(\text{g}) \rightarrow \text{E}^{3+}(\text{g}) + \text{e}^-(\text{g})$ ,  $I_3 = E(\text{E}^{3+}) - E(\text{E}^{2+})$ . For data, see the links to databases of atomic properties provided in the text's web site.

## TOPIC 9C Atomic spectra

### Discussion questions

**9C.1** Discuss the origin of the series of lines in the emission spectra of hydrogen. What region of the electromagnetic spectrum is associated with each of the series shown in Fig. 9C.1?

**9C.2** Specify and account for the selection rules for transitions in hydrogenic atoms.

**9C.3** Explain the origin of spin-orbit coupling and how it affects the appearance of a spectrum.

## Exercises

- 9C.1(a)** Identify the shortest and longest wavelength lines in the Lyman series.
- 9C.1(b)** The Pfund series has  $n_1=5$ . Identify the shortest and longest wavelength lines in the Pfund series.
- 9C.2(a)** Compute the wavelength, frequency, and wavenumber of the  $n=2 \rightarrow n=1$  transition in  $\text{He}^+$ .
- 9C.2(b)** Compute the wavelength, frequency, and wavenumber of the  $n=5 \rightarrow n=4$  transition in  $\text{Li}^{+2}$ .
- 9C.3(a)** When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of krypton, electrons are ejected with a speed of  $1.59 \text{ Mm s}^{-1}$ . Calculate the ionization energy of krypton.
- 9C.3(b)** When ultraviolet radiation of wavelength 58.4 nm from a helium lamp is directed on to a sample of xenon, electrons are ejected with a speed of  $1.79 \text{ Mm s}^{-1}$ . Calculate the ionization energy of xenon.
- 9C.4(a)** Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (i)  $2s \rightarrow 1s$ , (ii)  $2p \rightarrow 1s$ , (iii)  $3d \rightarrow 2p$ ?
- 9C.4(b)** Which of the following transitions are allowed in the normal electronic emission spectrum of an atom: (i)  $5d \rightarrow 2s$ , (ii)  $5p \rightarrow 3s$ , (iii)  $6p \rightarrow 4f$ ?
- 9C.5(a)** Calculate the permitted values of  $j$  for (i) a d electron, (ii) an f electron.
- 9C.5(b)** Calculate the permitted values of  $j$  for (i) a p electron, (ii) an h electron.
- 9C.6(a)** An electron in two different states of an atom is known to have  $j = \frac{3}{2}$  and  $\frac{1}{2}$ . What is its orbital angular momentum quantum number in each case?
- 9C.6(b)** What are the allowed total angular momentum quantum numbers of a composite system in which  $j_1 = 5$  and  $j_2 = 3$ ?
- 9C.7(a)** What information does the term symbol  $^1D_2$  provide about the angular momentum of an atom?

## Problems

- 9C.1** The *Humphreys series* is a group of lines in the spectrum of atomic hydrogen. It begins at 12 368 nm and has been traced to 3281.4 nm. What are the transitions involved? What are the wavelengths of the intermediate transitions?
- 9C.2** A series of lines in the spectrum of atomic hydrogen lies at 656.46 nm, 486.27 nm, 434.17 nm, and 410.29 nm. What is the wavelength of the next line in the series? What is the ionization energy of the atom when it is in the lower state of the transitions?
- 9C.3** The  $\text{Li}^{2+}$  ion is hydrogenic and has a Lyman series at  $740\,747 \text{ cm}^{-1}$ ,  $877\,924 \text{ cm}^{-1}$ ,  $925\,933 \text{ cm}^{-1}$ , and beyond. Show that the energy levels are of the form  $-hc\tilde{R}_{\text{Li}}/n^2$  and find the value of  $\tilde{R}_{\text{Li}}$  for this ion. Go on to predict the wavenumbers of the two longest-wavelength transitions of the Balmer series of the ion and find the ionization energy of the ion.
- 9C.4** A series of lines in the spectrum of neutral Li atoms rise from combinations of  $1s^2 2p^1 \ ^2P$  with  $1s^2 nd^1 \ ^2D$  and occur at 610.36 nm, 460.29 nm, and 413.23 nm. The d orbitals are hydrogenic. It is known that the  $^2P$  term lies at 670.78 nm above the ground state, which is  $1s^2 2s^1 \ ^2S$ . Calculate the ionization energy of the ground-state atom.
- 9C.5\*** W.P. Wijesundera et al. (*Phys. Rev. A* 51, 278 (1995)) attempted to determine the electron configuration of the ground state of lawrencium, element 103. The two contending configurations are  $[\text{Rn}]5f^{14}7s^2 7p^1$  and  $[\text{Rn}]5f^{14}6d^1 7s^2$ . Write down the term symbols for each of these configurations, and identify the lowest level within each configuration. Which level would be lowest according to a simple estimate of spin-orbit coupling?

\* These problems were supplied by Charles Trapp and Carmen Giunta.

- 9C.7(b)** What information does the term symbol  $^3F_4$  provide about the angular momentum of an atom?
- 9C.8(a)** Suppose that an atom has (i) 2, (ii) 3 electrons in different orbitals. What are the possible values of the total spin quantum number  $S$ ? What is the multiplicity in each case?
- 9C.8(b)** Suppose that an atom has (i) 4, (ii) 5, electrons in different orbitals. What are the possible values of the total spin quantum number  $S$ ? What is the multiplicity in each case?
- 9C.9(a)** What atomic terms are possible for the electron configuration  $ns^1 nd^1$ ? Which term is likely to lie lowest in energy?
- 9C.9(b)** What atomic terms are possible for the electron configuration  $np^1 nd^1$ ? Which term is likely to lie lowest in energy?
- 9C.10(a)** What values of  $J$  may occur in the terms (i)  $^1S$ , (ii)  $^2P$ , (iii)  $^3P$ ? How many states (distinguished by the quantum number  $M_J$ ) belong to each level?
- 9C.10(b)** What values of  $J$  may occur in the terms (i)  $^3D$ , (ii)  $^4D$ , (iii)  $^2G$ ? How many states (distinguished by the quantum number  $M_J$ ) belong to each level?
- 9C.11(a)** Give the possible term symbols for (i) Li  $[\text{He}]2s^1$ , (ii) Na  $[\text{Ne}]3p^1$ .
- 9C.11(b)** Give the possible term symbols for (i) Sc  $[\text{Ar}]3d^1 4s^2$ , (ii) Br  $[\text{Ar}]3d^1 4s^2 4p^5$ .
- 9C.12(a)** Which of the following transitions between terms are allowed in the normal electronic emission spectrum of a many-electron atom: (i)  $^3D_2 \rightarrow ^3P_1$ , (ii)  $^3P_2 \rightarrow ^1S_0$ , (iii)  $^3F_4 \rightarrow ^3D_3$ ?
- 9C.12(b)** Which of the following transitions between terms are allowed in the normal electronic emission spectrum of a many-electron atom: (i)  $^2P_{3/2} \rightarrow ^2S_{1/2}$ , (ii)  $^3P_0 \rightarrow ^3S_1$ , (iii)  $^3D_3 \rightarrow ^1P_1$ ?

**9C.6** An emission line from K atoms is found to have two closely spaced components, one at 766.70 nm and the other at 770.11 nm. Account for this observation, and deduce what information you can.

**9C.7** Calculate the mass of the deuteron given that the first line in the Lyman series of H lies at  $82\,259,098 \text{ cm}^{-1}$  whereas that of D lies at  $82\,281,476 \text{ cm}^{-1}$ . Calculate the ratio of the ionization energies of H and D.

**9C.8** Positronium consists of an electron and a positron (same mass, opposite charge) orbiting round their common centre of mass. The broad features of the spectrum are therefore expected to be hydrogen-like, the differences arising largely from the mass differences. Predict the wavenumbers of the first three lines of the Balmer series of positronium. What is the binding energy of the ground state of positronium?

**9C.9** The *Zeeman effect* is the modification of an atomic spectrum by the application of a strong magnetic field. It arises from the interaction between applied magnetic fields and the magnetic moments due to orbital and spin angular momenta (recall the evidence provided for electron spin by the Stern-Gerlach experiment, Topic 8C). To gain some appreciation for the so-called *normal Zeeman effect*, which is observed in transitions involving singlet states, consider a p electron, with  $l=1$  and  $m_l=0, \pm 1$ . In the absence of a magnetic field, these three states are degenerate. When a field of magnitude  $\mathcal{B}$  is present, the degeneracy is removed and it is observed that the state with  $m_l=+1$  moves up in energy by  $\mu_B \mathcal{B}$ , the state with  $m_l=0$  is unchanged, and the state with  $m_l=-1$  moves down in energy by  $\mu_B \mathcal{B}$ , where  $\mu_B = e\hbar/2m_e = 9.274 \times 10^{-24} \text{ J T}^{-1}$  is the 'Bohr magneton'. Therefore, a transition between a  $^1S_0$  term and a  $^1P_1$  term consists of three spectral lines in the presence of a magnetic field where, in the absence of the magnetic field, there is only one. (a) Calculate the splitting in reciprocal centimetres between the three spectral lines of a transition between a  $^1S_0$  term and a  $^1P_1$  term in the presence of a magnetic field of 2 T (where

$1 \text{ T} = 1 \text{ kg s}^{-2} \text{ A}^{-1}$ ). (b) Compare the value you calculated in (a) with typical optical transition wavenumbers, such as those for the Balmer series of the H atom. Is the line splitting caused by the normal Zeeman effect relatively small or relatively large?

**9C.10** Some of the selection rules for hydrogenic atoms were derived in *Justification* 9C.1. Complete the derivation by considering the  $x$ - and  $y$ -components of the electric dipole moment operator.

**9C.11\*** Stern–Gerlach splittings of atomic beams are small and require either large magnetic field gradients or long magnets for their observation. For a beam of atoms with zero orbital angular momentum, such as H or Ag, the deflection is given by  $x = \pm(\mu_B L^2 / 4E_k) d\mathcal{B}/dz$ , where  $\mu_B$  is the Bohr magneton

(Problem 9C.9),  $L$  is the length of the magnet,  $E_k$  is the average kinetic energy of the atoms in the beam, and  $d\mathcal{B}/dz$  is the magnetic field gradient across the beam. (a) Use the Maxwell–Boltzmann velocity distribution (eqn 1B.4 of Topic 1B) to show that the average translational kinetic energy of the atoms emerging as a beam from a pinhole in an oven at temperature  $T$  is  $2kT$ . (b) Calculate the magnetic field gradient required to produce a splitting of 1.00 mm in a beam of Ag atoms from an oven at 1000 K with a magnet of length 50 cm.

**9C.12** Hydrogen is the most abundant element in all stars. However, neither absorption nor emission lines due to neutral hydrogen are found in the spectra of stars with effective temperatures higher than 25 000 K. Account for this observation.

## Integrated activities

**9.1** An electron in the ground-state  $\text{He}^+$  ion undergoes a transition to a state described by the wavefunction  $R_{4,1}(r)Y_{1,1}(\theta, \phi)$ . (a) Describe the transition using term symbols. (b) Compute the wavelength, frequency, and wavenumber of the transition. (c) By how much does the mean radius of the electron change due to the transition?

**9.2\*** Highly excited atoms have electrons with large principal quantum numbers. Such *Rydberg atoms* have unique properties and are of interest to astrophysicists. (a) For hydrogen atoms with large  $n$ , derive a relation for

the separation of energy levels. (b) Calculate this separation for  $n=100$ ; also calculate the average radius, the geometric cross section, and the ionization energy. (c) Could a thermal collision with another hydrogen atom ionize this Rydberg atom? (d) What minimum velocity of the second atom is required? (e) Could a normal sized neutral H atom simply pass through the Rydberg atom leaving it undisturbed? (f) What might the radial wavefunction for a 100s orbital be like?

## Mathematical background 5 Vectors

A **scalar physical property** (such as temperature) in general varies through space and is represented by a single value at each point of space. A **vector physical property** (such as the velocity or the electric field strength) can also vary through space, but in general has a different direction as well as a different magnitude at each point.

### MB5.1 Definitions

A vector  $\mathbf{v}$  has the general form (in three dimensions):

$$\mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k} \quad (\text{MB5.1})$$

where  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  are **unit vectors**, vectors of magnitude 1, pointing along the positive directions on the  $x$ ,  $y$ , and  $z$  axes and  $v_x$ ,  $v_y$ , and  $v_z$  are the **components** of the vector on each axis (Fig. MB5.1). The **magnitude** of the vector is denoted  $v$  or  $|\mathbf{v}|$  and is given by

$$v = (v_x^2 + v_y^2 + v_z^2)^{1/2} \quad \text{Magnitude} \quad (\text{MB5.2})$$

The vector makes an angle  $\theta$  to the  $z$ -axis and an angle  $\phi$  to the  $x$ -axis in the  $xy$ -plane. It follows that

$$\begin{aligned} v_x &= v \sin \theta \cos \phi & v_y &= v \sin \theta \sin \phi \\ v_z &= v \cos \theta \end{aligned} \quad \text{Orientation} \quad (\text{MB5.3a})$$

and therefore that

$$\theta = \arccos(v_z/v) \quad \phi = \arctan(v_y/v_x) \quad (\text{MB5.3b})$$

#### Brief illustration MB5.1 Vector orientation

The vector  $\mathbf{v} = 2\mathbf{i} + 3\mathbf{j} - \mathbf{k}$  has magnitude

$$v = \{2^2 + 3^2 + (-1)^2\}^{1/2} = 14^{1/2} = 3.74$$

Its direction is given by

$$\theta = \arccos(-1/14^{1/2}) = 105.5^\circ \quad \phi = \arctan(3/2) = 56.3^\circ$$

**Figure MB5.1** The vector  $\mathbf{v}$  has components  $v_x$ ,  $v_y$ , and  $v_z$  on the  $x$ ,  $y$ , and  $z$  axes, respectively. It has a magnitude  $v$  and makes an angle  $\theta$  to the  $z$ -axis and an angle  $\theta$  to the  $x$ -axis in the  $xy$ -plane.

### MB5.2 Operations

Consider the two vectors

$$\mathbf{u} = u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k} \quad \mathbf{v} = v_x \mathbf{i} + v_y \mathbf{j} + v_z \mathbf{k}$$

The operations of addition, subtraction, and multiplication are as follows:

1. **Addition:**

$$\mathbf{u} + \mathbf{v} = (v_x + u_x)\mathbf{i} + (v_y + u_y)\mathbf{j} + (v_z + u_z)\mathbf{k} \quad (\text{MB5.4a})$$

2. **Subtraction:**

$$\mathbf{v} - \mathbf{u} = (v_x - u_x)\mathbf{i} + (v_y - u_y)\mathbf{j} + (v_z - u_z)\mathbf{k} \quad (\text{MB5.4b})$$

#### Brief illustration MB5.2 Addition and subtraction

Consider the vectors  $\mathbf{u} = \mathbf{i} - 4\mathbf{j} + \mathbf{k}$  (of magnitude 4.24) and  $\mathbf{v} = -4\mathbf{i} + 2\mathbf{j} + 3\mathbf{k}$  (of magnitude 5.39). Their sum is

$$\mathbf{u} + \mathbf{v} = (1-4)\mathbf{i} + (-4+2)\mathbf{j} + (1+3)\mathbf{k} = -3\mathbf{i} - 2\mathbf{j} + 4\mathbf{k}$$

The magnitude of the resultant vector is  $29^{1/2} = 5.39$ . The difference of the two vectors is

$$\mathbf{u} - \mathbf{v} = (1+4)\mathbf{i} + (-4-2)\mathbf{j} + (1-3)\mathbf{k} = 5\mathbf{i} - 6\mathbf{j} - 2\mathbf{k}$$

The magnitude of this resultant is 8.06. Note that in this case the difference is longer than either individual vector.

3. **Multiplication:**

(a) The **scalar product**, or *dot product*, of the two vectors  $\mathbf{u}$  and  $\mathbf{v}$  is

$$\mathbf{u} \cdot \mathbf{v} = u_x v_x + u_y v_y + u_z v_z \quad \text{Scalar product} \quad (\text{MB5.4c})$$

and is itself a scalar quantity. We can always choose a new coordinate system—we shall write it  $X$ ,  $Y$ ,  $Z$ —in which the  $Z$ -axis lies parallel to  $\mathbf{u}$ , so  $\mathbf{u} = u\mathbf{K}$ , where  $\mathbf{K}$  is the unit vector parallel to  $\mathbf{u}$ . It then follows from eqn MB5.4c that  $\mathbf{u} \cdot \mathbf{v} = uv_Z$ . Then, with  $v_Z = v \cos \theta$ , where  $\theta$  is the angle between  $\mathbf{u}$  and  $\mathbf{v}$ , we find

$$\mathbf{u} \cdot \mathbf{v} = uv \cos \theta \quad \text{Scalar product} \quad (\text{MB5.4d})$$

(b) The **vector product**, or *cross product*, of two vectors is

$$\mathbf{u} \times \mathbf{v} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ u_x & u_y & u_z \\ v_x & v_y & v_z \end{vmatrix}$$

**Figure MB5.2** A depiction of the ‘right-hand rule’. When the fingers of the right hand rotate  $u$  into  $v$ , the thumb points in the direction of  $u \times v$ .

$$= (u_y v_z - u_z v_y)\mathbf{i} - (u_x v_z - u_z v_x)\mathbf{j} + (u_x v_y - u_y v_x)\mathbf{k}$$

Vector product (MB5.4e)

(Determinants are discussed in *The chemist’s toolkit* 9B.1.) Once again, choosing the coordinate system so that  $u = u\mathbf{k}$ , leads to the simple expression:

$$u \times v = (uv \sin \theta)l$$

Vector product (MB5.4f)

where  $\theta$  is the angle between the two vectors and  $l$  is a unit vector perpendicular to both  $u$  and  $v$ , with a direction determined by the ‘right-hand rule’ as in Fig. MB5.2. A special case is when each vector is a unit vector, for then

$$\mathbf{i} \times \mathbf{j} = \mathbf{k} \quad \mathbf{j} \times \mathbf{k} = \mathbf{i} \quad \mathbf{k} \times \mathbf{i} = \mathbf{j}$$

(MB5.5)

It is important to note that the order of vector multiplication is important and that  $u \times v = -v \times u$ .

### Brief illustration MB5.3 Scalar and vector products

The scalar and vector products of the two vectors in *Brief illustration* MB5.2,  $u = \mathbf{i} - 4\mathbf{j} + \mathbf{k}$  (of magnitude 4.24) and  $v = -4\mathbf{i} + 2\mathbf{j} + 3\mathbf{k}$  (of magnitude 5.39) are

$$u \cdot v = \{1 \times (-4)\} + \{(-4) \times 2\} + \{1 \times 3\} = -9$$

$$u \times v = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ 1 & -4 & 1 \\ -4 & 2 & 3 \end{vmatrix}$$

$$= \{(-4)(3) - (1)(2)\}\mathbf{i} - \{(1)(3) - (1)(-4)\}\mathbf{j} + \{(1)(2) - (-4)(-4)\}\mathbf{k}$$

$$= -14\mathbf{i} - 7\mathbf{j} - 14\mathbf{k}$$

The vector product is a vector of magnitude 21.00 pointing in a direction perpendicular to the plane defined by the two individual vectors.

### MB5.3 The graphical representation of vector operations

Consider two vectors  $v$  and  $u$  making an angle  $\theta$  (Fig. MB5.3). The first step in the addition of  $u$  to  $v$  consists of joining the tip (the ‘head’) of  $u$  to the starting point (the ‘tail’) of  $v$ . In the second step, we draw a vector  $v_{\text{res}}$ , the **resultant vector**, originating from the tail of  $u$  to the head of  $v$ . Reversing the order of addition leads to the same result; that is, we obtain the same  $v_{\text{res}}$  whether we add  $u$  to  $v$  or  $v$  to  $u$ . To calculate the magnitude of  $v_{\text{res}}$ , we note that

$$v_{\text{res}}^2 = (u+v) \cdot (u+v) = u \cdot u + v \cdot v + 2u \cdot v = u^2 + v^2 + 2uv \cos \theta$$

where  $\theta$  is the angle between  $u$  and  $v$ . In terms of the angle  $\theta' = \pi - \theta$  shown in the figure, and  $\cos(\pi - \theta) = -\cos \theta$ , we obtain the law of cosines:

$$v_{\text{res}}^2 = u^2 + v^2 - 2uv \cos \theta$$

Law of cosines (MB5.6)

for the relation between the lengths of the sides of a triangle.

Subtraction of  $v$  from  $u$  amounts to addition of  $-v$  to  $u$ . It follows that in the first step of subtraction we draw  $-v$  by reversing

**Figure MB5.3** (a) The vectors  $v$  and  $u$  make an angle  $\theta$ . (b) To add  $u$  to  $v$ , we first join the head of  $u$  to the tail of  $v$ , making sure that the angle  $\theta$  between the vectors remains unchanged. (c) To finish the process, we draw the resultant vector by joining the tail of  $u$  to the head of  $v$ .

**Figure MB5.4** The graphical method for subtraction of the vector  $v$  from the vector  $u$  (as shown in Fig. MB5.3a) consists of two steps: (a) reversing the direction of  $v$  to form  $-v$ , and (b) adding  $-v$  to  $u$ .

**Figure MB5.5** The direction of the cross products of two vectors  $\mathbf{u}$  and  $\mathbf{v}$  with an angle  $\theta$  between them: (a)  $\mathbf{u} \times \mathbf{v}$  and (b)  $\mathbf{v} \times \mathbf{u}$ . Note that the cross product, and the unit vector  $\mathbf{l}$  of eqn MB5.4f, are perpendicular to both  $\mathbf{u}$  and  $\mathbf{v}$  but the direction depends on the order in which the product is taken. The magnitude of the cross product, in either case, is  $uv \sin \theta$ .

the direction of  $\mathbf{v}$  (Fig. MB5.4). Then, the second step consists of adding  $-\mathbf{v}$  to  $\mathbf{u}$  by using the strategy shown in the figure; we draw a resultant vector  $\mathbf{v}_{\text{res}}$  by joining the tail of  $-\mathbf{v}$  to the head of  $\mathbf{u}$ .

Vector multiplication is represented graphically by drawing a vector (using the right-hand rule) perpendicular to the plane defined by the vectors  $\mathbf{u}$  and  $\mathbf{v}$ , as shown in Fig. MB5.5. Its length is equal to  $uv \sin \theta$ , where  $\theta$  is the angle between  $\mathbf{u}$  and  $\mathbf{v}$ .

### MB5.4 Vector differentiation

The derivative  $d\mathbf{v}/dt$ , where the components  $v_x$ ,  $v_y$ , and  $v_z$  are themselves functions of  $t$ , is

$$\frac{d\mathbf{v}}{dt} = \left( \frac{dv_x}{dt} \right) \mathbf{i} + \left( \frac{dv_y}{dt} \right) \mathbf{j} + \left( \frac{dv_z}{dt} \right) \mathbf{k} \quad \text{Derivative (MB5.7)}$$

The derivatives of scalar and vector products are obtained using the rules of differentiating a product:

$$\frac{d\mathbf{u} \cdot \mathbf{v}}{dt} = \left( \frac{d\mathbf{u}}{dt} \right) \cdot \mathbf{v} + \mathbf{u} \cdot \left( \frac{d\mathbf{v}}{dt} \right) \quad \text{(MB5.8a)}$$

$$\frac{d\mathbf{u} \times \mathbf{v}}{dt} = \left( \frac{d\mathbf{u}}{dt} \right) \times \mathbf{v} + \mathbf{u} \times \left( \frac{d\mathbf{v}}{dt} \right) \quad \text{(MB5.8b)}$$

In the latter, note the importance of preserving the order of vectors.

The **gradient** of a scalar function  $f(x, y, z)$ , denoted  $\text{grad } f$  or  $\nabla f$ , is

$$\nabla f = \left( \frac{\partial f}{\partial x} \right) \mathbf{i} + \left( \frac{\partial f}{\partial y} \right) \mathbf{j} + \left( \frac{\partial f}{\partial z} \right) \mathbf{k} \quad \text{Gradient (MB5.9)}$$

where partial derivatives are described in *Mathematical background 2*. Note that the gradient of a scalar function is a vector. We can treat  $\nabla$  as a vector operator (in the sense that it operates on a function and results in a vector), and write

$$\nabla = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \quad \text{(MB5.10)}$$

The scalar product of  $\nabla$  and  $\nabla f$ , using eqns MB5.9 and MB5.10, is

$$\begin{aligned} \nabla \cdot \nabla f &= \left( \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \right) \cdot \left( \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z} \right) f \\ &= \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} \quad \text{Laplacian (MB5.11)} \end{aligned}$$

Equation MB5.11 defines the **Laplacian** ( $\nabla^2 = \nabla \cdot \nabla$ ) of a function.

# CHAPTER 10

## Molecular structure

The concepts developed in Chapter 9, particularly those of orbitals, can be extended to a description of the electronic structures of molecules. There are two principal quantum mechanical theories of molecular electronic structure. In ‘valence-bond theory’, the starting point is the concept of the shared electron pair.

### 10A Valence-bond theory

In this Topic we see how to write the wavefunction for a shared electron pair, and how it may be extended to account for the structures of a wide variety of molecules. The theory introduces the concepts of  $\sigma$  and  $\pi$  bonds, promotion, and hybridization that are used widely in chemistry.

### 10B Principles of molecular orbital theory

Almost all modern computational work makes use of molecular orbital theory (MO theory), and we concentrate on that theory in this chapter. In MO theory, the concept of atomic orbital is extended to that of ‘molecular orbital’, which is a wavefunction that spreads over all the atoms in a molecule. The Topic begins with an account of the hydrogen molecule, which sets the scene for the application of MO theory to more complicated molecules.

### 10C Homonuclear diatomic molecules

The principles established for the hydrogen molecule are readily extended to other homonuclear diatomic molecules, the principal difference being that more types of atomic orbital must be included to give a more varied collection of molecular orbitals. The building-up principle for atoms is extended to the occupation of molecular orbitals and used to predict the electronic structure of molecules.

### 10D Heteronuclear diatomic molecules

The MO theory of heteronuclear diatomic molecules introduces the possibility that the atomic orbitals on the two atoms contribute unequally to the molecular orbital. As a result, the molecule is polar. The polarity can be expressed in terms of the concept of electronegativity.

### 10E Polyatomic molecules

Most molecules are polyatomic, so it is important to be able to account for their electronic structure. An early approach to the electronic structure of planar conjugated polyenes is the ‘Hückel method’. This procedure introduces severe approximations, but sets the scene for more sophisticated procedures. These more sophisticated procedures have given rise to what is essentially a huge and vibrant theoretical chemistry industry in which elaborate computations are used to predict molecular properties. In this Topic we see a little of how those calculations are formulated.

### What is the impact of this material?

The concepts introduced in this chapter pervade the whole of chemistry and are encountered throughout the text. We focus on two biochemical aspects here. In *Impact* I10.1 we see how simple concepts account for the reactivity of small molecules that occur in organisms. In *Impact* I10.2 we see a little of the contribution of computational chemistry to the explanation of the thermodynamic and spectroscopic properties of several biologically significant molecules.

### ► Why do you need to know this material?

Valence-bond theory was the first quantum mechanical theory of bonding to be developed. The language it introduced, which includes concepts such as spin pairing,  $\sigma$  and  $\pi$  bonds, and hybridization, is widely used throughout chemistry, especially in the description of the properties and reactions of organic compounds.

### ► What is the key idea?

A bond forms when an electron in an atomic orbital on one atom pairs its spin with that of an electron in an atomic orbital on another atom.

### ► What do you need to know already?

You need to know about atomic orbitals (Topic 9A) and the concepts of normalization and orthogonality (Topic 7C). This Topic also makes use of the Pauli principle (Topic 9B).

Here we summarize essential topics of valence-bond theory (VB theory) that should be familiar from introductory chemistry and set the stage for the development of molecular orbital theory (MO theory). However, there is an important preliminary point. All theories of molecular structure make the same

simplification at the outset. Whereas the Schrödinger equation for a hydrogen atom can be solved exactly, an exact solution is not possible for any molecule because even the simplest molecule consists of three particles (two nuclei and one electron). We therefore adopt the **Born–Oppenheimer approximation** in which it is supposed that the nuclei, being so much heavier than an electron, move relatively slowly and may be treated as stationary while the electrons move in their field. That is, we think of the nuclei as fixed at arbitrary locations, and then solve the Schrödinger equation for the wavefunction of the electrons alone.

The Born–Oppenheimer approximation allows us to select an internuclear separation in a diatomic molecule and then to solve the Schrödinger equation for the electrons at that nuclear separation. Then we choose a different separation and repeat the calculation, and so on. In this way we can explore how the energy of the molecule varies with bond length and obtain a **molecular potential energy curve** (Fig. 10A.1). It is called a *potential* energy curve because the kinetic energy of the stationary nuclei is zero. Once the curve has been calculated or determined experimentally (by using the spectroscopic techniques described in Topics 12C–12E and 13A), we can identify the **equilibrium bond length**,  $R_e$ , the internuclear separation at the minimum of the curve, and the **bond dissociation energy**,  $D_0$ , which is closely related to the depth,  $D_e$ , of the minimum below the energy of the infinitely widely separated and stationary atoms. When more than one molecular parameter is changed in a polyatomic molecule, such as its various bond lengths and angles, we obtain a potential energy *surface*; the overall equilibrium shape of the molecule corresponds to the global minimum of the surface.

**Figure 10A.1** A molecular potential energy curve. The equilibrium bond length corresponds to the energy minimum.

## 10A.1 Diatomic molecules

We begin the account of VB theory by considering the simplest possible chemical bond, the one in molecular hydrogen,  $\text{H}_2$ .

### (a) The basic formulation

The spatial wavefunction for an electron on each of two widely separated H atoms is

$$\Psi(1,2) = \chi_{\text{H}1s_A}(r_1) \chi_{\text{H}1s_B}(r_2) \quad (10A.1)$$

if electron 1 is on atom A and electron 2 is on atom B; in this chapter, and as is common in the chemical literature, we use  $\chi$  (chi) to denote atomic orbitals. For simplicity, we shall write this wavefunction as  $\Psi(1,2) = A(1)B(2)$ . When the atoms are close, it is not possible to know whether it is electron 1 or electron 2 that is on A. An equally valid description is therefore  $\Psi(1,2) = A(2)B(1)$ , in which electron 2 is on A and electron 1 is on B. When two outcomes are equally probable, quantum mechanics instructs us to describe the true state of the system as a superposition of the wavefunctions for each possibility (Topic 7C), so a better description of the molecule than either wavefunction alone is one of the (unnormalized) linear combinations  $\Psi(1,2) = A(1)B(2) \pm A(2)B(1)$ . The combination with lower energy is the one with a + sign, so the valence-bond wavefunction of the electrons in an  $\text{H}_2$  molecule is

$$\Psi(1,2) = A(1)B(2) + A(2)B(1) \quad \text{A valence-bond wavefunction} \quad (10A.2)$$

The reason why this linear combination has a lower energy than either the separate atoms or the linear combination with a negative sign can be traced to the constructive interference between the wave patterns represented by the terms  $A(1)B(2)$  and  $A(2)B(1)$ , and the resulting enhancement of the probability density of the electrons in the internuclear region (Fig. 10A.2).

#### Brief illustration 10A.1 A valence-bond wavefunction

The wavefunction in eqn 10A.2 might look abstract, but in fact it can be expressed in terms of simple exponential functions. Thus, if we use the wavefunction for an  $\text{H}1s$  orbital ( $Z=1$ ) given in Topic 9A, then, with the radii measured from their respective nuclei (1),

$$\begin{aligned} \Psi(1,2) &= \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{A1}/a_0} \times \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{B2}/a_0} + \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{A2}/a_0} \\ &\times \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{B1}/a_0} = \frac{1}{\pi a_0^3} \{ e^{-(r_{A1}+r_{B2})/a_0} + e^{-(r_{A2}+r_{B1})/a_0} \} \end{aligned}$$

**Self-test 10A.1** Express this wavefunction in terms of the Cartesian coordinates of each electron given that the internuclear separation (along the  $z$ -axis) is  $R$ .

Answer:  $r_{Ai} = (x_i^2 + y_i^2 + z_i^2)^{1/2}$ ,  $r_{Bi} = (x_i^2 + y_i^2 + (z_i - R)^2)^{1/2}$

**Figure 10A.2** It is very difficult to represent valence-bond wavefunctions because they refer to two electrons simultaneously. However, this illustration is an attempt. The atomic orbital for electron 1 is represented by the purple shading, and that of electron 2 is represented by the green shading. The left illustration represents  $A(1)B(2)$ , and the right illustration represents the contribution  $A(2)B(1)$ . When the two contributions are superimposed, there is interference between the purple contributions and between the green contributions, resulting in an enhanced (two-electron) density in the internuclear region.

The electron distribution described by the wavefunction in eqn 10A.2 is called a  $\sigma$  bond. A  $\sigma$  bond has cylindrical symmetry around the internuclear axis, and is so called because, when viewed along the internuclear axis, it resembles a pair of electrons in an  $s$  orbital (and  $\sigma$  is the Greek equivalent of  $s$ ).

A chemist's picture of a covalent bond is one in which the spins of two electrons pair as the atomic orbitals overlap. The origin of the role of spin, as we show in the following *Justification*, is that the wavefunction in eqn 10A.2 can be formed only by a pair of spin-paired electrons. Spin pairing is not an end in itself: it is a means of achieving a wavefunction and the probability distribution it implies that corresponds to a low energy.

#### Justification 10A.1 Electron pairing in VB theory

The Pauli principle requires the overall wavefunction of two electrons, the wavefunction including spin, to change sign when the labels of the electrons are interchanged (Topic 9B). The overall VB wavefunction for two electrons is

$$\Psi(1,2) = \{A(1)B(2) + A(2)B(1)\}\sigma(1,2)$$

where  $\sigma$  represents the spin component of the wavefunction. When the labels 1 and 2 are interchanged, this wavefunction becomes

$$\begin{aligned}\Psi(2,1) &= \{A(2)B(1) + A(1)B(2)\}\sigma(2,1) \\ &= \{A(1)B(2) + A(2)B(1)\}\sigma(2,1)\end{aligned}$$

The Pauli principle requires that  $\Psi(2,1) = -\Psi(1,2)$ , which is satisfied only if  $\sigma(2,1) = -\sigma(1,2)$ . The combination of two spins that has this property is

$$\sigma_{-}(1,2) = (1/2^{1/2})\{\alpha(1)\beta(2) - \beta(1)\alpha(2)\}$$

which corresponds to paired electron spins (Topic 9C). Therefore, we conclude that the state of lower energy (and hence the formation of a chemical bond) is achieved if the electron spins are paired.

The VB description of  $H_2$  can be applied to other homonuclear diatomic molecules. For  $N_2$ , for instance, we consider the valence electron configuration of each atom, which is  $2s^2 2p_x^1 2p_y^1 2p_z^1$ . It is conventional to take the  $z$ -axis to be the internuclear axis, so we can imagine each atom as having a  $2p_z$  orbital pointing towards a  $2p_z$  orbital on the other atom (Fig. 10A.3), with the  $2p_x$  and  $2p_y$  orbitals perpendicular to the axis. A  $\sigma$  bond is then formed by spin pairing between the two electrons in the two  $2p_z$  orbitals. Its spatial wavefunction is given by eqn 10A.2, but now  $A$  and  $B$  stand for the two  $2p_z$  orbitals.

The remaining  $N2p$  orbitals cannot merge to give  $\sigma$  bonds as they do not have cylindrical symmetry around the internuclear axis. Instead, they merge to form two  $\pi$  bonds. A  $\pi$  bond arises from the spin pairing of electrons in two p orbitals that approach side-by-side (Fig. 10A.4). It is so called because, viewed along the inter-nuclear axis, a  $\pi$  bond resembles a pair of electrons in a p orbital (and  $\pi$  is the Greek equivalent of p).

There are two  $\pi$  bonds in  $N_2$ , one formed by spin pairing in two neighbouring  $2p_x$  orbitals and the other by spin pairing in two neighbouring  $2p_y$  orbitals. The overall bonding pattern in

Figure 10A.3 The orbital overlap and spin pairing between electrons in two collinear p orbitals that results in the formation of a  $\sigma$  bond.

Figure 10A.4 A  $\pi$  bond results from orbital overlap and spin pairing between electrons in p orbitals with their axes perpendicular to the internuclear axis. The bond has two lobes of electron density separated by a nodal plane.

Figure 10A.5 The structure of bonds in a nitrogen molecule, with one  $\sigma$  bond and two  $\pi$  bonds. The overall electron density has cylindrical symmetry around the internuclear axis.

$N_2$  is therefore a  $\sigma$  bond plus two  $\pi$  bonds (Fig. 10A.5), which is consistent with the Lewis structure  $:N \equiv N:$  for nitrogen.

### (b) Resonance

Another term introduced into chemistry by VB theory is **resonance**, the superposition of the wavefunctions representing different electron distributions in the same nuclear framework. To understand what this means, consider the VB description of a purely covalently bonded HCl molecule, which could be written as  $\Psi = A(1)B(2) + A(2)B(1)$ , with  $A$  now a H1s orbital and  $B$  a Cl2p orbital. However, this description is physically unlikely: it allows electron 1 to be on the H atom when electron 2 is on the Cl atom, and vice versa, but it does not allow for the possibility that both electrons are on the Cl atom ( $\Psi = B(1)B(2)$ , representing  $H^+Cl^-$ ) or even on the H atom ( $\Psi = A(1)A(2)$ , representing the much less likely  $H^-Cl^+$ ). A better description of the wavefunction for the molecule is as a superposition of the covalent and ionic descriptions, and we write (with a slightly simplified notation, and ignoring the less likely  $H^-Cl^+$  possibility)  $\Psi_{HCl} = \Psi_{H-Cl} + \lambda \Psi_{H^+Cl^-}$  with  $\lambda$  (lambda) some numerical coefficient. In general, we write

$$\Psi = \Psi_{\text{covalent}} + \lambda \Psi_{\text{ionic}} \quad (10A.3)$$

where  $\Psi_{\text{covalent}}$  is the two-electron wavefunction for the purely covalent form of the bond and  $\Psi_{\text{ionic}}$  is the two-electron wavefunction for the ionic form of the bond. The approach summarized by eqn 10A.3, in which we express a wavefunction as the superposition of wavefunctions corresponding to a variety of structures *with the nuclei in the same locations*, is called **resonance**. In this case, where one structure is pure covalent and the other pure ionic, it is called **ionic-covalent resonance**. The interpretation of the wavefunction, which is called a **resonance hybrid**, is that if we were to inspect the molecule, then the probability that it would be found with an ionic structure is proportional to  $\lambda^2$ . If  $\lambda^2$  is very small, the covalent description is dominant. If  $\lambda^2$  is very large, the ionic description is dominant. Resonance is not a flickering between the contributing states: it is a blending of their characteristics, much as a mule is a blend of a horse and a donkey. It is only a mathematical device for achieving a closer approximation to the true wavefunction of the molecule than that represented by any single contributing structure alone.

A systematic way of calculating the value of  $\lambda$  is provided by the **variation principle** which is proved in Topic 10C:

If an arbitrary wavefunction is used to calculate the energy, then the value calculated is never less than the true energy.

Variation principle

The arbitrary wavefunction is called the **trial wavefunction**. The principle implies that, if we vary the parameter  $\lambda$  in the trial wavefunction until the lowest energy is achieved (by evaluating the expectation value of the hamiltonian for the wavefunction), then that value of  $\lambda$  will be the best and through  $\lambda^2$  represents the appropriate contribution of the ionic wavefunction to the resonance hybrid.

### Brief illustration 10A.2 Resonance hybrids

Consider a bond described by eqn 10A.3. We might find that the lowest energy is reached when  $\lambda=0.1$ , so the best description of the bond in the molecule is a resonance structure described by the wavefunction  $\Psi = \Psi_{\text{covalent}} + 0.1\Psi_{\text{ionic}}$ . This wavefunction implies that the probabilities of finding the molecule in its covalent and ionic forms are in the ratio 100:1 (because  $0.1^2=0.01$ ).

## 10A.2 Polyatomic molecules

Each  $\sigma$  bond in a polyatomic molecule is formed by the spin pairing of electrons in atomic orbitals with cylindrical symmetry around the relevant internuclear axis. Likewise,  $\pi$  bonds are formed by pairing electrons that occupy atomic orbitals of the appropriate symmetry.

### Brief illustration 10A.3 A polyatomic molecule

The VB description of  $\text{H}_2\text{O}$  will make this approach clear. The valence-electron configuration of an O atom is  $2s^2 2p_x^2 2p_y^1 2p_z^1$ . The two unpaired electrons in the  $\text{O}2p$  orbitals can each pair with an electron in an  $\text{H}1s$  orbital, and each combination results in the formation of a  $\sigma$  bond (each bond has cylindrical symmetry about the respective O–H internuclear axis). Because the  $2p_x$  and  $2p_y$  orbitals lie at  $90^\circ$  to each other, the two  $\sigma$  bonds also lie at  $90^\circ$  to each other (Fig. 10A.6). We predict, therefore, that  $\text{H}_2\text{O}$  should be an angular molecule, which it is. However, the theory predicts a bond angle of  $90^\circ$ , whereas the actual bond angle is  $104.5^\circ$ .

**Figure 10A.6** In a primitive view of the structure of an  $\text{H}_2\text{O}$  molecule, each bond is formed by the overlap and spin pairing of an  $\text{H}1s$  electron and an  $\text{O}2p$  electron.

**Self-test 10A.2** Use VB theory to suggest a shape for the ammonia molecule,  $\text{NH}_3$ .

Answer: Trigonal pyramidal with HNH bond angle  $90^\circ$ ; experimental:  $107^\circ$

Resonance plays an important role in the valence-bond description of polyatomic molecules. One of the most famous examples of resonance is in the VB description of benzene, where the wavefunction of the molecule is written as a superposition of the many-electron wavefunctions of the two covalent Kekulé structures:

$$\psi = \psi \left( \text{Kekulé structure 1} \right) + \psi \left( \text{Kekulé structure 2} \right) \quad (10A.4)$$

The two contributing structures have identical energies, so they contribute equally to the superposition. The effect of resonance (which is represented by a double-headed arrow,  $\text{Kekulé structure 1} \leftrightarrow \text{Kekulé structure 2}$ , in this case) is to distribute double-bond character around the ring and to make the lengths and strengths of all the carbon-carbon bonds identical. The wavefunction is improved by allowing resonance because it allows for a more accurate description of the location of the electrons, and in particular the distribution can adjust into a state of lower energy. This lowering is called the **resonance stabilization** of the molecule and, in the context of VB theory, is largely responsible for the unusual stability of

aromatic rings. Resonance always lowers the energy, and the lowering is greatest when the contributing structures have similar energies. The wavefunction of benzene is improved still further, and the calculated energy of the molecule is lowered further still, if we allow ionic-covalent resonance too, by allowing a small admixture of structures such as .

### (a) Promotion

As pointed out in *Brief illustration 10A.3*, simple VB theory predicts a bond angle of  $90^\circ$ , whereas the actual bond angle is  $104.5^\circ$ . Another deficiency of this initial formulation of VB theory is its inability to account for carbon's tetravalence (its ability to form four bonds). The ground-state configuration of C is  $2s^2 2p_x^1 2p_y^1$ , which suggests that a carbon atom should be capable of forming only two bonds, not four.

This deficiency is overcome by allowing for **promotion**, the excitation of an electron to an orbital of higher energy. In carbon, for example, the promotion of a  $2s$  electron to a  $2p$  orbital can be thought of as leading to the configuration  $2s^1 2p_x^1 2p_y^1 2p_z^1$ , with four unpaired electrons in separate orbitals. These electrons may pair with four electrons in orbitals provided by four other atoms (such as four H1s orbitals if the molecule is  $\text{CH}_4$ ), and hence form four  $\sigma$  bonds. Although energy was required to promote the electron, it is more than recovered by the promoted atom's ability to form four bonds in place of the two bonds of the unpromoted atom.

Promotion, and the formation of four bonds, is a characteristic feature of carbon because the promotion energy is quite small: the promoted electron leaves a doubly occupied  $2s$  orbital and enters a vacant  $2p$  orbital, hence significantly relieving the electron-electron repulsion it experiences in the former. However, it is important to remember that promotion is not a 'real' process in which an atom somehow becomes excited and then forms bonds: it is a notional contribution to the overall energy change that occurs when bonds form.

#### Brief illustration 10A.4 Promotion

Sulfur can form six bonds (an 'expanded octet'), as in the molecule  $\text{SF}_6$ . Because the ground-state electron configuration of sulfur is  $[\text{Ne}]3s^2 3p^4$ , this bonding pattern requires the promotion of a  $3s$  electron and a  $3p$  electron to two different  $3d$  orbitals, which are nearby in energy, to produce the notional configuration  $[\text{Ne}]3s^1 3p^3 3d^2$  with all six of the valence electrons in different orbitals and capable of bond formation with six electrons provided by six F atoms.

**Self-test 10A.3** Account for the ability of phosphorus to form five bonds, as in  $\text{PF}_5$ .

Answer: Promotion of a  $3s$  electron from  $[\text{Ne}]3s^2 3p^3$  to  $[\text{Ne}]3s^1 3p^3 3d^1$

### (b) Hybridization

The description of the bonding in  $\text{CH}_4$  (and other alkanes) is still incomplete because it implies the presence of three  $\sigma$  bonds of one type (formed from H1s and  $\text{C}2p$  orbitals) and a fourth  $\sigma$  bond of a distinctly different character (formed from H1s and  $\text{C}2s$ ). This problem is overcome by realizing that the electron density distribution in the promoted atom is equivalent to the electron density in which each electron occupies a **hybrid orbital** formed by interference between the  $\text{C}2s$  and  $\text{C}2p$  orbitals of the same atom. The origin of the hybridization can be appreciated by thinking of the four atomic orbitals centred on a nucleus as waves that interfere destructively and constructively in different regions, and give rise to four new shapes.

As we show in the following *Justification*, the specific linear combinations that give rise to four equivalent hybrid orbitals are

$$\begin{aligned} h_1 &= s + p_x + p_y + p_z & h_2 &= s - p_x - p_y + p_z \\ h_3 &= s - p_x + p_y - p_z & h_4 &= s + p_x - p_y - p_z \end{aligned} \quad \begin{array}{l} \text{sp}^3 \text{ hybrid} \\ \text{orbitals} \end{array} \quad (10A.5)$$

As a result of the interference between the component orbitals, each hybrid orbital consists of a large lobe pointing in the direction of one corner of a regular tetrahedron (Fig. 10A.7). The angle between the axes of the hybrid orbitals is the tetrahedral angle,  $\arccos(-1/3) = 109.47^\circ$ . Because each hybrid is built from one  $s$  orbital and three  $p$  orbitals, it is called an  **$\text{sp}^3$  hybrid orbital**.

#### Justification 10A.2 Determining the form of tetrahedral hybrid orbitals

We begin by supposing that each hybrid can be written in the form  $h = as + b_x p_x + b_y p_y + b_z p_z$ . The hybrid  $h_1$  that points to the (1,1,1) corner of a cube must have equal contributions from all three  $p$  orbitals, so we can set the three  $b$  coefficients equal to each other and write  $h_1 = as + b(p_x + p_y + p_z)$ . The other three hybrids have the same composition (they are equivalent, apart from their direction in space), but are orthogonal to  $h_1$ . This orthogonality is achieved by choosing different signs for the  $p$ -orbitals but the same overall composition. For instance, we might choose  $h_2 = as + b(-p_x - p_y + p_z)$ , in which case the orthogonality condition is

$$\begin{aligned} \int h_1 h_2 d\tau &= \int (as + b(p_x + p_y + p_z))(as + b(-p_x - p_y + p_z)) d\tau \\ &= a^2 \int s^2 d\tau - b^2 \int p_x^2 d\tau - \dots - ab \int sp_x d\tau - \dots \\ &\quad - b^2 \int p_x p_y d\tau + \dots = a^2 - b^2 - b^2 + b^2 = a^2 - b^2 = 0 \end{aligned}$$

We conclude that a solution is  $a = b$  (the alternative solution,  $a = -b$ , simply corresponds to choosing different absolute

phases for the p orbitals) and the two hybrid orbitals are the  $h_1$  and  $h_2$  in eqn 10A.3. A similar argument but with  $h_3 = as + b(-p_x + p_y - p_z)$  or  $h_4 = as + b(p_x - p_y - p_z)$  leads to the other two hybrids in eqn 10A.3.

**Figure 10A.7** An  $sp^3$  hybrid orbital formed from the superposition of s and p orbitals on the same atom. There are four such hybrids: each one points towards the corner of a regular tetrahedron. The overall electron density remains spherically symmetrical.

It is now easy to see how the valence-bond description of the  $\text{CH}_4$  molecule leads to a tetrahedral molecule containing four equivalent C–H bonds. Each hybrid orbital of the promoted C atom contains a single unpaired electron; an H1s electron can pair with each one, giving rise to a  $\sigma$  bond pointing in a tetrahedral direction. For example, the (un-normalized) two-electron wavefunction for the bond formed by the hybrid orbital  $h_1$  and the  $1s_A$  orbital (with wavefunction that we shall denote A) is

$$\Psi(1,2) = h_1(1)A(2) + h_1(2)A(1) \quad (10A.6)$$

As for  $\text{H}_2$ , to achieve this wavefunction, the two electrons it describes must be paired. Because each  $sp^3$  hybrid orbital has the same composition, all four  $\sigma$  bonds are identical apart from their orientation in space (Fig. 10A.8).

**Figure 10A.8** Each  $sp^3$  hybrid orbital forms a  $\sigma$  bond by overlap with an H1s orbital located at the corner of the tetrahedron. This model accounts for the equivalence of the four bonds in  $\text{CH}_4$ .

A hybrid orbital has enhanced amplitude in the internuclear region, which arises from the constructive interference between the s orbital and the positive lobes of the p orbitals. As a result, the bond strength is greater than for a bond formed from an s or p orbital alone. This increased bond strength is another factor that helps to repay the promotion energy.

Hybridization is used to describe the structure of an ethene molecule,  $\text{H}_2\text{C}=\text{CH}_2$ , and the torsional rigidity of double bonds. An ethene molecule is planar, with HCH and HCC bond angles close to  $120^\circ$ . To reproduce the  $\sigma$  bonding structure, each C atom is regarded as promoted to a  $2s^1 2p^3$  configuration. However, instead of using all four orbitals to form hybrids, we form  $sp^2$  hybrid orbitals:

$$\begin{aligned} h_1 &= s + 2^{1/2} p_y \\ h_2 &= s + \left(\frac{3}{2}\right)^{1/2} p_x - \left(\frac{1}{2}\right)^{1/2} p_y \\ h_3 &= s - \left(\frac{3}{2}\right)^{1/2} p_x - \left(\frac{1}{2}\right)^{1/2} p_y \end{aligned} \quad \text{sp}^2 \text{ hybrid orbitals} \quad (10A.7)$$

These hybrids lie in a plane and point towards the corners of an equilateral triangle at  $120^\circ$  to each other (Fig. 10A.9 and Problem 10A.3). The third 2p orbital ( $2p_z$ ) is not included in the hybridization; its axis is perpendicular to the plane in which the hybrids lie. The different signs of the coefficients, as well as ensuring that the hybrids are mutually orthogonal, also ensure that constructive interference takes place in different regions of space, so giving the patterns in the illustration. The  $sp^2$ -hybridized C atoms each form three  $\sigma$  bonds by spin pairing with either the  $h_1$  hybrid of the other C atom or with H1s orbitals. The  $\sigma$  framework therefore consists of C–H and C–C  $\sigma$  bonds at  $120^\circ$  to each other. When the two  $\text{CH}_2$  groups lie in the same plane, the two electrons in the unhybridized p orbitals can pair and form a  $\pi$  bond (Fig. 10A.10). The formation of this  $\pi$  bond locks the framework into the planar arrangement, for any rotation of one  $\text{CH}_2$  group relative to the other leads to a weakening of the  $\pi$  bond (and consequently an increase in energy of the molecule).

**Figure 10A.9** (a) An s orbital and two p orbitals can be hybridized to form three equivalent orbitals that point towards the corners of an equilateral triangle. (b) The remaining, unhybridized p orbital is perpendicular to the plane.

**Figure 10A.10** A representation of the structure of a double bond in ethene; only the  $\pi$  bond is shown explicitly.

A similar description applies to ethyne,  $\text{HC}\equiv\text{CH}$ , a linear molecule. Now the C atoms are **sp hybridized**, and the  $\sigma$  bonds are formed using hybrid atomic orbitals of the form

$$h_1 = s + p_z \quad h_2 = s - p_z \quad \text{sp hybrid orbitals} \quad (10A.8)$$

These two hybrids lie along the internuclear axis. The electrons in them pair either with an electron in the corresponding hybrid orbital on the other C atom or with an electron in one of the H1s orbitals. Electrons in the two remaining p orbitals on each atom, which are perpendicular to the molecular axis, pair to form two perpendicular  $\pi$  bonds (Fig. 10A.11).

Other hybridization schemes, particularly those involving d orbitals, are often invoked in elementary descriptions of molecular structure to be consistent with other molecular geometries (Table 10A.1). The hybridization of  $N$  atomic orbitals

**Figure 10A.11** A representation of the structure of a triple bond in ethyne; only the  $\pi$  bonds are shown explicitly. The overall electron density has cylindrical symmetry around the axis of the molecule.

**Table 10A.1** Some hybridization schemes

Coordination number	Arrangement	Composition
2	Linear	sp, pd, sd
	Angular	sd
3	Trigonal planar	$sp^2$ , $p^2d$
	Unsymmetrical planar	spd
	Trigonal pyramidal	$pd^2$
4	Tetrahedral	$sp^3$ , $sd^3$
	Irregular tetrahedral	$sp^2d^2$ , $p^3d$ , $dp^3$
	Square planar	$p^2d^2$ , $sp^2d$
	Trigonal bipyramidal	$sp^3d$ , $sp^3d$
5	Tetragonal pyramidal	$sp^2d^2$ , $sd^4$ , $pd^4$ , $p^3d^2$
	Pentagonal planar	$p^2d^3$
	Octahedral	$sp^3d^2$
6	Trigonal prismatic	$sp^4d$ , $pd^5$
	Trigonal antiprismatic	$p^3d^3$

always results in the formation of  $N$  hybrid orbitals, which may either form bonds or may contain lone pairs of electrons.

#### Brief illustration 10A.5 Hybrid structures

For example,  $sp^3d^2$  hybridization results in six equivalent hybrid orbitals pointing towards the corners of a regular octahedron; it is sometimes invoked to account for the structure of octahedral molecules, such as  $\text{SF}_6$  (recall the promotion of sulfur's electrons in *Brief illustration 10A.4*). Hybrid orbitals do not always form bonds: they may also contain lone pairs of electrons. For example, in the hydrogen peroxide molecule,  $\text{H}_2\text{O}_2$ , each O atom can be regarded as  $sp^3$  hybridized. Two of the hybrid orbitals form bonds, one O—O bond and one O—H bond at approximately  $109^\circ$  (the experimental value is much less, at  $94.8^\circ$ ). The remaining two hybrids on each atom accommodate lone pairs of electrons. Rotation around the O—O bond is possible, so the molecule is conformationally mobile.

**Self-test 10A.4** Account for the structure of methylamine,  $\text{CH}_3\text{NH}_2$ .

Answer: C, N both  $sp^3$  hybridized; a lone pair on N

## Checklist of concepts

1. The **Born–Oppenheimer approximation** treats the nuclei as stationary while the electrons move in their field.
2. A **molecular potential energy curve** depicts the variation of the energy of the molecule as a function of bond length.

- 3. The **equilibrium bond length** is the internuclear separation at the minimum of the curve.
- 4. The **bond dissociation energy** is the minimum energy need to separate the two atoms of a molecule.
- 5. A bond forms when an electron in an atomic orbital on one atom pairs its spin with that of an electron in an atomic orbital on another atom.
- 6. A  **$\sigma$  bond** has cylindrical symmetry around the internuclear axis.
- 7. A  **$\pi$  bond** has symmetry like that of a p orbital perpendicular to the internuclear axis.
- 8. **Promotion** is the notional excitation of an electron to an empty orbital to enable the formation of additional bonds.
- 9. **Hybridization** is the blending together of atomic orbitals on the same atom to achieve the appropriate directional properties and enhanced overlap.
- 10. **Resonance** is the superposition of structures with different electron distributions but the same nuclear arrangement.

### ► Why do you need to know this material?

Molecular orbital theory is the basis of almost all descriptions of chemical bonding, including that of individual molecules and of solids. It is the basis of almost all computational techniques for the prediction and analysis of the properties of molecules.

### ► What is the key idea?

Molecular orbitals are wavefunctions that spread over all the atom in a molecule and each one can accommodate up to two electrons.

### ► What do you need to know already?

You need to be familiar with the shapes of atomic orbitals (Topic 9B) and how an energy is calculated from a wavefunction (Topic 7C). The entire discussion is within the framework of the Born–Oppenheimer approximation (Topic 10A).

In **molecular orbital theory** (MO theory), electrons do not belong to particular bonds but spread throughout the entire molecule. This theory has been more fully developed than valence-bond theory (Topic 10A) and provides the language that is widely used in modern discussions of bonding. To introduce it, we follow the same strategy as in Topic 9B, where the one-electron H atom was taken as the fundamental species for

discussing atomic structure and then developed into a description of many-electron atoms. In this chapter we use the simplest molecular species of all, the hydrogen molecule-ion,  $\text{H}_2^+$ , to introduce the essential features of bonding and then use it to describe the structures of more complex systems.

## 10B.1 Linear combinations of atomic orbitals

The hamiltonian for the single electron in  $\text{H}_2^+$  is

$$\hat{H} = -\frac{\hbar^2}{2m_e} \nabla_1^2 + V \quad V = -\frac{e^2}{4\pi\epsilon_0} \left( \frac{1}{r_{A1}} + \frac{1}{r_{B1}} - \frac{1}{R} \right) \quad (10B.1)$$

where  $r_{A1}$  and  $r_{B1}$  are the distances of the electron from the two nuclei A and B (1) and  $R$  is the distance between the two nuclei. In the expression for  $V$ , the first two terms in parentheses are the attractive contribution from the interaction between the electron and the nuclei; the remaining term is the repulsive interaction between the nuclei. The collection of fundamental constant  $e^2/4\pi\epsilon_0$  occurs widely throughout this chapter, and we shall denote it  $j_0$ .

The one-electron wavefunctions obtained by solving the Schrödinger equation  $H\psi = E\psi$  are called **molecular orbitals** (MOs). A molecular orbital  $\psi$  gives, through the value of  $|\psi|^2$ , the distribution of the electron in the molecule. A molecular orbital is like an atomic orbital, but spreads throughout the molecule.

### (a) The construction of linear combinations

The Schrödinger equation can be solved analytically for  $\text{H}_2^+$  (within the Born–Oppenheimer approximation), but the wavefunctions are very complicated functions; moreover, the solution cannot be extended to polyatomic systems. Therefore, we adopt a simpler procedure that, while more approximate, can be extended readily to other molecules.

If an electron can be found in an atomic orbital belonging to atom A and also in an atomic orbital belonging to atom B, then the overall wavefunction is a superposition of the two atomic orbitals:

$$\psi_{\pm} = N(A \pm B) \quad \text{Linear combination of atomic orbitals} \quad (10B.2)$$

where, for  $H_2^+$ ,  $A$  denotes a  $1s$  atomic orbital on atom A, which we denote (as in Topic 10A)  $\chi_{H1s_A}$ ,  $B$  likewise denotes  $\chi_{H1s_B}$ , and  $N$  is a normalization factor. The technical term for the superposition in eqn 10B.2 is a **linear combination of atomic orbitals** (LCAO). An approximate molecular orbital formed from a linear combination of atomic orbitals is called an **LCAO-MO**. A molecular orbital that has cylindrical symmetry around the internuclear axis, such as the one we are discussing, is called a  **$\sigma$  orbital** because it resembles an  $s$  orbital when viewed along the axis and, more precisely, because it has zero orbital angular momentum around the internuclear axis.

### Example 10.B1 Normalizing a molecular orbital

Normalize the molecular orbital  $\psi_+$  in eqn 10B.2.

**Method** We need to find the factor  $N$  such that  $\int \psi^* \psi d\tau = 1$ , where the integration is over the whole of space. To proceed, substitute the LCAO into this integral, and make use of the fact that the atomic orbitals are individually normalized.

**Answer** Substitution of the wavefunction gives

$$\int \psi^* \psi d\tau = N^2 \left\{ \int A^2 d\tau + \int B^2 d\tau + 2 \int AB d\tau \right\} = 2(1+S)N^2$$

where  $S = \int AB d\tau$  and has a value that depends on the nuclear separation (this ‘overlap integral’ will play a significant role later). For the integral to be equal to 1, we require

$$N = \frac{1}{\{2(1+S)\}^{1/2}}$$

In  $H_2^+$ ,  $S \approx 0.59$ , so  $N = 0.56$ .

**Self-test 10B.1** Normalize the orbital  $\psi_-$  in eqn 10B.2.

Answer:  $N = 1/\{2(1-S)\}^{1/2}$ , so  $N = 1.10$

Figure 10B.1 shows the contours of constant amplitude for the molecular orbital  $\psi_+$  in eqn 10B.2. Plots like these are readily obtained using commercially available software. The calculation is quite straightforward, because all we need do is feed in the mathematical forms of the two atomic orbitals and then let the program do the rest.

**Figure 10B.1** (a) The amplitude of the bonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude.

### Brief illustration 10B.1 A molecular orbital

We can use the same two  $H1s$  orbitals as in Topic 10A, namely

$$A = \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{A1}/a_0} \quad B = \frac{1}{(\pi a_0^3)^{1/2}} e^{-r_{B1}/a_0}$$

and note that  $r_A$  and  $r_B$  are not independent (1), but when expressed in Cartesian coordinates based on atom A (2) are related by  $r_{A1} = \{x^2 + y^2 + z^2\}^{1/2}$  and  $r_{B1} = \{x^2 + y^2 + (z-R)^2\}^{1/2}$ , where  $R$  is the bond length. The resulting surfaces of constant amplitude are shown in Fig. 10B.2.

**Figure 10B.2** Surfaces of constant amplitude of the wavefunction  $\psi_+$  of the hydrogen molecule-ion.

**Self-test 10B.2** Repeat the analysis for  $\psi_-$ .

Answer: See Fig. 10B.3.

**Figure 10B.3** Surfaces of constant amplitude of the wavefunction  $\psi_-$  of the hydrogen molecule-ion.

### (b) Bonding orbitals

According to the Born interpretation, the probability density of the electron at each point in  $\text{H}_2^+$  is proportional to the square modulus of its wavefunction at that point. The probability density corresponding to the (real) wavefunction  $\psi_+$  in eqn 10B.2 is

$$\psi_+^2 = N^2(A^2 + B^2 + 2AB) \quad \text{Bonding probability density} \quad (10B.3)$$

This probability density is plotted in Fig. 10B.4. An important feature becomes apparent when we examine the internuclear region, where both atomic orbitals have similar amplitudes. According to eqn 10B.3, the total probability density is proportional to the sum of:

- $A^2$ , the probability density if the electron were confined to the atomic orbital  $A$ .
- $B^2$ , the probability density if the electron were confined to the atomic orbital  $B$ .
- $2AB$ , an extra contribution to the density from both atomic orbitals.

Physical interpretation

The last contribution, the **overlap density**, is crucial, because it represents an enhancement of the probability of finding the electron in the internuclear region. The enhancement can be traced to the constructive interference of the two atomic orbitals: each has a positive amplitude in the internuclear region, so the total amplitude is greater there than if the electron were confined to a single atomic orbital.

We shall frequently make use of the observation *bonds form due to a build-up of electron density where atomic orbitals overlap and interfere constructively*. The conventional explanation of this observation is based on the notion that accumulation of electron density between the nuclei puts the electron in a position where it interacts strongly with both nuclei. Hence,

**Figure 10B.4** The electron density calculated by forming the square of the wavefunction used to construct Fig. 10B.3. Note the accumulation of electron density in the internuclear region.

the energy of the molecule is lower than that of the separate atoms, where each electron can interact strongly with only one nucleus. This conventional explanation, however, has been called into question, because shifting an electron away from a nucleus into the internuclear region *raises* its potential energy. The modern (and still controversial) explanation does not emerge from the simple LCAO treatment given here. It seems that, at the same time as the electron shifts into the internuclear region, the atomic orbitals shrink. This orbital shrinkage improves the electron–nucleus attraction more than it is decreased by the migration to the internuclear region, so there is a net lowering of potential energy. The kinetic energy of the electron is also modified because the curvature of the wavefunction is changed, but the change in kinetic energy is dominated by the change in potential energy. Throughout the following discussion we ascribe the strength of chemical bonds to the accumulation of electron density in the internuclear region. We leave open the question whether in molecules more complicated than  $\text{H}_2^+$  the true source of energy lowering is that accumulation itself or some indirect but related effect.

The  $\sigma$  orbital we have described is an example of a **bonding orbital**, an orbital which, if occupied, helps to bind two atoms together. Specifically, we label it  $1\sigma$  as it is the  $\sigma$  orbital of lowest energy. An electron that occupies a  $\sigma$  orbital is called a  **$\sigma$  electron**, and if that is the only electron present in the molecule (as in the ground state of  $\text{H}_2^+$ ), then we report the configuration of the molecule as  $1\sigma^1$ .

The energy  $E_{1\sigma}$  of the  $1\sigma$  orbital is (see Problem 10B.3):

$$E_{1\sigma} = E_{\text{H}1s} + \frac{j_0}{R} - \frac{j+k}{1+S} \quad \text{Energy of bonding orbital} \quad (10B.4)$$

where  $E_{\text{H}1s}$  is the energy of a  $\text{H}1s$  orbital,  $j_0/R$  is the potential energy of repulsion between the two nuclei (remember that  $j_0$  is shorthand for  $e^2/4\pi\epsilon_0$ ), and

$$S = \int AB \, d\tau = \left\{ 1 + \frac{R}{a_0} + \frac{1}{3} \left( \frac{R}{a_0} \right)^2 \right\} e^{-R/a_0} \quad (10B.5a)$$

$$j = j_0 \int \frac{A^2}{r_B} d\tau = \frac{j_0}{R} \left\{ 1 - \left( 1 + \frac{R}{a_0} \right) e^{-2R/a_0} \right\} \quad (10B.5b)$$

$$k = j_0 \int \frac{AB}{r_B} d\tau = \frac{j_0}{a_0} \left( 1 + \frac{R}{a_0} \right) e^{-R/a_0} \quad (10B.5c)$$

To express  $j_0/a_0 = e^2/4\pi\epsilon_0 a_0$  in electronvolts, divide it by  $e$ , and then find

$$\frac{j_0}{ea_0} = \frac{e}{4\pi\epsilon_0 a_0} = \frac{e}{4\pi\epsilon_0} \times \frac{\pi m_e e^2}{\epsilon_0 h^2} = \frac{m_e e^3}{4\epsilon_0^2 h^2} = 27.211\dots V \quad (10B.5d)$$

This value should be recognized as  $2hc\tilde{R}_\infty$ . The integrals are plotted in Fig. 10B.5. We can interpret them as follows:

- All three integrals are positive and decline towards zero at large internuclear separations ( $S$  and  $k$  on account of the exponential term,  $j$  on account of the factor  $1/R$ ). The integral  $S$  is discussed in more detail in Topic 10B.4c.
- The integral  $j$  is a measure of the interaction between a nucleus and electron density centred on the other nucleus.
- The integral  $k$  is a measure of the interaction between a nucleus and the excess electron density in the internuclear region arising from overlap.

Physical interpretation

Figure 10B.5 The integrals (a)  $S$ , (b)  $j$  and  $k$  calculated for  $H_2^+$  as a function of internuclear distance.

### Brief illustration 10B.2 Molecular integrals

It turns out (see next paragraph of text) that the minimum value of  $E_{1\sigma}$  occurs at  $R = 2.45a_0$ . At this separation

$$S = \left\{ 1 + 2.45 + \frac{2.45^2}{3} \right\} e^{-2.45} = 0.47$$

$$j = \frac{j_0/a_0}{2.45} \{ 1 - 3.45e^{-4.90} \} = 0.40 j_0/a_0$$

$$k = \frac{j_0}{a_0} (1 + 2.45)e^{-2.45} = 0.30 j_0/a_0$$

Therefore, from eqn 10B.5d,  $j = 11$  eV and  $k = 8.2$  eV.

**Self-test 10B.3** Evaluate the integrals when the internuclear separation is twice its value at the minimum.

Answer: 0.10, 5.5 eV, 1.2 eV

Figure 10B.6 shows a plot of  $E_{1\sigma}$  against  $R$  relative to the energy of the separated atoms. The energy of the  $1\sigma$  orbital decreases as the internuclear separation decreases from large values because electron density accumulates in the internuclear region as the constructive interference between the atomic orbitals increases (Fig. 10B.7). However, at small separations there is too little space between the nuclei for significant accumulation of electron density there. In addition, the nucleus–nucleus repulsion (which is proportional to  $1/R$ ) becomes large. As a result, the energy of the molecule rises at short distances, and there is a minimum in the potential energy curve. Calculations on  $H_2^+$  give  $R_e = 2.45a_0 = 130$  pm and  $D_e = 1.76$  eV ( $171$  kJ mol $^{-1}$ ); the experimental values are 106 pm and 2.6 eV,

Figure 10B.6 The calculated molecular potential energy curves for a hydrogen molecule-ion showing the variation of the energies of the bonding and antibonding orbitals as the bond length is changed. The alternative notation of the orbitals is explained later.

Figure 10B.7 A representation of the constructive interference that occurs when two  $H1s$  orbitals overlap and form a bonding  $\sigma$  orbital.

**Figure 10B.8** A representation of the destructive interference that occurs when two  $1s$  orbitals overlap and form an antibonding  $2\sigma$  orbital.

so this simple LCAO-MO description of the molecule, while inaccurate, is not absurdly wrong.

### (c) Antibonding orbitals

The linear combination  $\psi_-$  in eqn 10B.2 corresponds to an energy higher than that of  $\psi_+$ . Because it is also a  $\sigma$  orbital we label it  $2\sigma$ . This orbital has an internuclear nodal plane where  $A$  and  $B$  cancel exactly (Figs. 10B.8 and 10B.9). The probability density is

$$\psi_-^2 = N^2(A^2 + B^2 - 2AB) \quad \text{Antibonding probability density} \quad (10B.6)$$

There is a reduction in probability density between the nuclei due to the  $-2AB$  term (Fig. 10B.10); in physical terms, there is destructive interference where the two atomic orbitals overlap. The  $2\sigma$  orbital is an example of an **antibonding orbital**, an orbital that, if occupied, contributes to a reduction in the cohesion between two atoms and helps to raise the energy of the molecule relative to the separated atoms.

The energy  $E_{2\sigma}$  of the  $2\sigma$  antibonding orbital is given by (see Problem 10B.3)

$$E_{2\sigma} = E_{\text{H1s}} + \frac{j_0}{R} - \frac{j-k}{1-S} \quad (10B.7)$$

**Figure 10B.9** (a) The amplitude of the antibonding molecular orbital in a hydrogen molecule-ion in a plane containing the two nuclei and (b) a contour representation of the amplitude. Note the internuclear node.

**Figure 10B.10** The electron density calculated by forming the square of the wavefunction used to construct Fig. 10B.9. Note the reduction of electron density in the internuclear region.

**Figure 10B.11** A partial explanation of the origin of bonding and antibonding effects. (a) In a bonding orbital, the nuclei are attracted to the accumulation of electron density in the internuclear region. (b) In an antibonding orbital, the nuclei are attracted to an accumulation of electron density outside the internuclear region.

where the integrals  $S$ ,  $j$ , and  $k$  are the same as before (eqn 10B.5). The variation of  $E_{2\sigma}$  with  $R$  is shown in Fig. 10B.6, where we see the destabilizing effect of an antibonding electron. The effect is partly due to the fact that an antibonding electron is excluded from the internuclear region and hence is distributed largely outside the bonding region. In effect, whereas a bonding electron pulls two nuclei together, an antibonding electron pulls the nuclei apart (Fig. 10B.11). The illustration also shows another feature that we draw on later:  $|E_- - E_{\text{H1s}}| > |E_+ - E_{\text{H1s}}|$ , which indicates that *the antibonding orbital is more antibonding than the bonding orbital is bonding*. This important conclusion stems in part from the presence of the nucleus–nucleus repulsion ( $j_0/R$ ): this contribution raises the energy of both molecular orbitals. Antibonding orbitals are often labelled with an asterisk (\*), so the  $2\sigma$  orbital could also be denoted  $2\sigma^*$  (and read ‘2 sigma star’).

#### Brief illustration 10B.3 Antibonding energies

At the minimum of the bonding orbital energy we have seen that  $R=2.45$ , and from *Brief illustration 10B.2* we know that  $S=0.60$ ,  $j=11$  eV, and  $k=8.2$  eV. It follows that at that

separation, the energy of the antibonding orbital relative to that of a hydrogen atom 1s orbital is

$$(E_{2\sigma} - E_{\text{H}1s})/eV = \frac{27.2}{2.45} - \frac{11-8.2}{1-0.60} = 4.1$$

That is, the antibonding orbital lies  $(4.1 + 1.76)$  eV = 5.9 eV above the bonding orbital at this internuclear separation.

**Self-test 10B.4** What is the separation at twice that internuclear distance?

Answer: 1.4 Ev

**Figure 10B.12** The parity of an orbital is even (g) if its wavefunction is unchanged under inversion through the centre of symmetry of the molecule, but odd (u) if the wavefunction changes sign. Heteronuclear diatomic molecules do not have a centre of inversion, so for them the g, u classification is irrelevant.

## 10B.2 Orbital notation

For homonuclear diatomic molecules (molecules consisting of two atoms of the same element, such as  $\text{N}_2$ ), it proves helpful to label a molecular orbital according to its **inversion symmetry**, the behaviour of the wavefunction when it is inverted through the centre (more formally, the centre of inversion) of the molecule. Thus, if we consider any point on the bonding  $\sigma$  orbital, and then project it through the centre of the molecule and out an equal distance on the other side, then we arrive at an identical value of the wavefunction (Fig. 10B.12). This so-called **gerade symmetry** (from the German word for ‘even’) is denoted by a subscript g, as in  $\sigma_g$ . The same procedure applied to the antibonding  $2\sigma$  orbital results in the same amplitude but

opposite sign of the wavefunction. This **ungerade symmetry** (‘odd symmetry’) is denoted by a subscript u, as in  $\sigma_u$ .

When using the g,u notation, each set of orbitals of the same inversion symmetry is labelled separately so, whereas  $1\sigma$  becomes  $1\sigma_g$ , its antibonding partner, which so far we have called  $2\sigma$ , is the first orbital of a different symmetry, and is denoted  $1\sigma_u$ . The general rule is that *each set of orbitals of the same symmetry designation is labelled separately*. This point is developed in Topic 10C. The inversion symmetry classification is not applicable to heteronuclear diatomic molecules (diatomic molecules formed by atoms from two different elements, such as CO) because these molecules do not have a centre of inversion.

## Checklist of concepts

- 1. A **molecular orbital** is constructed as a linear combination of atomic orbitals.
- 2. A **bonding orbital** arises from the constructive overlap of neighbouring atomic orbitals.
- 3. An **antibonding orbital** arises from the destructive overlap of neighbouring atomic orbitals.
- 4.  **$\sigma$  Orbitals** have cylindrical symmetry and zero orbital angular momentum around the internuclear axis.
- 5. A molecular orbital in a homonuclear diatomic molecule is labelled ‘gerade’ (g) or ‘ungerade’ (u) according to its behaviour under **inversion symmetry**.

### ► Why do you need to know this material?

Although the hydrogen molecule-ion establishes the basic approach to the construction of molecular orbitals, almost all chemically significant molecules have more than one electron, and we need to see how to construct their electron configurations. Homonuclear diatomic molecules are a good starting point, not only because they are simple to describe but because they include such important species as  $H_2$ ,  $N_2$ ,  $O_2$ , and the dihalogens.

### ► What is the key idea?

Each molecular orbital can accommodate up to two electrons.

### ► What do you need to know already?

You need to be familiar with the discussion of the bonding and antibonding linear combinations of atomic orbitals in Topic 10B and the building-up principle for atoms (Topic 9B).

In Topic 9C the hydrogenic atomic orbitals and the building-up principle are used as a basis for the discussion and prediction of the ground electronic configurations of many-electron atoms. We now do the same for many-electron diatomic molecules by using the  $H_2^+$  molecular orbitals developed in Topic 10B as a basis for their discussion.

## 10C.1 Electron configurations

The starting point of the building-up principle for diatomic molecules is the construction of molecular orbitals by combining the available atomic orbitals. Once they are available, we adopt the following procedure, which is essentially the same as the building-up principle for atoms (Topic 9B):

- The electrons supplied by the atoms are accommodated in the orbitals so as to achieve the lowest overall energy subject to the constraint of the Pauli exclusion principle, that no more than two electrons may occupy a single orbital (and then must be paired).
- If several degenerate molecular orbitals are available, electrons are added singly to each individual orbital before doubly occupying any one orbital (because that minimizes electron–electron repulsions).
- According to Hund’s maximum multiplicity rule (Topic 9B), if two electrons do occupy different degenerate orbitals, then a lower energy is obtained if they do so with parallel spins.

Building-up principle for molecules

### (a) $\sigma$ Orbitals and $\pi$ orbitals

Consider  $H_2$ , the simplest many-electron diatomic molecule. Each H atom contributes a  $1s$  orbital (as in  $H_2^+$ ), so we can form the  $1\sigma_g$  and  $1\sigma_u$  orbitals from them, as explained in Topic 10B. At the experimental internuclear separation these orbitals will have the energies shown in Fig. 10C.1, which is called a **molecular orbital energy level diagram**. Note that from two atomic orbitals we can build two molecular orbitals. In general, from  $N$  atomic orbitals we can build  $N$  molecular orbitals.

There are two electrons to accommodate, and both can enter  $1\sigma_g$  by pairing their spins, as required by the Pauli principle (just as for atoms, Topic 9B). The ground-state configuration is therefore  $1\sigma_g^2$  and the atoms are joined by a bond consisting of an electron pair in a bonding  $\sigma$  orbital. This approach shows that an electron pair, which was the focus of Lewis’s account of chemical bonding, represents the maximum number of electrons that can enter a bonding molecular orbital.

The same argument explains why He does not form diatomic molecules. Each He atom contributes a  $1s$  orbital, so  $1\sigma_g$  and  $1\sigma_u$  molecular orbitals can be constructed. Although these orbitals differ in detail from those in  $H_2$ , their general shapes

**Figure 10C.1** A molecular orbital energy level diagram for orbitals constructed from the overlap of H1s orbitals; the separation of the levels corresponds to that found at the equilibrium bond length. The ground electronic configuration of H<sub>2</sub> is obtained by accommodating the two electrons in the lowest available orbital (the bonding orbital).

are the same and we can use the same qualitative energy level diagram in the discussion. There are four electrons to accommodate. Two can enter the  $1\sigma_g$  orbital, but then it is full, and the next two must enter the  $1\sigma_u$  orbital (Fig. 10C.2). The ground electronic configuration of He<sub>2</sub> is therefore  $1\sigma_g^2 1\sigma_u^2$ . We see that there is one bond and one antibond. Because  $1\sigma_u$  is raised in energy relative to the separate atoms more than  $1\sigma_g$  is lowered, an He<sub>2</sub> molecule has a higher energy than the separated atoms, so it is unstable relative to them.

We shall now see how the concepts we have introduced apply to homonuclear diatomic molecules in general. In elementary treatments, only the orbitals of the valence shell are used to form molecular orbitals so, for molecules formed with atoms from Period 2 elements, only the 2s and 2p atomic orbitals are considered. We shall make that approximation here too.

A general principle of molecular orbital theory is that *all orbitals of the appropriate symmetry* contribute to a molecular orbital. Thus, to build  $\sigma$  orbitals, we form linear combinations of all atomic orbitals that have cylindrical symmetry about the internuclear axis. These orbitals include the 2s orbitals on each atom and the  $2p_z$  orbitals on the two atoms (Fig. 10C.3). The general form of the  $\sigma$  orbitals that may be formed is therefore

$$\Psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} + c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (10C.1)$$

**Figure 10C.2** The ground electronic configuration of the hypothetical four-electron molecule He<sub>2</sub> has two bonding electrons and two antibonding electrons. It has a higher energy than the separated atoms, and so is unstable.

**Figure 10C.3** According to molecular orbital theory,  $\sigma$  orbitals are built from all orbitals that have the appropriate symmetry. In homonuclear diatomic molecules of Period 2, that means that two 2s and two  $2p_z$  orbitals should be used. From these four orbitals, four molecular orbitals can be built.

From these four atomic orbitals we can form four molecular orbitals of  $\sigma$  symmetry by an appropriate choice of the coefficients  $c$ .

The procedure for calculating the coefficients is described in Topic 10D and more fully in Topic 10E. Here we adopt a simpler route, and suppose that, because the 2s and  $2p_z$  orbitals have distinctly different energies, they may be treated separately. That is, the four  $\sigma$  orbitals fall approximately into two sets, one consisting of two molecular orbitals of the form

$$\Psi = c_{A2s}\chi_{A2s} + c_{B2s}\chi_{B2s} \quad (10C.2a)$$

and another consisting of two orbitals of the form

$$\Psi = c_{A2p_z}\chi_{A2p_z} + c_{B2p_z}\chi_{B2p_z} \quad (10C.2b)$$

Because atoms A and B are identical, the energies of their 2s orbitals are the same, so the coefficients are equal (apart from a possible difference in sign); the same is true of the  $2p_z$  orbitals. Therefore, the two sets of orbitals have the form  $\chi_{A2s} \pm \chi_{B2s}$  and  $\chi_{A2p_z} \pm \chi_{B2p_z}$ .

The 2s orbitals on the two atoms overlap to give a bonding and an antibonding  $\sigma$  orbital ( $1\sigma_g$  and  $1\sigma_u$ , respectively) in exactly the same way as we have already seen for 1s orbitals. The two  $2p_z$  orbitals directed along the internuclear axis overlap strongly. They may interfere either constructively or destructively, and give a bonding or antibonding  $\sigma$  orbital (Fig. 10C.4). These two  $\sigma$  orbitals are labelled  $2\sigma_g$  and  $2\sigma_u$ , respectively. In general, note how the numbering follows the order of increasing energy. We number only the molecular orbitals formed from atomic orbitals in the valence shell and ignore any combinations of core atomic orbitals.

**Figure 10C.4** A representation of the composition of bonding and antibonding  $\sigma$  orbitals built from the overlap of p orbitals. These illustrations are schematic.

### Brief illustration 10C.1 Ground-state configurations

The valence configuration of a sodium atom is  $[\text{Ne}]3s^1$ , so 3s and 3p orbitals are used to construct molecular orbitals. At this level of approximation, we consider (3s,3s)- and (3p,3p)-overlap separately. In fact, because there are only two electrons to accommodate (one from each 3s orbital), we need consider only the former. That overlap results in  $1\sigma_g$  and  $1\sigma_u$  molecular orbitals. The only two valence electrons occupy the former, so the ground-state configuration of  $\text{Na}_2$  is  $1\sigma_g^2$ .

**Self-test 10C.1** Identify the ground-state configuration of  $\text{Be}_2$ .

Answer:  $1\sigma_g^2 1\sigma_u^2$  built from  $\text{Be}2s$  orbitals

Now consider the  $2p_x$  and  $2p_y$  orbitals of each atom. These orbitals are perpendicular to the internuclear axis and may overlap broadside-on. This overlap may be constructive or destructive and results in a bonding or an antibonding  $\pi$  orbital (Fig. 10C.5). The notation  $\pi$  is the analogue of p in atoms, for when viewed along the axis of the molecule, a  $\pi$  orbital looks like a p orbital and has one unit of orbital angular momentum around the internuclear axis. The two neighbouring  $2p_x$  orbitals overlap to give a bonding and antibonding  $\pi_x$  orbital, and the two  $2p_y$  orbitals overlap to give two  $\pi_y$  orbitals. The  $\pi_x$  and  $\pi_y$  bonding orbitals are degenerate; so too are their antibonding partners. We also see from Fig. 10C.5 that a bonding  $\pi$  orbital has odd parity (Topic 10B) and is denoted  $\pi_u$  and an antibonding  $\pi$  orbital has even parity, denoted  $\pi_g$ .

### (b) The overlap integral

The extent to which two atomic orbitals on different atoms overlap is measured by the **overlap integral**,  $S$ :

$$S = \int \chi_A^* \chi_B d\tau \quad \text{Definition} \quad \text{Overlap integral} \quad (10C.3)$$

This integral also occurs in Topic 10B (in *Example 10B.1* and eqn 10B.5a). If the atomic orbital  $\chi_A$  on A is small wherever the orbital  $\chi_B$  on B is large, or vice versa, then the product of their amplitudes is everywhere small and the integral—the sum of these products—is small (Fig. 10C.6). If  $\chi_A$  and  $\chi_B$  are

**Figure 10C.5** A schematic representation of the structure of  $\pi$  bonding and antibonding molecular orbitals. The figure also shows that the bonding  $\pi$  orbital has odd parity, whereas the antibonding  $\pi$  orbital has even parity.

both large in some region of space, then  $S$  may be large. If the two normalized atomic orbitals are identical (for instance, 1s orbitals on the same nucleus), then  $S=1$ . In some cases, simple formulas can be given for overlap integrals. For instance, the variation of  $S$  with internuclear separation for hydrogenic 1s orbitals on atoms of atomic number  $Z$  is given by

$$S(1s, 1s) = \left\{ 1 + \frac{ZR}{a_0} + \frac{1}{3} \left( \frac{ZR}{a_0} \right)^2 \right\} e^{-ZR/a_0} \quad \text{(1s,1s)-overlap integral} \quad (10C.4)$$

and is plotted in Fig. 10C.7 (eqn 10C.4 is a generalization of eqn 10B.5a, which is for H1s orbitals).

**Figure 10C.6** (a) When two orbitals are on atoms that are far apart, the wavefunctions are small where they overlap, so  $S$  is small. (b) When the atoms are closer, both orbitals have significant amplitudes where they overlap, and  $S$  may approach 1. Note that  $S$  will decrease again as the two atoms approach more closely than shown here because the region of negative amplitude of the p orbital starts to overlap the positive amplitude of the s orbital. When the centres of the atoms coincide,  $S=0$ .

**Figure 10C.7** The overlap integral,  $S$ , between two H1s orbitals as a function of their separation  $R$ .

### Brief illustration 10C.2 Overlap integrals

Familiarity with the magnitudes of overlap integrals is useful when considering bonding abilities of atoms, and hydrogenic orbitals give an indication of their values. The overlap integral between two hydrogenic 2s orbitals is

$$S(2s, 2s) = \left\{ 1 + \frac{ZR}{2a_0} + \frac{1}{12} \left( \frac{ZR}{a_0} \right)^2 + \frac{1}{240} \left( \frac{ZR}{a_0} \right)^4 \right\} e^{-ZR/2a_0}$$

**Figure 10C.8** The overlap integral,  $S$ , between two hydrogenic  $2s$  orbitals and between two side-by-side  $2p$  orbitals as a function of their separation  $R$ .

This expression is plotted in Fig. 10C.8. For an internuclear distance of  $8a_0/Z$ ,  $S(2s, 2s) = 0.50$ .

**Self-test 10C.2** The side-by-side overlap of two  $2p$  orbitals of atoms of atomic number  $Z$  is

$$S(2p, 2p) = \left\{ 1 + \frac{ZR}{2a_0} + \frac{1}{10} \left( \frac{ZR}{a_0} \right)^2 + \frac{1}{120} \left( \frac{ZR}{a_0} \right)^3 \right\} e^{-ZR/2a_0}$$

Evaluate this overlap integral for  $R = 8a_0/Z$ .

*Answer:* See Fig. 10C.8, 0.29

**Figure 10C.9** A  $p$  orbital in the orientation shown here has zero net overlap ( $S=0$ ) with the  $s$  orbital at all internuclear separations.

Now consider the arrangement in which an  $s$  orbital is superimposed on a  $p_x$  orbital of a different atom (Fig. 10C.9). The integral over the region where the product of orbitals is positive exactly cancels the integral over the region where the product of orbitals is negative, so overall  $S=0$  exactly. Therefore, there is no net overlap between the  $s$  and  $p$  orbitals in this arrangement.

### (c) Period 2 diatomic molecules

To construct the molecular orbital energy level diagram for Period 2 homonuclear diatomic molecules, we form eight molecular orbitals from the eight valence shell orbitals (four from each atom).

**Figure 10C.10** The molecular orbital energy level diagram for homonuclear diatomic molecules. The lines in the middle are an indication of the energies of the molecular orbitals that can be formed by overlap of atomic orbitals. As remarked in the text, this diagram should be used for  $O_2$  (the configuration shown) and  $F_2$ .

bonding than  $\sigma$  orbitals because their maximum overlap occurs off-axis. This relative weakness suggests that the molecular orbital energy level diagram ought to be as shown in Fig. 10C.10. However, we must remember that we have assumed that  $2s$  and  $2p_z$  orbitals contribute to different sets of molecular orbitals whereas in fact all four atomic orbitals have the same symmetry around the internuclear axis and contribute jointly to the four  $\sigma$  orbitals. Hence, there is no guarantee that this order of energies should prevail, and it is found experimentally (by spectroscopy) and by detailed calculation that the order varies along Period 2 (Fig. 10C.11). The order shown in Fig. 10C.12 is appropriate as far as  $N_2$ , and Fig. 10C.10 is appropriate for  $O_2$  and  $F_2$ . The relative order is controlled by the separation of the  $2s$  and  $2p$  orbitals in the atoms, which increases across the group. The consequent switch in order occurs at about  $N_2$ .

With the molecular orbital energy level diagram established, we can deduce the probable ground configurations of the molecules by adding the appropriate number of electrons to the orbitals and following the building-up rules. Anionic species (such as the peroxide ion,  $O_2^{2-}$ ) need more electrons than the

**Figure 10C.11** The variation of the orbital energies of Period 2 homonuclear diatomics

**Figure 10C.12** An alternative molecular orbital energy level diagram for homonuclear diatomic molecules. As remarked in the text, this diagram should be used for diatomics up to and including  $N_2$  (the configuration shown).

parent neutral molecules; cationic species (such as  $O_2^+$ ) need fewer.

Consider  $N_2$ , which has 10 valence electrons. Two electrons pair, occupy, and fill the  $1\sigma_g$  orbital; the next two occupy and fill the  $1\sigma_u$  orbital. Six electrons remain. There are two  $1\pi_u$  orbitals, so four electrons can be accommodated in them. The last two enter the  $2\sigma_g$  orbital. Therefore, the ground-state configuration of  $N_2$  is  $1\sigma_g^2 1\sigma_u^2 1\pi_u^4 2\sigma_g^2$ . It is sometimes helpful to include an asterisk to denote an antibonding orbital, in which case this configuration would be denoted  $1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^2$ .

A measure of the net bonding in a diatomic molecule is its **bond order**,  $b$ :

$$b = \frac{1}{2}(N - N^*) \quad \text{Definition} \quad \text{Bond order} \quad (10C.5)$$

where  $N$  is the number of electrons in bonding orbitals and  $N^*$  is the number of electrons in antibonding orbitals.

### Brief illustration 10C.3 Bond order

Each electron pair in a bonding orbital increases the bond order by 1 and each pair in an antibonding orbital decreases  $b$  by 1. For  $H_2$ ,  $b=1$ , corresponding to a single bond, H–H, between the two atoms. In  $He_2$ ,  $b=0$ , and there is no bond. In  $N_2$ ,  $b = \frac{1}{2}(8 - 2) = 3$ . This bond order accords with the Lewis structure of the molecule ( $:N \equiv N:$ ).

**Self-test 10C.3** Evaluate the bond orders of  $O_2$ ,  $O_2^+$ , and  $O_2^-$ .

Answer: 2,  $\frac{5}{2}$ , 1

The ground-state electron configuration of  $O_2$ , with 12 valence electrons, is based on Fig. 10C.10, and is  $1\sigma_g^2 1\sigma_u^2 2\sigma_g^2 1\pi_u^4 1\pi_g^2$  (or  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*2}$ ). Its bond order is 2. According to the building-up principle, however, the two  $1\pi_g$  electrons occupy different orbitals: one will enter  $1\pi_{g,x}$  and

the other will enter  $1\pi_{g,y}$ . Because the electrons are in different orbitals, they will have parallel spins. Therefore, we can predict that an  $O_2$  molecule will have a net spin angular momentum  $S=1$  and, in the language introduced in Topic 9C, be in a triplet state. As electron spin is the source of a magnetic moment, we can go on to predict that oxygen should be paramagnetic, a substance that tends to move into a magnetic field (see Topic 18C). This prediction, which VB theory does not make, is confirmed by experiment.

An  $F_2$  molecule has two more electrons than an  $O_2$  molecule. Its configuration is therefore  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*4}$  and  $b=1$ . We conclude that  $F_2$  is a singly-bonded molecule, in agreement with its Lewis structure. The hypothetical molecule dineon,  $Ne_2$ , has two additional electrons: its configuration is  $1\sigma_g^2 1\sigma_u^{*2} 2\sigma_g^2 1\pi_u^4 1\pi_g^{*4} 2\sigma_u^{*2}$  and  $b=0$ . The zero bond order is consistent with the monatomic nature of Ne.

The bond order is a useful parameter for discussing the characteristics of bonds, because it correlates with bond length and bond strength. For bonds between atoms of a given pair of elements:

- The greater the bond order, the shorter the bond.
- The greater the bond order, the greater the bond strength.

Physical interpretation

Table 10C.1 lists some typical bond lengths in diatomic and polyatomic molecules. The strength of a bond is measured by its bond dissociation energy,  $D_0$ , the energy required to separate the atoms to infinity or by the well depth  $D_e$ , with  $D_0 = D_e - \frac{1}{2}\hbar\omega$ . Table 10C.2 lists some experimental values of  $D_0$ .

### Example 10C.1 Judging the relative bond strengths of molecules and ions

Predict whether  $N_2^+$  is likely to have a larger or smaller dissociation energy than  $N_2$ .

**Method** Because the molecule with the higher bond order is likely to have the higher dissociation energy, compare their electronic configurations and assess their bond orders.

**Answer** From Fig. 10C.12, the electron configurations and bond orders are

$$N_2 \quad 1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^2 \quad b=3$$

$$N_2^+ \quad 1\sigma_g^2 1\sigma_u^{*2} 1\pi_u^4 2\sigma_g^1 \quad b=2\frac{1}{2}$$

Because the cation has the smaller bond order, we expect it to have the smaller dissociation energy. The experimental dissociation energies are  $945 \text{ kJ mol}^{-1}$  for  $N_2$  and  $842 \text{ kJ mol}^{-1}$  for  $N_2^+$ .

**Self-test 10C.4** Which can be expected to have the higher dissociation energy,  $F_2$  or  $F_2^+$ ?

Answer:  $F_2^+$

## 10C.2 Photoelectron spectroscopy

So far we have treated molecular orbitals as purely theoretical constructs, but is there experimental evidence for their existence? **Photoelectron spectroscopy** (PES) measures the ionization energies of molecules when electrons are ejected from different orbitals by absorption of a photon of known energy, and uses the information to infer the energies of molecular orbitals. The technique is also used to study solids, and in Topic 22A we see the important information that it gives about species at or on surfaces.

Because energy is conserved when a photon ionizes a sample, the sum of the ionization energy,  $I$ , of the sample and the kinetic energy of the photoelectron, the ejected electron, must be equal to the energy of the incident photon  $h\nu$  (Fig. 10C.13):

$$h\nu = \frac{1}{2}m_e v^2 + I \quad (10C.6)$$

This equation (which is like the one used for the photoelectric effect, eqn 7A.13 of Topic 7A,  $E_k = \frac{1}{2}m_e v^2 = h\nu - \Phi$ , written as  $h\nu = \frac{1}{2}m_e v^2 + \Phi$ ) can be refined in two ways. First, photoelectrons may originate from one of a number of different orbitals, and each one has a different ionization energy. Hence, a series of different kinetic energies of the photoelectrons will be obtained, each one satisfying  $h\nu = \frac{1}{2}m_e v^2 + I_i$ , where  $I_i$  is the ionization energy for ejection of an electron from an orbital  $i$ . Therefore, by measuring the kinetic energies of the

Figure 10C.13 An incoming photon carries an energy  $h\nu$ ; an energy  $I_i$  is needed to remove an electron from an orbital  $i$ , and the difference appears as the kinetic energy of the electron.

photoelectrons, and knowing the frequency  $\nu$ , these ionization energies can be determined. Photoelectron spectra are interpreted in terms of an approximation called **Koopmans' theorem**, which states that the ionization energy  $I_i$  is equal to the orbital energy of the ejected electron (formally:  $I_i = -\epsilon_i$ ). That is, we can identify the ionization energy with the energy of the orbital from which it is ejected. The theorem is only an approximation because it ignores the fact that the remaining electrons adjust their distributions when ionization occurs.

The ionization energies of molecules are several electronvolts even for valence electrons, so it is essential to work in at least the ultraviolet region of the spectrum and with wavelengths of less than about 200 nm. Much work has been done with radiation generated by a discharge through helium: the He(I) line ( $1s^1 2p^1 \rightarrow 1s^2$ ) lies at 58.43 nm, corresponding to a photon energy of 21.22 eV. Its use gives rise to the technique of **ultraviolet photoelectron spectroscopy** (UPS). When core electrons are being studied, photons of even higher energy are needed to expel them: X-rays are used, and the technique is denoted XPS.

The kinetic energies of the photoelectrons are measured using an electrostatic deflector that produces different deflections in the paths of the photoelectrons as they pass between charged

Figure 10C.14 A photoelectron spectrometer consists of a source of ionizing radiation (such as a helium discharge lamp for UPS and an X-ray source for XPS), an electrostatic analyser, and an electron detector. The deflection of the electron path caused by the analyser depends on the speed of the electrons.

plates (Fig. 10C.14). As the field strength is increased, electrons of different speeds, and therefore kinetic energies, reach the detector. The electron flux can be recorded and plotted against kinetic energy to obtain the photoelectron spectrum.

#### Brief illustration 10C.4 A photoelectron spectrum

Photoelectrons ejected from  $\text{N}_2$  with He(I) radiation have kinetic energies of 5.63 eV (1 eV = 8065.5  $\text{cm}^{-1}$ , Fig. 10C.15). Helium(I) radiation of wavelength 58.43 nm has wavenumber  $1.711 \times 10^5 \text{ cm}^{-1}$  and therefore corresponds to an energy of 21.22 eV. Then, from eqn 10C.6 with  $I_i$  in place of  $I$ ,  $21.22 \text{ eV} = 5.63 \text{ eV} + I_i$ , so  $I_i = 15.59 \text{ eV}$ . This ionization energy is the energy needed to remove an electron from the occupied molecular orbital with the highest energy of the  $\text{N}_2$  molecule, the  $2\sigma_g$  bonding orbital.

Figure 10C.15 The photoelectron spectrum of  $\text{N}_2$ .

**Self-test 10C.5** Under the same circumstances, photoelectrons are also detected at 4.53 eV. To what ionization energy does that correspond? Suggest an origin.

Answer: 16.7 eV,  $1\pi_u$

It is often observed that photoejection results in cations that are excited vibrationally. Because different energies are needed to excite different vibrational states of the ion, the photoelectrons appear with different kinetic energies. The result is **vibrational fine structure**, a progression of lines with a frequency spacing that corresponds to the vibrational frequency of the molecule. Figure 10C.16 shows an example of vibrational fine structure in the photoelectron spectrum of HBr.

Figure 10C.16 The photoelectron spectrum of HBr.

## Checklist of concepts

1. Electrons are added to available molecular orbitals in a manner that achieves the lowest total energy.
2. As a first approximation,  $\sigma$  orbitals are constructed separately from valence s and p orbitals.
3. An **overlap integral** is a measure of the extent of orbital overlap.
4. The greater the **bond order** of a molecule, the shorter and stronger is the bond.
5. **Photoelectron spectroscopy** is a technique for determining the energies of electrons in molecular orbitals.

## Checklist of equations

Property	Equation	Comment	Equation number
Overlap integral	$S = \int \chi_A \chi_B d\tau$	Integration over all space	10C.3
Bond order	$b = \frac{1}{2}(N - N^*)$	$N$ and $N^*$ are the numbers of electrons in bonding and antibonding orbitals, respectively	10C.5
Photoelectron spectroscopy	$h\nu = \frac{1}{2}m_e v^2 + I$	Interpret $I$ as $I_i$ , the ionization energy from orbital $i$ .	10C.6

### ► Why do you need to know this material?

Most molecules are heteronuclear, so you need to appreciate the differences in their electronic structure from homonuclear species, and how to treat those differences quantitatively.

### ► What is the key idea?

The bonding molecular orbital of a heteronuclear diatomic molecule is composed mostly of the atomic orbital of the more electronegative atom; the opposite is true of the antibonding orbital.

### ► What do you need to know already?

You need to know about the molecular orbitals of homonuclear diatomic molecules (Topic 10C) and the concepts of normalization and orthogonality (Topic 7C). This Topic makes use of determinants (*The chemist's toolkit* 9B.1) and the rules of differentiation (*Mathematical background* 1).

The electron distribution in a covalent bond in a heteronuclear diatomic molecule is not shared equally by the atoms because it is energetically favourable for the electron pair to be found closer to one atom than to the other. This imbalance

results in a **polar bond**, a covalent bond in which the electron pair is shared unequally by the two atoms. The bond in HF, for instance, is polar, with the electron pair closer to the F atom. The accumulation of the electron pair near the F atom results in that atom having a net negative charge, which is called a **partial negative charge** and denoted  $\delta^-$ . There is a matching **partial positive charge**,  $\delta^+$ , on the H atom (Fig. 10D.1).

## 10D.1 Polar bonds

The description of polar bonds in terms of molecular orbital theory is a straightforward extension of that for homonuclear diatomic molecules (Topic 10C), the principal difference being that the atomic orbitals on the two atoms have different energies and spatial extensions.

### (a) The molecular orbital formulation

A polar bond consists of two electrons in a bonding molecular orbital of the form

$$\psi = c_A A + c_B B \quad \text{Wavefunction of a polar bond} \quad (10D.1)$$

with unequal coefficients. The proportion of the atomic orbital  $A$  in the bond is  $|c_A|^2$  and that of  $B$  is  $|c_B|^2$ . A nonpolar bond has  $|c_A|^2 = |c_B|^2$  and a pure ionic bond has one coefficient zero (so the species  $A^+B^-$  would have  $c_A = 0$  and  $c_B = 1$ ). The atomic orbital with the lower energy makes the larger contribution

**Figure 10D.1** The electron density of the molecule HF, computed with one of the methods described in Topic 10E. Different colours show the distribution of electrostatic potential and hence net charge, with blue representing the region with largest partial positive charge, and red the region with largest partial negative charge.

Figure 10D.2 The procedure for estimating the energy of an atomic orbital in a molecule.

to the bonding molecular orbital. The opposite is true of the antibonding orbital, for which the dominant component comes from the atomic orbital with higher energy.

Deciding what values to use for the energies of the atomic orbitals in eqn 10D.1 presents a dilemma because they are known only after a complicated calculation of the kind described in Topic 10E has been performed. An alternative, one that gives some insight into the origin of the energies, is to estimate them from ionization energies and electron affinities. Thus, the extreme cases of an atom X in a molecule are  $X^+$  if it has lost control of the electron it supplied, X if it is sharing the electron pair equally with its bonded partner, and  $X^-$  if it has gained control of both electrons in the bond. If  $X^+$  is taken as defining the energy 0, then X lies at  $-I(X)$  and  $X^-$  lies at  $-I(X) + E_{ea}(X)$ , where  $I$  is the ionization energy and  $E_{ea}$  the electron affinity (Fig. 10D.2). The actual energy of the orbital lies at an intermediate value, and in the absence of further information, we shall estimate it as half-way down to the lowest of these values, namely  $-\frac{1}{2}\{I(X) + E_{ea}(X)\}$ . Then, to establish the MO composition and energies, we form linear combinations of atomic orbitals with these values of the energy and anticipate that the atom with the more negative value of  $-\frac{1}{2}\{I(X) + E_{ea}(X)\}$  contributes the greater amount to the bonding orbital. As we shall see shortly, the quantity  $\frac{1}{2}\{I(X) + E_{ea}(X)\}$  also has a further significance.

#### Brief illustration 10D.1 Heteronuclear diatomic molecules 1

These points can be illustrated by considering HF. The general form of the molecular orbital is  $\psi = c_H\chi_H + c_F\chi_F$ , where  $\chi_H$  is an H1s orbital and  $\chi_F$  is an F2p<sub>z</sub> orbital (with  $z$  along the internuclear axis, the convention for linear molecules). The relevant data are as follows:

	$I/\text{eV}$	$E_{ea}/\text{eV}$	$\frac{1}{2}\{I + E_{ea}\}/\text{eV}$
H	13.6	0.75	7.2
F	17.4	3.34	10.4

We see that the electron distribution in HF is likely to be predominantly on the F atom. We take the calculation further below (in *Brief illustrations* 10D.3 and 10D.4).

**Self-test 10D.1** Which atomic orbital, H1s or N2p<sub>z</sub>, makes the dominant contribution to the bonding  $\sigma$  orbital in the HN molecular radical? For data, see Tables 9B.2 and 9B.3.

Answer: N2p<sub>z</sub>

### (b) Electronegativity

The charge distribution in bonds is commonly discussed in terms of the **electronegativity**,  $\chi$  (chi), of the elements involved (there should be little danger of confusing this use of  $\chi$  with its use to denote an atomic orbital, which is another common convention). The electronegativity is a parameter introduced by Linus Pauling as a measure of the power of an atom to attract electrons to itself when it is part of a compound. Pauling used valence-bond arguments to suggest that an appropriate numerical scale of electronegativities could be defined in terms of bond dissociation energies,  $D_0$ , and proposed that the difference in electronegativities could be expressed as

$$|\chi_A - \chi_B| = \{D_0(AB) - \frac{1}{2}[D_0(AA) + D_0(BB)]\}^{1/2}$$

*Definition* Pauling electronegativity (10D.2)

where  $D_0(AA)$  and  $D_0(BB)$  are the dissociation energies of A–A and B–B bonds and  $D_0(AB)$  is the dissociation energy of an A–B bond, all in electronvolts. (In later work Pauling used the geometrical mean of dissociation energies in place of the arithmetic mean.) This expression gives differences of electronegativities; to establish an absolute scale Pauling chose individual values that gave the best match to the values obtained from eqn 10D.2. Electronegativities based on this definition are called **Pauling electronegativities** (Table 10D.1). The most electronegative elements are those close to F (excluding the noble gases); the least are those close to Cs. It is found that the greater the difference in electronegativities, the greater the polar character of the bond. The difference for HF, for instance, is 1.78; a C–H bond, which is commonly regarded as almost nonpolar, has an electronegativity difference of 0.51.

Table 10D.1\* Pauling electronegativities

Element	$\chi_P$
H	2.2
C	2.6
N	3.0
O	3.4
F	4.0
Cl	3.2
Cs	0.79

\* More values will be found in the *Resource section*.

**Brief illustration 10D.2** Electronegativity

The bond dissociation energies of hydrogen, chlorine, and hydrogen chloride are 4.52 eV, 2.51 eV, and 4.47 eV, respectively. From eqn 10D.2 we find

$$|\chi_{\text{Pauling}}(\text{H}) - \chi_{\text{Pauling}}(\text{Cl})| = \{4.47 - \frac{1}{2}(4.52 + 2.51)\}^{1/2} = 0.98 \approx 1.0$$

**Self-test 10D.2** Repeat the analysis for HBr. Use data from Table 10D.1.

Answer:  $|\chi_{\text{Pauling}}(\text{H}) - \chi_{\text{Pauling}}(\text{Br})| = 0.73$

The spectroscopist Robert Mulliken proposed an alternative definition of electronegativity. He argued that an element is likely to be highly electronegative if it has a high ionization energy (so it will not release electrons readily) and a high electron affinity (so it is energetically favourable to acquire electrons). The **Mulliken electronegativity scale** is therefore based on the definition

$$\chi = \frac{1}{2}(I + E_{\text{ea}}) \quad \text{Definition} \quad \text{Mulliken electronegativity} \quad (10D.3)$$

where  $I$  is the ionization energy of the element and  $E_{\text{ea}}$  is its electron affinity (both in electronvolts). It will be recognized that this combination of energies is precisely the one we have used to estimate the energy of an atomic orbital in a molecule, and can therefore see that the greater the value of the Mulliken electronegativity the greater is the contribution of that atom to the electron distribution in the bond. There is one word of caution: the values of  $I$  and  $E_{\text{ea}}$  in eqn 10D.3 are strictly those for a special 'valence state' of the atom, not a true spectroscopic state. We ignore that complication here. The Mulliken and Pauling scales are approximately in line with each other. A reasonably reliable conversion relation between the two is

$$\chi_{\text{Pauling}} = 1.35 \chi_{\text{Mulliken}}^{1/2} - 1.37 \quad (10D.4)$$

## 10D.2 The variation principle

A more systematic way of discussing bond polarity and finding the coefficients in the linear combinations used to build molecular orbitals is provided by the **variation principle** which is proved in the following *Justification*:

If an arbitrary wavefunction is used to calculate the energy, the value calculated is never less than the true energy.

Variation principle

This principle is the basis of all modern molecular structure calculations. The arbitrary wavefunction is called the **trial wavefunction**. The principle implies that, if we vary the coefficients in the trial wavefunction until the lowest energy is

achieved (by evaluating the expectation value of the hamiltonian for each wavefunction), then those coefficients will be the best for that particular form of trial function. We might get a lower energy if we use a more complicated wavefunction (for example, by taking a linear combination of several atomic orbitals on each atom), but we shall have the optimum (minimum energy) molecular orbital that can be built from the chosen **basis set**, the given set of atomic orbitals.

### Justification 10D.1 The variation principle

To justify the variation principle, consider a trial (normalized) wavefunction written as a linear combination  $\psi_{\text{trial}} = \sum_n c_n \psi_n$  of the true (but unknown), normalized, and orthogonal eigenfunctions of the hamiltonian,  $\hat{H}$ . The energy associated with this trial function is the expectation value

$$E = \int \psi_{\text{trial}}^* \hat{H} \psi_{\text{trial}} \, d\tau$$

The true lowest energy of the system is  $E_0$ , the eigenvalue corresponding to  $\psi_0$ . Consider the following difference:

$$\begin{aligned} E - E_0 &= \int \psi_{\text{trial}}^* \hat{H} \psi_{\text{trial}} \, d\tau - E_0 \int \psi_{\text{trial}}^* \psi_{\text{trial}} \, d\tau \\ &= \int \psi_{\text{trial}}^* \hat{H} \psi_{\text{trial}} \, d\tau - \int \psi_{\text{trial}}^* E_0 \psi_{\text{trial}} \, d\tau \\ &= \int \psi_{\text{trial}}^* (\hat{H} - E_0) \psi_{\text{trial}} \, d\tau \\ &= \int \left( \sum_n c_n^* \psi_n^* \right) (\hat{H} - E_0) \left( \sum_{n'} c_{n'} \psi_{n'} \right) \, d\tau \\ &= \sum_{n,n'} c_n^* c_{n'} \int \psi_n^* (\hat{H} - E_0) \psi_{n'} \, d\tau \end{aligned}$$

Because  $\int \psi_n^* \hat{H} \psi_{n'} \, d\tau = E_{n'} \int \psi_n^* \psi_{n'} \, d\tau$  and  $\int \psi_n^* E_0 \psi_{n'} \, d\tau = E_0 \int \psi_n^* \psi_{n'} \, d\tau$ , we write

$$\int \psi_n^* (\hat{H} - E_0) \psi_{n'} \, d\tau = (E_{n'} - E_0) \int \psi_n^* \psi_{n'} \, d\tau$$

and

$$E - E_0 = \sum_{n,n'} c_n^* c_{n'} (E_{n'} - E_0) \int \psi_n^* \psi_{n'} \, d\tau$$

The eigenfunctions are orthogonal, so only  $n' = n$  contributes to this sum, and as each eigenfunction is normalized, each surviving integral is 1. Consequently

$$E - E_0 = \sum_n \overbrace{c_n^* c_n}^{\geq 0} \overbrace{(E_n - E_0)}^{\geq 0} \geq 0$$

That is,  $E \geq E_0$ , as we set out to prove.

**(a) The procedure**

The method can be illustrated by the trial wavefunction in eqn 10D.1. We show in the following *Justification* that the coefficients are given by the solutions of the two **secular equations**<sup>1</sup>

$$(\alpha_A - E)c_A + (\beta - ES)c_B = 0 \quad (10D.5a)$$

$$(\beta - ES)c_A + (\alpha_A - E)c_B = 0 \quad (10D.5b)$$

where

$$\alpha_A = \int A\hat{H}A d\tau \quad \alpha_B = \int B\hat{H}B d\tau \quad \text{Coulomb integrals} \quad (10D.5c)$$

$$\beta = \int A\hat{H}B d\tau = \int B\hat{H}A d\tau \quad \text{Resonance integral} \quad (10D.5d)$$

The parameter  $\alpha$  is called a **Coulomb integral**. It is negative and can be interpreted as the energy of the electron when it occupies A (for  $\alpha_A$ ) or B (for  $\alpha_B$ ). In a homonuclear diatomic molecule,  $\alpha_A = \alpha_B$ . The parameter  $\beta$  is called a **resonance integral** (for classical reasons). It vanishes when the orbitals do not overlap, and at equilibrium bond lengths it is normally negative.

**Justification 10D.2** The variation principle applied to a heteronuclear diatomic molecule

The trial wavefunction in eqn 10D.1 is real but not normalized because at this stage the coefficients can take arbitrary values. Therefore, we can write  $\psi^* = \psi$  but do not assume that  $\int \psi^2 d\tau = 1$ . When a wavefunction is not normalized, we write the expression for the energy as

$$E = \frac{\int \psi^* \hat{H} \psi d\tau}{\int \psi^* \psi d\tau} \xrightarrow{\psi \text{ real}} \frac{\int \psi \hat{H} \psi d\tau}{\int \psi^2 d\tau} \quad \text{Energy} \quad (10D.6)$$

We now search for values of the coefficients in the trial function that minimize the value of  $E$ . This is a standard problem in calculus, and is solved by finding the coefficients for which

$$\frac{\partial E}{\partial c_A} = 0 \quad \frac{\partial E}{\partial c_B} = 0$$

The first step is to express the two integrals in eqn 10D.6 in terms of the coefficients. The denominator is

$$\begin{aligned} \int \psi^2 d\tau &= \int (c_A A + c_B B)^2 d\tau \\ &= c_A^2 \int A^2 d\tau + c_B^2 \int B^2 d\tau + 2c_A c_B \int AB d\tau = c_A^2 + c_B^2 + 2c_A c_B S \end{aligned}$$

<sup>1</sup> The name 'secular' is derived from the Latin word for age or generation. The term comes from astronomy, where the same equations appear in connection with slowly accumulating modifications of planetary orbits.

because the individual atomic orbitals are normalized and the third integral is the overlap integral  $S$  (eqn 10C.3,  $S = \int \chi_A \chi_B d\tau$ ). The numerator is

$$\begin{aligned} \int \psi \hat{H} \psi d\tau &= \int (c_A A + c_B B) \hat{H} (c_A A + c_B B) d\tau \\ &= c_A^2 \int A \hat{H} A d\tau + c_B^2 \int B \hat{H} B d\tau + c_A c_B \int A \hat{H} B d\tau + c_A c_B \int B \hat{H} A d\tau \end{aligned}$$

With the integrals written as shown (the two  $\beta$  integrals are equal by hermiticity, Topic 7C), the numerator is

$$\int \psi \hat{H} \psi d\tau = c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta$$

At this point we can write the complete expression for  $E$  as

$$E = \frac{c_A^2 \alpha_A + c_B^2 \alpha_B + 2c_A c_B \beta}{c_A^2 + c_B^2 + 2c_A c_B S}$$

Its minimum is found by differentiation with respect to the two coefficients and setting the results equal to 0. After some straightforward work we obtain

$$\begin{aligned} \frac{\partial E}{\partial c_A} &= \frac{2\{(\alpha_A - E)c_A + (\beta - SE)c_B\}}{c_A^2 + c_B^2 + 2c_A c_B S} \\ \frac{\partial E}{\partial c_B} &= \frac{2\{(\alpha_B - E)c_B + (\beta - SE)c_A\}}{c_A^2 + c_B^2 + 2c_A c_B S} \end{aligned}$$

For the derivatives to be equal to 0, the numerators, and specifically the terms in blue, of these expressions must vanish. That is, we must find values of  $c_A$  and  $c_B$  that satisfy the conditions

$$\begin{aligned} (\alpha_A - E)c_A + (\beta - SE)c_B &= 0 \\ (\alpha_B - E)c_B + (\beta - SE)c_A &= 0 \end{aligned}$$

which are the secular equations (eqn 10D.5).

To solve the secular equations for the coefficients we need to know the energy  $E$  of the orbital. As for any set of simultaneous equations, the secular equations have a solution if the **secular determinant**, the determinant of the coefficients, is zero; that is, if

$$\begin{aligned} \begin{vmatrix} \alpha_A - E & \beta - SE \\ \beta - SE & \alpha_B - E \end{vmatrix} &= (\alpha_A - E)(\alpha_B - E) - (\beta - SE)^2 \\ &= (1 - S^2)E^2 + \{2\beta S - (\alpha_A + \alpha_B)\}E + (\alpha_A \alpha_B - \beta^2) \\ &= 0 \end{aligned} \quad (10D.7)$$

Because a quadratic equation of the form  $ax^2 + bx + c = 0$  has the solutions

$$x = \frac{-b \pm (b^2 - 4ac)^{1/2}}{2a}$$

this quadratic equation for  $E$  with  $a=1-S^2$ ,  $b=2\beta S-(\alpha_A+\alpha_B)$ , and  $c=\alpha_A\alpha_B-\beta^2$  has the solutions

$$E_{\pm} = \frac{\alpha_A + \alpha_B - 2\beta S \pm \{( \alpha_A + \alpha_B - 2\beta S )^2 - 4(1-S^2)(\alpha_A\alpha_B - \beta^2)\}^{1/2}}{2(1-S^2)} \quad (10D.8a)$$

which are the energies of the bonding and antibonding molecular orbitals formed from the two atomic orbitals.

Equation 10D.8a becomes easier to understand in two cases. For a *homonuclear diatomic molecule* we can set  $\alpha_A = \alpha_B = \alpha$  and obtain

$$E_{\pm} = \frac{2\alpha - 2\beta S \pm \left\{ \overbrace{(2\alpha - 2\beta S)^2 - 4(1-S^2)(\alpha^2 - \beta^2)}^{(2\beta - 2\alpha S)^2} \right\}^{1/2}}{2(1-S^2)}$$

$$= \frac{\alpha - \beta S \pm (\beta - \alpha S)}{(1+S)(1-S)} = \frac{(\alpha \pm \beta)(1 \mp S)}{(1+S)(1-S)}$$

and therefore

$$E_+ = \frac{\alpha_A + \beta}{1+S} \quad E_- = \frac{\alpha_A - \beta}{1-S} \quad \begin{array}{l} \text{Homo-} \\ \text{nuclear} \\ \text{diatomic} \\ \text{molecules} \end{array} \quad \begin{array}{l} \text{Molecular} \\ \text{orbital} \\ \text{energies} \end{array} \quad (10D.8b)$$

For  $\beta < 0$ ,  $E_+$  is the lower energy solution. For *heteronuclear diatomic molecules* we can make the approximation that  $S=0$  (simply to get a more transparent expression), and find

$$E_{\pm} = \frac{1}{2}(\alpha_A + \alpha_B) \pm \frac{1}{2}(\alpha_A - \alpha_B) \left\{ 1 + \left( \frac{2\beta}{\alpha_A - \alpha_B} \right)^2 \right\}^{1/2}$$

Zero overlap approximation (10D.8c)

### Brief illustration 10D.3 Heteronuclear diatomic molecules 2

In *Brief illustration 10D.1* we estimated the H1s and F2p orbital energies in HF as  $-7.2$  eV and  $-10.4$  eV, respectively. Therefore we set  $\alpha_H = -7.2$  eV and  $\alpha_F = -10.4$  eV. We take  $\beta = -1.0$  eV as a typical value and  $S=0$ . Substitution of these values into eqn 10D.8c gives

$$E_{\pm}/\text{eV} = \frac{1}{2}(-7.2 - 10.4) \pm \frac{1}{2}(-7.2 + 10.4) \left\{ 1 + \left( \frac{-2.0}{-7.2 + 10.4} \right)^2 \right\}^{1/2}$$

$$= -8.8 \pm 1.9 = -10.7 \text{ and } -6.9$$

These values, representing a bonding orbital at  $-10.7$  eV and an antibonding orbital at  $-6.9$  eV, are shown in Fig. 10D.3.

Figure 10D.3 The estimated energies of the atomic orbitals in HF and the molecular orbitals they form.

**Self-test 10D.3** Does the neglect of overlap make much difference? Use  $S=0.20$  (a typical value), to find the two energies.

Answer:  $E_+ = -10.8$  eV,  $E_- = -7.1$  eV

### (b) The features of the solutions

An important feature of eqn 10D.8c is that as the energy difference  $|\alpha_A - \alpha_B|$  between the interacting atomic orbitals increases, the bonding and antibonding effects decrease (Fig. 10D.4). Thus, when  $|\alpha_B - \alpha_A| \gg 2|\beta|$  we can make the approximation  $(1+x)^{1/2} \approx 1 + \frac{1}{2}x$  and obtain

$$E_+ \approx \alpha_A + \frac{\beta^2}{\alpha_A - \alpha_B} \quad E_- \approx \alpha_B - \frac{\beta^2}{\alpha_A - \alpha_B} \quad (10D.9)$$

As these expressions show, and as can be seen from the graph, when the energy difference is very large, the energies of the resulting molecular orbitals differ only slightly from those of the atomic orbitals, which implies in turn that the bonding and antibonding effects are small. That is:

Figure 10D.4 The variation of the energies of the molecular orbitals as the energy difference of the contributing atomic orbitals is changed. The plots are for  $\beta = -1$ ; the blue lines are for the energies in the absence of mixing (that is,  $\beta = 0$ ).

The strongest bonding and antibonding effects are obtained when the two contributing orbitals have similar energies.

Orbital contribution criterion

The large difference in energy between core and valence orbitals is the justification for neglecting the contribution of core orbitals to molecular orbitals constructed from valence atomic orbitals. Although the core orbitals of one atom have a similar energy to the core orbitals of the other atom, so might be expected to combine strongly, core–core interaction is largely negligible because the overlap between them (and hence the value of  $\beta$ ) is so small.

The values of the coefficients in the linear combination in eqn 10D.1 are obtained by solving the secular equations using the two energies obtained from the secular determinant. The lower energy,  $E_+$ , gives the coefficients for the bonding molecular orbital, the upper energy,  $E_-$ , the coefficients for the antibonding molecular orbital. The secular equations give expressions for the ratio of the coefficients. Thus, the first of the two secular equations in eqn 10D.5a,  $(\alpha_A - E)c_A + (\beta - ES)c_B = 0$ , gives

$$c_B = -\left(\frac{\alpha_A - E}{\beta - ES}\right)c_A \quad (10D.10)$$

The wavefunction should also be normalized. This condition means that the term  $c_A^2 + c_B^2 + 2c_Ac_BS$  established in the preceding *Justification* must satisfy

$$c_A^2 + c_B^2 + 2c_Ac_BS = 1 \quad (10D.11)$$

When the preceding relation is substituted into this expression, we find

$$c_A = \frac{1}{\left\{1 + \left(\frac{\alpha_A - E}{\beta - ES}\right)^2 - 2S\left(\frac{\alpha_A - E}{\beta - ES}\right)\right\}^{1/2}} \quad (10D.12)$$

which, together with eqn 10D.10, gives explicit expressions for the coefficients once we substitute the appropriate values of  $E = E_{\pm}$  given in eqn 10D.8a.

As before, this expression becomes more transparent in two cases. First, for a homonuclear diatomic molecule, with  $\alpha_A = \alpha_B = \alpha$  and  $E_{\pm}$  given in eqn 10D.8b we find

$$E_+ = \frac{\alpha + \beta}{1 + S}, \quad c_A = \frac{1}{\{2(1 + S)\}^{1/2}}, \quad c_B = c_A \quad \text{Homonuclear} \quad (10D.13a)$$

$$E_- = \frac{\alpha - \beta}{1 - S}, \quad c_A = \frac{1}{\{2(1 - S)\}^{1/2}}, \quad c_B = -c_A \quad \text{diatomic molecules} \quad (10D.13b)$$

For a heteronuclear diatomic molecule with  $S = 0$ , the coefficients are given by

$$c_A = \frac{1}{\left\{1 + \left(\frac{\alpha_A - E}{\beta}\right)^2\right\}^{1/2}}, \quad c_B = \frac{1}{\left\{1 + \left(\frac{\beta}{\alpha_A - E}\right)^2\right\}^{1/2}} \quad \text{Zero overlap approximation} \quad (10D.14)$$

with the appropriate values of  $E = E_{\pm}$  taken from eqn 10D.8c.

#### Brief illustration 10D.4 Heteronuclear diatomic molecules 3

Here we continue the previous *Brief illustration* using HF. With  $\alpha_H = -7.2$  eV,  $\alpha_F = -10.4$  eV,  $\beta = -1.0$  eV, and  $S = 0$  the two orbital energies were found to be  $E_+ = -10.7$  eV and  $E_- = -6.9$  eV. When these values are substituted into eqn 10D.14 we find the following coefficients:

$$\begin{aligned} E_+ = -10.7 \text{ eV} & \quad \psi_+ = 0.28\chi_H + 0.96\chi_F \\ E_- = -6.9 \text{ eV} & \quad \psi_- = 0.96\chi_H - 0.28\chi_F \end{aligned}$$

Notice how the lower energy orbital (the one with energy  $-10.7$  eV) has a composition that is more F2p orbital than H1s, and that the opposite is true of the higher energy, antibonding orbital.

**Self-test 10D.4** Find the energies and forms of the  $\sigma$  orbitals in the HCl molecule using  $\beta = -1.0$  eV and  $S = 0$ . Use data from Tables 9C.2 and 9C.3.

$$\text{Answer: } E_+ = -8.9 \text{ eV}, E_- = -6.6 \text{ eV}; \psi_- = 0.86\chi_H - 0.51\chi_{Cl}; \psi_+ = 0.51\chi_H + 0.86\chi_{Cl}$$

## Checklist of concepts

- 1. A **polar bond** can be regarded as arising from a molecular orbital that is concentrated more on one atom than its partner.
- 2. The **electronegativity** of an element is a measure of the power of an atom to attract electrons to itself when it is part of a compound.

- 3. The **variation principle** provides a criterion of acceptability of an approximate wavefunction.
- 4. A **basis set** refers to the given set of atomic orbitals from which the molecular orbitals are constructed.
- 5. The bonding and antibonding effects are strongest when contributing atomic orbitals have similar energies.

## Checklist of equations

### ► Why do you need to know this material?

Most molecules of interest in chemistry are polyatomic, so it is important to be able to discuss their electronic structure. Although computational procedures are now widely available, to understand them it is helpful to see how they emerged from the more primitive approach described here.

### ► What is the key idea?

Molecular orbitals can be expressed as linear combinations of all the atomic orbitals of the appropriate symmetry.

### ► What do you need to know already?

This Topic extends the approach used for heteronuclear diatomic molecules in Topic 10D, particularly the concepts of secular determinants and secular equations. The principal mathematical technique used is matrix algebra (*Mathematical background 6*); you should be, or become, familiar with the use of mathematical software to manipulate matrices numerically.

The molecular orbitals of polyatomic molecules are built in the same way as in diatomic molecules (Topic 10D), the only difference being that more atomic orbitals are used to construct them. As for diatomic molecules, polyatomic molecular orbitals spread over the entire molecule. A molecular orbital has the general form

$$\psi = \sum_o c_o \chi_o \quad \text{General form of LCAO} \quad (10E.1)$$

where  $\chi_o$  is an atomic orbital and the sum extends over all the valence orbitals of all the atoms in the molecule. To find the coefficients, we set up the secular equations and the secular determinant, just as for diatomic molecules, solve the latter for the energies, and then use these energies in the secular equations to find the coefficients of the atomic orbitals for each molecular orbital.

The principal difference between diatomic and polyatomic molecules lies in the greater range of shapes that are possible: a diatomic molecule is necessarily linear, but a triatomic molecule, for instance, may be either linear or angular (bent) with a characteristic bond angle. The shape of a polyatomic molecule—the specification of its bond lengths and its bond angles—can be predicted by calculating the total energy of the molecule for a variety of nuclear positions, and then identifying the conformation that corresponds to the lowest energy. Such calculations are best done using the latest software, but a more primitive approach gives useful insight for conjugated polyenes, in which there is an alternation of single and double bonds along a chain of carbon atoms. We focus on them in the first two sections of this Topic, to set the scene for the more sophisticated approaches mentioned in Section 10E.3.

The planarity of conjugated polyenes is an aspect of their symmetry, and considerations of molecular symmetry play a vital role in setting up and labelling molecular orbitals (see Topic 11B). In the present case, planarity provides a distinction between the  $\sigma$  and  $\pi$  orbitals of the molecule, and in elementary approaches such molecules are commonly discussed in terms of the characteristics of their  $\pi$  orbitals with the  $\sigma$  bonds providing a rigid framework that determines the general shape of the molecule.

## 10E.1 The Hückel approximation

The  $\pi$  molecular orbital energy level diagrams of conjugated molecules can be constructed using a set of approximations

suggested by Erich Hückel in 1931. All the C atoms are treated identically, so all the Coulomb integrals  $\alpha$  for the atomic orbitals that contribute to the  $\pi$  orbitals are set equal. For example, in ethene, which we use to introduce the method, we take the  $\sigma$  bonds as fixed, and concentrate on finding the energies of the single  $\pi$  bond and its companion antibond.

### (a) An introduction to the method

We express the  $\pi$  orbitals as linear combinations of the C2p orbitals that lie perpendicular to the molecular plane. In ethene, for instance, we would write

$$\psi = c_A A + c_B B \quad (10E.2)$$

where the  $A$  is a C2p orbital on atom  $A$ , and likewise for  $B$ . Next, the optimum coefficients and energies are found by the variation principle as explained in Topic 10D. That is, we solve the secular determinant, which in the case of ethene is eqn 10D.7 with  $\alpha_A = \alpha_B = \alpha$ :

$$\begin{vmatrix} \alpha - E & \beta - ES \\ \beta - ES & \alpha - E \end{vmatrix} = 0 \quad (10E.3)$$

In a modern computation all the resonance integrals and overlap integrals would be included, but an indication of the molecular orbital energy level diagram can be obtained very readily if we make the following additional **Hückel approximations**:

- All overlap integrals are set equal to zero.
- All resonance integrals between non-neighbours are set equal to zero.
- All remaining resonance integrals are set equal (to  $\beta$ ).

Hückel approximation

These approximations are obviously very severe, but they let us calculate at least a general picture of the molecular orbital energy levels with very little work. The approximations result in the following structure of the secular determinant:

- All diagonal elements:  $\alpha - E$ .
- Off-diagonal elements between neighbouring atoms:  $\beta$ .
- All other elements: 0.

These approximations convert eqn 10E.3 to

$$\begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha - E \end{vmatrix} = (\alpha - E)^2 - \beta^2 = (\alpha - E + \beta)(\alpha - E - \beta) = 0 \quad (10E.4)$$

Figure 10E.1 The Hückel molecular orbital energy levels of ethene. Two electrons occupy the lower  $\pi$  orbital.

The roots of the equation are  $E_{\pm} = \alpha \pm \beta$ . The + sign corresponds to the bonding combination ( $\beta$  is negative) and the - sign corresponds to the antibonding combination (Fig. 10E.1).

The building-up principle leads to the configuration  $1\pi^2$ , because each carbon atom supplies one electron to the  $\pi$  system and both electrons can occupy the bonding orbital. The **highest occupied molecular orbital** in ethene, its HOMO, is the  $1\pi$  orbital; the **lowest unoccupied molecular orbital**, its LUMO, is the  $2\pi$  orbital (or, as it is sometimes denoted, the  $2\pi^*$  orbital). These two orbitals jointly form the **frontier orbitals** of the molecule. The frontier orbitals are important because they are largely responsible for many of the chemical and spectroscopic properties of this and analogous molecules.

#### Brief illustration 10E.1 Ethene

We can estimate that the  $\pi^* \leftarrow \pi$  excitation energy of ethene is  $2|\beta|$ , the energy required to excite an electron from the  $1\pi$  to the  $2\pi$  orbital. This transition occurs at close to  $40\,000\text{ cm}^{-1}$ , corresponding to 4.8 eV. It follows that a plausible value of  $\beta$  is about  $-2.4\text{ eV}$  ( $-230\text{ kJ mol}^{-1}$ ).

**Self-test 10E.1** The ionization energy of ethene is 10.5 eV. Estimate  $\alpha$ .

Answer:  $-8.1\text{ eV}$

### (b) The matrix formulation of the method

In preparation for making Hückel theory more sophisticated and readily applicable to bigger molecules, we need to reformulate it in terms of matrices (see *Mathematical background 6* following this chapter). Our starting point is the pair of secular equations developed for a heteronuclear diatomic molecule in Topic 10D:

$$\begin{aligned} (\alpha_A - E)c_A + (\beta - ES)c_B &= 0 \\ (\beta - ES)c_A + (\alpha_B - E)c_B &= 0 \end{aligned}$$

To prepare to generalize this expression we shall write  $\alpha_j = H_{jj}$  (with  $J = A$  or  $B$ ),  $\beta = H_{AB}$ , and label the overlap integrals with

their respective atoms, so  $S$  becomes  $S_{AB}$ . We can introduce more symmetry into the equations (which makes it simpler to generalize them) by replacing the  $E$  in  $\alpha_j - E$  by  $ES_{jj}$ , with  $S_{jj} = 1$ . At this point, the two equations are

$$\begin{aligned}(H_{AA} - ES_{AA})c_A + (H_{AB} - ES_{AB})c_B &= 0 \\ (H_{BA} - ES_{BA})c_A + (H_{BB} - ES_{BB})c_B &= 0\end{aligned}$$

There is one further notational change. The coefficients  $c_j$  depend on the value of  $E$ , so we need to distinguish the two sets corresponding to the two energies, which we denote  $E_i$  with  $i = 1$  and  $2$ . We therefore write the coefficients as  $c_{i,j}$  with  $i = 1$  (the coefficients  $c_{1A}$  and  $c_{1B}$  for energy  $E_1$ ) or  $2$  (the coefficients  $c_{2A}$  and  $c_{2B}$  for energy  $E_2$ ). With this notational change, the two equations become

$$(H_{AA} - E_i S_{AA})c_{i,A} + (H_{AB} - E_i S_{AB})c_{i,B} = 0 \quad (10E.5a)$$

$$(H_{BA} - E_i S_{BA})c_{i,A} + (H_{BB} - E_i S_{BB})c_{i,B} = 0 \quad (10E.5b)$$

with  $i = 1$  and  $2$ , giving four equations in all. Each pair of equations can be written in matrix form as

$$\begin{pmatrix} H_{AA} - E_i S_{AA} & H_{AB} - E_i S_{AB} \\ H_{BA} - E_i S_{BA} & H_{BB} - E_i S_{BB} \end{pmatrix} \begin{pmatrix} c_{i,A} \\ c_{i,B} \end{pmatrix} = 0 \quad (10E.5c)$$

because multiplying out the matrices gives the two expressions in eqns 10E.5a and 10.5b. If we introduce the following matrices

$$\mathbf{H} = \begin{pmatrix} H_{AA} & H_{AB} \\ H_{BA} & H_{BB} \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix}, \quad \mathbf{c}_i = \begin{pmatrix} c_{i,A} \\ c_{i,B} \end{pmatrix} \quad (10E.6)$$

so that

$$\mathbf{H} - E_i \mathbf{S} = \begin{pmatrix} H_{AA} - E_i S_{AA} & H_{AB} - E_i S_{AB} \\ H_{BA} - E_i S_{BA} & H_{BB} - E_i S_{BB} \end{pmatrix}$$

then eqn 10E.5c may be written more succinctly as

$$(\mathbf{H} - E_i \mathbf{S})\mathbf{c}_i = 0 \quad \text{or} \quad \mathbf{H}\mathbf{c}_i = \mathbf{S}\mathbf{c}_i E_i \quad (10E.7)$$

As shown in the following *Justification*, these two sets of equations (with  $i = 1$  and  $2$ ) can be combined into a single matrix equation by introducing the matrices

$$\mathbf{c} = (\mathbf{c}_1 \quad \mathbf{c}_2) = \begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix}, \quad \mathbf{E} = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \quad (10E.8)$$

for then all four equations in eqn 10E.7 are summarized by the single expression

$$\mathbf{H}\mathbf{c} = \mathbf{S}\mathbf{c}\mathbf{E} \quad (10E.9)$$

### Justification 10E.1 The matrix formulation

Substitution of the matrices defined in eqn 10E.8 into eqn 10E.9 gives

$$\overbrace{\begin{pmatrix} H_{AA} & H_{AB} \\ H_{BA} & H_{BB} \end{pmatrix}}^{\mathbf{H}} \overbrace{\begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix}}^{\mathbf{c}} = \overbrace{\begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix}}^{\mathbf{S}} \overbrace{\begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix}}^{\mathbf{c}} \overbrace{\begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix}}^{\mathbf{E}}$$

The product on the left is

$$\begin{aligned}\begin{pmatrix} H_{AA} & H_{AB} \\ H_{BA} & H_{BB} \end{pmatrix} \begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix} \\ = \begin{pmatrix} H_{AA}c_{1,A} + H_{AB}c_{1,B} & H_{AA}c_{2,A} + H_{AB}c_{2,B} \\ H_{BA}c_{1,A} + H_{BB}c_{1,B} & H_{BA}c_{2,A} + H_{BB}c_{2,B} \end{pmatrix}\end{aligned}$$

The product on the right is

$$\begin{aligned}\begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix} \begin{pmatrix} c_{1,A} & c_{2,A} \\ c_{1,B} & c_{2,B} \end{pmatrix} \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} = \begin{pmatrix} S_{AA} & S_{AB} \\ S_{BA} & S_{BB} \end{pmatrix} \begin{pmatrix} c_{1,A}E_1 & c_{2,A}E_2 \\ c_{1,B}E_1 & c_{2,B}E_2 \end{pmatrix} \\ = \begin{pmatrix} E_1 S_{AA}c_{1,A} + E_1 S_{AB}c_{1,B} & E_2 S_{AA}c_{2,A} + E_2 S_{AB}c_{2,B} \\ E_1 S_{BA}c_{1,A} + E_1 S_{BB}c_{1,B} & E_2 S_{BA}c_{2,A} + E_2 S_{BB}c_{2,B} \end{pmatrix}\end{aligned}$$

Comparison of matching terms (like those in blue) recreates the four secular equations (two for each value of  $i$ ).

In the Hückel approximation,  $H_{AA} = H_{BB} = \alpha$ ,  $H_{AB} = H_{BA} = \beta$ , and we neglect overlap, setting  $S = \mathbf{1}$ , the unit matrix (with 1 on the diagonal and 0 elsewhere). Then

$$\mathbf{H}\mathbf{c} = \mathbf{c}\mathbf{E}$$

At this point, we multiply from the left by the inverse matrix  $\mathbf{c}^{-1}$ , use  $\mathbf{c}^{-1}\mathbf{c} = \mathbf{1}$ , and find

$$\mathbf{c}^{-1}\mathbf{H}\mathbf{c} = \mathbf{E} \quad (10E.10)$$

In other words, to find the eigenvalues  $E_i$ , we have to find a transformation of  $\mathbf{H}$  that makes it diagonal. This procedure is called **matrix diagonalization**. The diagonal elements then correspond to the eigenvalues  $E_i$  and the columns of the matrix  $\mathbf{c}$  that brings about this diagonalization are the coefficients of the members of the **basis set**, the set of atomic orbitals used in the calculation, and hence give us the composition of the molecular orbitals.

### Example 10E.1 Finding molecular orbitals by matrix diagonalization

Set up and solve the matrix equations within the Hückel approximation for the  $\pi$  orbitals of butadiene (1).

1 Butadiene

**Method** The matrices will be four-dimensional for this four-atom system. Ignore overlap, and construct the matrix  $H$  by using the Hückel approximation and the parameters  $\alpha$  and  $\beta$ . Find the matrix  $c$  that diagonalizes  $H$ : for this step, use mathematical software. Full details are given in *Mathematical background 6*, but note that if  $H = \alpha\mathbf{1} + M$ , where  $M$  is a non-diagonal matrix, then because  $\alpha c^{-1}c = \alpha c^{-1}c\mathbf{1} = \alpha\mathbf{1}$ , whatever matrix  $c$  diagonalizes  $M$  leaves  $\alpha\mathbf{1}$  unchanged, so to achieve the overall diagonalization of  $H$  we need to diagonalize only  $M$ .

**Answer** The hamiltonian matrix  $H$  is

$$H = \begin{pmatrix} \alpha & \beta & 0 & 0 \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{pmatrix} \xrightarrow{\text{Hückel approximation}} \begin{pmatrix} \alpha & \beta & 0 & 0 \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ 0 & 0 & \beta & \alpha \end{pmatrix}$$

which we write as

$$H = \alpha\mathbf{1} + \beta \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

because most mathematical software can deal only with numerical matrices. The diagonalized form of the matrix  $M$  is

$$\begin{pmatrix} +1.62 & 0 & 0 & 0 \\ 0 & -0.62 & 0 & 0 \\ 0 & 0 & -0.62 & 0 \\ 0 & 0 & 0 & -0.62 \end{pmatrix}$$

so we can infer that the diagonalized Hamiltonian matrix is

$$E = \begin{pmatrix} \alpha + 1.62\beta & 0 & 0 & 0 \\ 0 & \alpha + 0.62\beta & 0 & 0 \\ 0 & 0 & \alpha - 0.62\beta & 0 \\ 0 & 0 & 0 & \alpha - 1.62\beta \end{pmatrix}$$

The matrix that achieves the diagonalization is

$$c = \begin{pmatrix} 0.372 & 0.602 & 0.602 & -0.372 \\ 0.602 & 0.372 & -0.372 & 0.602 \\ 0.602 & -0.372 & -0.372 & -0.602 \\ 0.372 & -0.602 & 0.602 & -0.372 \end{pmatrix}$$

with each column giving the coefficients of the atomic orbitals for the corresponding molecular orbital. We can conclude that the energies and molecular orbitals are

$$\begin{aligned} E_1 &= \alpha + 1.62\beta & \psi_1 &= 0.372\chi_A + 0.602\chi_B + 0.602\chi_C + 0.372\chi_D \\ E_2 &= \alpha + 0.62\beta & \psi_2 &= 0.602\chi_A + 0.372\chi_B - 0.372\chi_C - 0.602\chi_D \\ E_3 &= \alpha - 0.62\beta & \psi_3 &= 0.602\chi_A - 0.372\chi_B - 0.372\chi_C + 0.602\chi_D \\ E_4 &= \alpha - 1.62\beta & \psi_4 &= -0.372\chi_A + 0.602\chi_B - 0.602\chi_C + 0.372\chi_D \end{aligned}$$

where the C2p atomic orbitals are denoted by  $\chi_A, \dots, \chi_D$ . Note that the molecular orbitals are mutually orthogonal and, with overlap neglected, normalized.

**Self-test 10E.2** Repeat the exercise for the allyl radical,  $\cdot\text{CH}_2 - \text{CH} = \text{CH}_2$ .

$$\text{Answer: } E = \alpha + 1.41\beta, \alpha, \alpha, \alpha - 1.41\beta; \psi_1 = 0.500\chi_A + 0.707\chi_B + 0.500\chi_C, \\ \psi_2 = 0.707\chi_A - 0.707\chi_C, \psi_3 = 0.500\chi_A - 0.707\chi_B + 0.500\chi_C$$

## 10E.2 Applications

Although the Hückel method is very primitive, it can be used to account for some of the properties of conjugated polyenes.

### (a) Butadiene and $\pi$ -electron binding energy

As we saw in *Example 10E.1*, the energies of the four LCAO-MOs for butadiene are

$$E = \alpha \pm 1.62\beta, \quad \alpha \pm 0.62\beta \quad (10E.11)$$

These orbitals and their energies are drawn in Fig. 10E.2. Note that the greater the number of internuclear nodes, the higher the energy of the orbital. There are four electrons to accommodate, so the ground-state configuration is  $1\pi^2 2\pi^2$ . The frontier orbitals of butadiene are the  $2\pi$  orbital (the HOMO, which is largely bonding) and the  $3\pi$  orbital (the LUMO, which is largely antibonding). ‘Largely bonding’ means that an orbital has both bonding and antibonding interactions between various neighbours, but the bonding effects dominate. ‘Largely antibonding’ indicates that the antibonding effects dominate.

An important point emerges when we calculate the total  $\pi$ -electron binding energy,  $E_\pi$ , the sum of the energies of each  $\pi$  electron, and compare it with what we find in ethene. In ethene the total energy is

$$E_\pi = 2(\alpha + \beta) = 2\alpha + 2\beta$$

**Figure 10E.2** The Hückel molecular orbital energy levels of butadiene and the top view of the corresponding  $\pi$  orbitals. The four p electrons (one supplied by each C) occupy the two lower  $\pi$  orbitals. Note that the orbitals are delocalized.

In butadiene it is

$$E_{\pi} = 2(\alpha + 1.62\beta) + 2(\alpha + 0.62\beta) = 4\alpha + 4.48\beta$$

Therefore, the energy of the butadiene molecule lies lower by  $0.48\beta$  (about  $110 \text{ kJ mol}^{-1}$ ) than the sum of two individual  $\pi$  bonds. This extra stabilization of a conjugated system compared with a set of localized  $\pi$  bonds is called the **delocalization energy** of the molecule.

A closely related quantity is the  **$\pi$ -bond formation energy**,  $E_{\text{bf}}$ , the energy released when a  $\pi$  bond is formed. Because the contribution of  $\alpha$  is the same in the molecule as in the atoms, we can find the  $\pi$ -bond formation energy from the  $\pi$ -electron binding energy by writing

$$E_{\text{bf}} = E_{\pi} - N_{\text{C}}\alpha \quad \text{Definition } \pi\text{-Bond formation energy} \quad (10\text{E.12})$$

where  $N_{\text{C}}$  is the number of carbon atoms in the molecule. The  $\pi$ -bond formation energy in butadiene, for instance, is  $4.48\beta$ .

### Example 10E.2 Estimating the delocalization energy

Use the Hückel approximation to find the energies of the  $\pi$  orbitals of cyclobutadiene, and estimate the delocalization energy.

**Method** Set up the secular determinant using the same basis as for butadiene, but note that atoms A and D are also now neighbours. Then solve for the roots of the secular equation and assess the total  $\pi$ -bond energy. For the delocalization energy, subtract from the total  $\pi$ -bond energy the energy of two  $\pi$ -bonds.

**Answer** The hamiltonian matrix is

$$H = \begin{pmatrix} \alpha & \beta & 0 & \beta \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ \beta & 0 & \beta & \alpha \end{pmatrix}$$

$$= \alpha 1 + \beta \begin{pmatrix} 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{pmatrix} \xrightarrow{\text{Diagonalize}} \begin{pmatrix} 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -2 \end{pmatrix}$$

Diagonalization gives the energies of the orbitals as

$$E = \alpha + 2\beta, \alpha, \alpha, \alpha - 2\beta$$

Four electrons must be accommodated. Two occupy the lowest orbital (of energy  $\alpha + 2\beta$ ), and two occupy the doubly degenerate orbitals (of energy  $\alpha$ ). The total energy is therefore  $4\alpha + 4\beta$ . Two isolated  $\pi$  bonds would have an energy  $4\alpha + 4\beta$ ; therefore, in this case, the delocalization energy is zero.

**Self-test 10E.3** Repeat the calculation for benzene (use software!).

Answer: See next subsection

## (b) Benzene and aromatic stability

The most notable example of delocalization conferring extra stability is benzene and the aromatic molecules based on its structure. In elementary accounts, benzene, and other aromatic compounds, is often expressed in a mixture of valence-bond and molecular orbital terms, with typically valence-bond language used for its  $\sigma$  framework and molecular orbital language used to describe its  $\pi$  electrons.

First, the valence-bond component. The six C atoms are regarded as  $sp^2$  hybridized, with a single unhybridized perpendicular  $2p$  orbital. One H atom is bonded by ( $Csp^2, H1s$ ) overlap to each C carbon, and the remaining hybrids overlap to give a regular hexagon of atoms (Fig. 10E.3). The internal angle of a regular hexagon is  $120^\circ$ , so  $sp^2$  hybridization is ideally suited for forming  $\sigma$  bonds. We see that the hexagonal shape of benzene permits strain-free  $\sigma$  bonding.

Now consider the molecular orbital component of the description. The six  $C2p$  orbitals overlap to give six  $\pi$  orbitals that spread all round the ring. Their energies are calculated within the Hückel approximation by diagonalizing the hamiltonian matrix

$$H = \begin{pmatrix} \alpha & \beta & 0 & 0 & 0 & \beta \\ \beta & \alpha & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha & \beta \\ \beta & 0 & 0 & 0 & \beta & \alpha \end{pmatrix}$$

$$= \alpha 1 + \beta \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 \end{pmatrix} \xrightarrow{\text{Diagonalize}} \begin{pmatrix} 2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -2 \end{pmatrix}$$

The MO energies, the eigenvalues of this matrix, are simply

$$E = \alpha \pm 2\beta, \alpha \pm \beta, \alpha \pm \beta \quad (10\text{E.13})$$

**Figure 10E.3** The  $\sigma$  framework of benzene is formed by the overlap of  $Csp^2$  hybrids, which fit without strain into a hexagonal arrangement.

**Figure 10E.4** The Hückel orbitals of benzene and the corresponding energy levels. The symmetry labels are explained in Topic 11B. The bonding and antibonding character of the delocalized orbitals reflects the numbers of nodes between the atoms. In the ground state, only the bonding orbitals are occupied.

as shown in Fig. 10E.4. The orbitals there have been given symmetry labels that are explained in Topic 11B. Note that the lowest energy orbital is bonding between all neighbouring atoms, the highest energy orbital is antibonding between each pair of neighbours, and the intermediate orbitals are a mixture of bonding, nonbonding, and antibonding character between adjacent atoms.

The simple form of the eigenvalues in eqn 10E.13 suggests that there is a more direct way of determining them than by using mathematical software. That is in fact the case, for symmetry arguments of the kind described in Topic 11B show that the  $6 \times 6$  matrix can be factorized into two  $1 \times 1$  matrices and two  $2 \times 2$  matrices, which are very easy to deal with.

We now apply the building-up principle to the  $\pi$  system. There are six electrons to accommodate (one from each C atom), so the three lowest orbitals ( $a_{2u}$  and the doubly-degenerate pair  $e_{1g}$ ) are fully occupied, giving the ground-state configuration  $a_{2u}^2 e_{1g}^4$ . A significant point is that the only molecular orbitals occupied are those with net bonding character (the analogy with the very stable  $N_2$  molecule, Topic 10B, should be noted).

The  $\pi$ -electron energy of benzene is

$$E = 2(\alpha + 2\beta) + 4(\alpha + \beta) = 6\alpha + 8\beta$$

If we ignored delocalization and thought of the molecule as having three isolated  $\pi$  bonds, it would be ascribed a  $\pi$ -electron energy of only  $3(2\alpha + 2\beta) = 6\alpha + 6\beta$ . The delocalization energy is therefore  $2\beta \approx -460 \text{ kJ mol}^{-1}$ , which is considerably more than for butadiene. The  $\pi$ -bond formation energy in benzene is  $8\beta$ .

This discussion suggests that aromatic stability can be traced to two main contributions. First, the shape of the regular hexagon is ideal for the formation of strong  $\sigma$  bonds: the  $\sigma$  framework is relaxed and without strain. Second, the  $\pi$  orbitals are

such as to be able to accommodate all the electrons in bonding orbitals, and the delocalization energy is large.

### Example 10E.3 Judging the aromatic character of a molecule

Decide whether the molecules  $C_4H_4$  and the molecular ion  $C_4H_4^+$  are aromatic when planar.

**Method** Follow the procedure for benzene. Set up and solve the secular equations within the Hückel approximation, assuming a planar  $\sigma$  framework, and then decide whether the ion has nonzero delocalization energy. Use mathematical software to diagonalize the hamiltonian (in Topic 11B it is shown how to use symmetry to arrive at the eigenvalues more simply.)

**Answer** The hamiltonian matrix is

$$H = \begin{pmatrix} \alpha & \beta & 0 & \beta \\ \beta & \alpha & \beta & 0 \\ 0 & \beta & \alpha & \beta \\ \beta & 0 & \beta & \alpha \end{pmatrix} = \alpha 1 + \beta \begin{pmatrix} 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{pmatrix}$$

The matrix multiplying  $\beta$  diagonalizes as follows:

$$\begin{pmatrix} 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{pmatrix} \xrightarrow{\text{Diagonalize}} \begin{pmatrix} -2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 \end{pmatrix}$$

It follows that the energy levels of the two species are  $E = \alpha \pm 2\beta, \alpha, \alpha$ . There are four  $\pi$  electrons to accommodate in  $C_4H_4$ , so the total  $\pi$ -bonding energy is  $2(\alpha + 2\beta) + 2\alpha = 4(\alpha + \beta)$ . The energy of two localized  $\pi$ -bonds is  $4(\alpha + \beta)$ . Therefore, the delocalization energy is zero, so the molecule is not aromatic. There are only two  $\pi$  electrons to accommodate in  $C_4H_4^+$ , so the total  $\pi$ -bonding energy is  $2(\alpha + 2\beta) = 2\alpha + 4\beta$ . The energy of a single localized  $\pi$ -bond is  $2(\alpha + \beta)$ , so the delocalization energy is  $2\beta$  and the molecular-ion is aromatic.

**Self-test 10E.4** What is the total  $\pi$ -bonding energy of  $C_3H_3^-$ ?

Answer:  $4\alpha + 2\beta$

## 10E.3 Computational chemistry

The severe assumptions of the Hückel method are now easy to avoid by using a variety of software packages that can be used not only to calculate the shapes and energies of molecular orbitals but also to predict with reasonable accuracy the

structure and reactivity of molecules. The full treatment of molecular electronic structure has received an enormous amount of attention by chemists and has become a keystone of modern chemical research. However, the calculations are very complex, and all this section seeks to do is to provide a brief introduction.<sup>1</sup> In every case, the procedures focus on the calculation or estimation of integrals like  $H_{ij}$  and  $H_{ij}$  rather than setting them equal to the constants  $\alpha$  or  $\beta$ , or ignoring them entirely.

In all cases the Schrödinger equation is solved iteratively and self-consistently, just as for the self-consistent field (SCF) approach to atoms (Topic 9B). First, the molecular orbitals for the electrons present in the molecule are formulated as LCAOs. One molecular orbital is then selected and all the others are used to set up an expression for the potential energy of an electron in the chosen orbital. The resulting Schrödinger equation is then solved numerically to obtain a better version of the chosen molecular orbital and its energy. The procedure is repeated for all the molecular orbitals and used to calculate the total energy of the molecule. The process is repeated until the computed orbitals and energy are constant to within some tolerance.

### (a) Semi-empirical and *ab initio* methods

In a **semi-empirical method**, many of the integrals are estimated by appealing to spectroscopic data or physical properties such as ionization energies, and using a series of rules to set certain integrals equal to zero. A primitive form of this procedure is used in *Brief illustration* 10D.1 of Topic 10D where we identify the integral  $\alpha$  with a combination of the ionization energy and electron affinity of an atom. In an ***ab initio* method** an attempt is made to calculate all the integrals, including overlap integrals. Both procedures employ a great deal of computational effort and, along with cryptanalysts and meteorologists, theoretical chemists are among the heaviest users of the fastest computers. The integrals that are required involve atomic orbitals that in general may be centred on different nuclei. It can be appreciated that, if there are several dozen atomic orbitals used to build the molecular orbitals, then there will be tens of thousands of integrals of this form to evaluate (the number of integrals increases as the fourth power of the number of atomic orbitals in the basis). Some kind of approximation scheme is necessary.

One severe semi-empirical approximation used in the early days of computational chemistry was called **complete neglect of differential overlap** (CNDO), in which all molecular integrals are set to zero unless  $A$  and  $B$  are the same orbitals centred on the same nucleus, and likewise for  $C$  and  $D$ . The surviving integrals are then adjusted until the energy levels are in good agreement with experiment or the computed enthalpy of

formation of the compound is in agreement with experiment. More recent semi-empirical methods make less draconian decisions about which integrals are to be ignored, but they are all descendants of the early CNDO technique.

Commercial packages are also available for *ab initio* calculations. Here the problem is to evaluate as efficiently as possible thousands of integrals that arise from the Coulombic interaction between two electrons and have the form

$$(AB|CD) = j_0 \iint A(1)B(1) \frac{1}{r_{12}} C(2)D(2) d\tau_1 d\tau_2$$

Notation Molecular integral (10E.14a)

with  $j_0 = e^2/4\pi\epsilon_0$  and the possibility that each of the atomic orbitals  $A, B, C, D$  is centred on a different atom, a so-called ‘four-centre integral’. This task is greatly facilitated by expressing the atomic orbitals used in the LCAOs as linear combinations of Gaussian orbitals. A **Gaussian type orbital** (GTO) is a function of the form  $e^{-r^2}$ . The advantage of GTOs over the correct orbitals (which for hydrogenic systems are proportional to exponential functions of the form  $e^{-r}$ ) is that the product of two Gaussian functions is itself a Gaussian function that lies between the centres of the two contributing functions (Fig. 10E.5). In this way, the four-centre integrals like these become two-centre integrals of the form

$$(AB|CD) = j_0 \iint X(1) \frac{1}{r_{12}} Y(2) d\tau_1 d\tau_2$$

(10E.14b)

where  $X$  is the Gaussian corresponding to the product  $AB$  and  $Y$  is the corresponding Gaussian from  $CD$ . Integrals of this form are much easier and faster to evaluate numerically than the original four-centre integrals. Although more GTOs have to be used to simulate the atomic orbitals, there is an overall increase in speed of computation.

**Figure 10E.5** The product of two Gaussian functions on different centres is itself a Gaussian function located at a point between the two contributing Gaussians. The scale of the product has been increased relative to that of its two components.

<sup>1</sup> A more complete account with detailed examples will be found in our companion volume, *Physical chemistry: Quanta, matter, and change* (2014).

**Brief illustration 10E.2** Gaussian type orbitals

Suppose we consider a one-dimensional ‘homonuclear’ system, with GTOs of the form  $e^{-ax^2}$  located at 0 and  $R$ . Then one of the integrals that would have to be evaluated would include the term

$$\chi_A(1)\chi_B(1) = e^{-ax^2} e^{-a(x-R)^2} = e^{-2ax^2 + 2axR - aR^2}$$

Next we note that  $-2a(x - \frac{1}{2}R)^2 = -2ax^2 + 2axR - \frac{1}{2}aR^2$ , so we can write

$$\chi_A(1)\chi_B(1) = e^{-2a(x - \frac{1}{2}R)^2 - \frac{1}{2}aR^2} = e^{-2a(x - \frac{1}{2}R)^2} e^{-\frac{1}{2}aR^2}$$

which is proportional to a single Gaussian (the term in blue) centred on the mid-point of the internuclear separation, at  $x = \frac{1}{2}R$ .

**Self-test 10E.5** Repeat the analysis for a heteronuclear species with GTOs of the form  $e^{-ax^2}$  and  $e^{-bx^2}$ .

$$\text{Answer: } \chi_A(1)\chi_B(1) = e^{-(cx - bR/c)^2 - a^2R^2/c^2}, \quad c = (a+b)^{1/2}$$

**(b) Density functional theory**

A technique that has gained considerable ground in recent years to become one of the most widely used techniques for the calculation of molecular structure is **density functional theory** (DFT). Its advantages include less demanding computational effort, less computer time, and—in some cases (particularly d-metal complexes)—better agreement with experimental values than is obtained from other procedures.

The central focus of DFT is the electron density,  $\rho$ , rather than the wavefunction,  $\psi$ . The ‘functional’ part of the name comes from the fact that the energy of the molecule is a function of the electron density, written  $E[\rho]$ , the electron density is itself a function of position,  $\rho(r)$ , and in mathematics a function of a function is called a ‘functional’. The occupied orbitals are used to construct the electron density from

$$\rho(r) = \sum_{m, \text{occupied}} |\psi_m(r)|^2 \quad \text{Electron probability density} \quad (10E.15)$$

and are calculated from modified versions of the Schrödinger equation known as the **Kohn–Sham equations**.

The Kohn–Sham equations are solved iteratively and self-consistently. First, the electron density is guessed. For this step it is common to use a superposition of atomic electron densities. Next, the Kohn–Sham equations are solved to obtain an initial set of orbitals. This set of orbitals is used to obtain a better approximation to the electron density and the process is repeated until the density and the computed energy are constant to within some tolerance.

**(c) Graphical representations**

One of the most significant developments in computational chemistry has been the introduction of graphical representations of molecular orbitals and electron densities. The raw output of a molecular structure calculation is a list of the coefficients of the atomic orbitals in each molecular orbital and the energies of these orbitals. The graphical representation of a molecular orbital uses stylized shapes to represent the basis set, and then scales their size to indicate the coefficient in the linear combination. Different signs of the wavefunctions are represented by different colours.

Once the coefficients are known, it is possible to construct a representation of the electron density in the molecule by noting which orbitals are occupied and then forming the squares of those orbitals. The total electron density at any point is then the sum of the squares of the wavefunctions evaluated at that point (as in eqn 10E.15). The outcome is commonly represented by an **isodensity surface**, a surface of constant total electron density (Fig. 10E.6). As shown in the illustration, there are several styles of representing an isodensity surface, as a solid form, as a transparent form with a ball-and-stick representation of the molecule within, or as a mesh. A related representation is a **solvent-accessible surface** in which the shape represents the shape of the molecule by imagining a sphere representing a solvent molecule rolling across the surface and plotting the locations of the centre of that sphere.

One of the most important aspects of a molecule other than its geometrical shape is the distribution of charge over its surface, which is commonly depicted as an **electrostatic potential surface** (an ‘elpot surface’). The potential energy,  $E_p$ , of an imaginary positive charge  $Q$  at a point is calculated by taking into account its interaction with the nuclei and the electron density throughout the molecule. Then, because  $E_p = Q\phi$ , where  $\phi$  is the electric potential, the potential energy can be interpreted as a potential and depicted as an appropriate colour (Fig. 10E.7). Electron-rich regions usually have negative potentials and electron-poor regions usually have positive potentials.

**Figure 10E.6** Various representations of an isodensity surface of ethanol: (a) solid surface, (b) transparent surface, and (c) mesh surface.

Figure 10E.7 An elpot diagram of ethanol; the molecule has the same orientation as in Fig. 10E.6. Red denotes regions of negative electrostatic potential and blue regions of positive potential (as in  $\delta^-$ -O- $\text{H}^{\delta+}$ ).

Representations such as those we have illustrated are of critical importance in a number of fields. For instance, they may be used to identify an electron-poor region of a molecule that is susceptible to association with or chemical attack by an electron-rich region of another molecule. Such considerations are important for assessing the pharmacological activity of potential drugs.

## Checklist of concepts

- 1. The **Hückel method** neglects overlap and interactions between atoms that are not neighbours.
- 2. The Hückel method may be expressed in a compact manner by introducing matrices.
- 3. The  **$\pi$ -bond formation energy** is the energy released when a  $\pi$  bond is formed.
- 4. The  **$\pi$ -electron binding energy** is the sum of the energies of each  $\pi$  electron.
- 5. The **delocalization energy** is the difference between the  $\pi$ -electron energy and the energy of the same molecule with localized  $\pi$  bonds.
- 6. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) form the **frontier orbitals** of a molecule.
- 7. The stability of benzene arises from the geometry of the ring and the high delocalization energy.
- 8. **Semi-empirical calculations** approximate integrals by estimating integrals using empirical data; **ab initio methods** evaluate all integrals numerically.
- 9. **Density functional theories** develop equations based on the electron density rather than the wavefunction itself.
- 10. Graphical techniques are used to plot a variety of surfaces based on electronic structure calculations.

## Checklist of equations

Property	Equation	Comment	Equation number
LCAO	$\psi = \sum_o c_o \chi_o$	$\chi_o$ are atomic orbitals	10E.1
Hückel equations	$Hc = ScE$	Hückel approximation: $S=0$ except between neighbours	10E.9
Diagonalization	$c^{-1}Hc = E$		10E.10
$\pi$ -Bond formation energy	$E_{\text{bf}} = E_{\pi} - N_C \alpha$	Definition; $N_C$ is the number of carbon atoms	10E.12
Molecular integrals	$(AB CD) = \int_0 \int_0 A(1)B(1)(1/r_{12})C(2)D(2) d\tau_1 d\tau_2$	$A, B, C, D$ are atomic orbitals	10E.14a
Electron probability density	$\rho(r) = \sum_{m, \text{occ}}  \psi_m(r) ^2$	Sum over occupied molecular orbitals $m$	10E.15

# CHAPTER 10 Molecular structure

## TOPIC 10A Valence-bond theory

### Discussion questions

- 10A.1** Discuss the role of the Born–Oppenheimer approximation in the calculation of a molecular potential energy curve or surface.
- 10A.2** Why are promotion and hybridization invoked in valence-bond theory?
- 10A.3** Describe the various types of hybrid orbitals and how they are used to describe the bonding in alkanes, alkenes, and alkynes. How does

hybridization explain that in allene,  $\text{CH}_2=\text{C}=\text{CH}_2$ , the two  $\text{CH}_2$  groups lie in perpendicular planes?

- 10A.4** Why is spin-pairing so common a feature of bond formation (in the context of valence-bond theory)?
- 10A.5** What are the consequences of resonance?

### Exercises

- 10A.1(a)** Write the valence-bond wavefunction for the single bond in HF.
- 10A.1(b)** Write the valence-bond wavefunction for the triple bond in  $\text{N}_2$ .
- 10A.2(a)** Write the valence-bond wavefunction for the resonance hybrid  $\text{HF} \leftrightarrow \text{H}^+\text{F}^- \leftrightarrow \text{H}^-\text{F}^+$  (allow for different contributions of each structure).
- 10A.2(b)** Write the valence-bond wavefunction for the resonance hybrid  $\text{N}_2 \leftrightarrow \text{N}^+\text{N}^- \leftrightarrow \text{N}^-\text{N}^+$  structures of similar energy.
- 10A.3(a)** Describe the structure of a  $\text{P}_2$  molecule in valence-bond terms. Why is  $\text{P}_4$  a more stable form of molecular phosphorus than  $\text{P}_2$ ?
- 10A.3(b)** Describe the structures of  $\text{SO}_2$  and  $\text{SO}_3$  in terms of valence bond theory.

- 10A.4(a)** Describe the bonding in 1,3-butadiene using hybrid orbitals.
- 10A.4(b)** Describe the bonding in 1,3-pentadiene using hybrid orbitals.
- 10A.5(a)** Show that the linear combinations  $h_1 = s + p_x + p_y + p_z$  and  $h_2 = s - p_x - p_y + p_z$  are mutually orthogonal.
- 10A.5(b)** Show that the linear combinations  $h_1 = (\sin \zeta)s + (\cos \zeta)p$  and  $h_2 = (\cos \zeta)s - (\sin \zeta)p$  are mutually orthogonal for all values of the angle  $\zeta$  (zeta).
- 10A.6(a)** Normalize the  $\text{sp}^2$  hybrid orbital  $h = s + 2^{1/2}p$  given that the s and p orbitals are each normalized to 1.
- 10A.6(b)** Normalize the linear combinations in Exercise 10A.5b given that the s and p orbitals are each normalized to 1.

### Problems

- 10A.1** An  $\text{sp}^2$  hybrid orbital that lies in the  $xy$  plane and makes an angle of  $120^\circ$  to the  $x$ -axis has the form

$$\psi = \frac{1}{3^{1/2}} \left( s - \frac{1}{2^{1/2}} p_x + \frac{3^{1/2}}{2^{1/2}} p_y \right)$$

Use hydrogenic atomic orbitals to write the explicit form of the hybrid orbital. Show that it has its maximum amplitude in the direction specified.

- 10A.2** Confirm that the hybrid orbitals in eqn 10A.5 make angles of  $120^\circ$  to each other.
- 10A.3** Show that two equivalent hybrid orbitals of the form  $\text{sp}^2$  make an angle  $\theta$  to each other, then  $\lambda = -1/\cos \theta$ . Plot a graph of  $\lambda$  against  $\theta$  and confirm that  $\theta = 180^\circ$  when no s orbital is included and  $\theta = 120^\circ$  when  $\lambda = 2$ .

## TOPIC 10B Principles of molecular orbital theory

### Discussion questions

- 10B.1** What feature of molecular orbital theory is responsible for bond formation?

- 10B.2** Why is spin-pairing so common a feature of bond formation (in the context of molecular orbital theory)?

### Exercises

- 10B.1(a)** Normalize the molecular orbital  $\psi = \psi_A + \lambda \psi_B$  in terms of the parameter  $\lambda$  and the overlap integral  $S$ .
- 10B.1(b)** A better description of the molecule in Exercise 10B.1(a) might be obtained by including more orbitals on each atom in the linear combination. Normalize the molecular orbital  $\psi = \psi_A + \lambda \psi_B + \lambda' \psi_B'$  in terms of the parameters  $\lambda$  and  $\lambda'$  and the appropriate overlap

integrals  $S$ , where  $\psi_B$  and  $\psi_B'$  are mutually orthogonal orbitals on atom B.

- 10B.2(a)** Suppose that a molecular orbital has the (unnormalized) form  $0.145A + 0.844B$ . Find a linear combination of the orbitals  $A$  and  $B$  that is orthogonal to this combination and determine the normalization constants of both combinations using  $S = 0.250$ .

**10B.2(b)** Suppose that a molecular orbital has the (unnormalized) form  $0.727A + 0.144B$ . Find a linear combination of the orbitals  $A$  and  $B$  that is orthogonal to this combination and determine the normalization constants of both combinations using  $S = 0.117$ .

**10B.3(a)** The energy of  $H_2^+$  with internuclear separation  $R$  is given by eqn 10B.4. The values of the contributions are given below. Plot the molecular potential energy curve and find the bond dissociation energy (in electronvolts) and the equilibrium bond length.

$R/a_0$	0	1	2	3	4
$j/E_h$	1.000	0.729	0.472	0.330	0.250
$k/E_h$	1.000	0.736	0.406	0.199	0.092
$S$	1.000	0.858	0.587	0.349	0.189

## Problems

**10B.1** Calculate the (molar) energy of electrostatic repulsion between two hydrogen nuclei at the separation in  $H_2$  (74.1 pm). The result is the energy that must be overcome by the attraction from the electrons that form the bond. Does the gravitational attraction between them play any significant role? *Hint:* The gravitational potential energy of two masses is equal to  $-Gm_1m_2/r$ ;  $G$  is listed inside the front cover.

**10B.2** Imagine a small electron-sensitive probe of volume  $1.00 \text{ pm}^3$  inserted into an  $H_2^+$  molecule-ion in its ground state. Calculate the probability that it will register the presence of an electron at the following positions: (a) at nucleus A, (b) at nucleus B, (c) half way between A and B, (c) at a point 20 pm along the bond from A and 10 pm perpendicularly. Do the same for the molecule-ion the instant after the electron has been excited into the antibonding LCAO-MO.

**10B.3** Derive eqns 10B.4 and 10B.7 by working with the normalized LCAO-MOs for the  $H_2^+$  molecule-ion. Proceed by evaluating the expectation value of the hamiltonian for the ion. Make use of the fact that  $A$  and  $B$  each individually satisfy the Schrödinger equation for an isolated H atom.

**10B.4** Examine whether occupation of the bonding orbital with one electron (as calculated in the preceding problem) has a greater or lesser bonding effect

than occupation of the antibonding orbital with one electron. Is that true at all internuclear separations?

where  $E_h = 27.2 \text{ eV}$ ,  $a_0 = 52.9 \text{ pm}$ , and  $E_H = -\frac{1}{2} E_h$ .

**10B.3(b)** The same data as in Exercise 10B.3(a) may be used to calculate the molecular potential energy curve for the antibonding orbital, which is given by eqn 10B.7. Plot the curve.

**10B.4(a)** Identify the g or u character of bonding and antibonding  $\pi$  orbitals formed by side-by-side overlap of p atomic orbitals.

**10B.4(b)** Identify the g or u character of bonding and antibonding  $\delta$  orbitals formed by face-to-face overlap of d atomic orbitals.

than occupation of the antibonding orbital with one electron. Is that true at all internuclear separations?

**10B.5\*** The LCAO-MO approach described in the text can be used to introduce numerical methods needed in quantum chemistry. In this problem we evaluate the overlap, Coulomb, and resonance integrals numerically and compare the results with the analytical equations (eqns 10B.5). (a) Use the LCAO-MO wavefunction and the  $H_2^+$  hamiltonian to derive equations for the relevant integrals and use mathematical software or an electronic spreadsheet to evaluate the overlap, Coulomb, and resonance integrals numerically, and the total energy for the  $1s\sigma_g$  MO in the range  $a_0 < R < 4a_0$ . Compare the results obtained by numerical integration with results obtained analytically. (b) Use the results of the numerical integrations to draw a graph of the total energy,  $E(R)$ , and determine the minimum of total energy, the equilibrium internuclear distance, and the dissociation energy ( $D_0$ ).

**10B.6** (a) Calculate the total amplitude of the normalized bonding and antibonding LCAO-MOs that may be formed from two  $H1s$  orbitals at a separation of  $2a_0 = 106 \text{ pm}$ . Plot the two amplitudes for positions along the molecular axis both inside and outside the internuclear region. (b) Plot the probability densities of the two orbitals. Then form the *difference density*, the difference between  $\psi^2$  and  $\frac{1}{2}(\psi_A^2 + \psi_B^2)$ .

## TOPIC 10C Homonuclear diatomic molecules

### Discussion questions

**10C.1** Draw diagrams to show the various orientations in which a p orbital and a d orbital on adjacent atoms may form bonding and antibonding molecular orbitals.

**10C.2** Outline the rules of the building-up principle for homonuclear diatomic molecules.

**10C.3** What is the role of the Born–Oppenheimer approximation in molecular orbital theory?

**10C.4** What is the justification for treating s and p atomic orbital contributions to molecular orbitals separately?

**10C.5** To what extent can orbital overlap be related to bond strength?

### Exercises

**10C.1(a)** Give the ground-state electron configurations and bond orders of (i)  $Li_2$ , (ii)  $Be_2$ , and (iii)  $C_2$ .

**10C.1(b)** Give the ground-state electron configurations of (i)  $F_2^-$ , (ii)  $N_2$ , and (iii)  $O_2^{2-}$ .

**10C.2(a)** From the ground-state electron configurations of  $B_2$  and  $C_2$ , predict which molecule should have the greater dissociation energy.

**10C.2(b)** From the ground-state electron configurations of  $Li_2$  and  $Be_2$ , predict which molecule should have the greater dissociation energy.

**10C.3(a)** Which has the higher dissociation energy,  $F_2$  or  $F_2^+$ ?

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**10C.3(b)** Arrange the species  $\text{O}_2^+$ ,  $\text{O}_2$ ,  $\text{O}_2^-$ ,  $\text{O}_2^{2-}$  in order of increasing bond length.

**10C.4(a)** Evaluate the bond order of each Period 2 homonuclear diatomic molecule.

**10C.4(b)** Evaluate the bond order of each Period 2 homonuclear diatomic cation,  $\text{X}_2^+$ , and anion,  $\text{X}_2^-$ .

**10C.5(a)** For each of the species in Exercise 10C.4(b), specify which molecular orbital is the HOMO.

**10C.5(b)** For each of the species in Exercise 10C.4(b), specify which molecular orbital is the LUMO.

**10C.6(a)** What is the speed of a photoelectron ejected from an orbital of ionization energy 12.0 eV by a photon of radiation of wavelength 100 nm?

**10C.6(b)** What is the speed of a photoelectron ejected from a molecule with radiation of energy 21 eV and known to come from an orbital of ionization energy 12 eV?

**10C.7(a)** The overlap integral between two hydrogenic 1s orbitals on nuclei separated by a distance  $R$  is given by eqn 10C.4. At what separation is  $S=0.20$  for (i)  $\text{H}_2$ , (ii)  $\text{He}_2$ ?

**10C.7(b)** The overlap integral between two hydrogenic 2s orbitals on nuclei separated by a distance  $R$  is given by the expression in *Brief illustration* 10C.2. At what separation is  $S=0.20$  for (i)  $\text{H}_2$ , (ii)  $\text{He}_2$ ?

## Problems

**10C.1** Before doing the calculation below, sketch how the overlap between a 1s orbital and a 2p orbital directed towards it can be expected to depend on their separation. The overlap integral between an H1s orbital and an H2p orbital directed towards it on nuclei separated by a distance  $R$  is  $S=(R/a_0)\{1+(R/a_0)+\frac{1}{3}(R/a_0)^2\}e^{-R/a_0}$ . Plot this function, and find the separation for which the overlap is a maximum.

**10C.2<sup>†</sup>** Use the  $2p_x$  and  $2p_z$  hydrogenic atomic orbitals to construct simple LCAO descriptions of  $2p\sigma$  and  $2p\pi$  molecular orbitals. (a) Make a probability density plot, and both surface and contour plots of the  $xz$ -plane amplitudes of the  $2p_z\sigma$  and  $2p_z\sigma^*$  molecular orbitals. (b) Make surface and contour plots of the  $xz$ -plane amplitudes of the  $2p_x\pi$  and  $2p_x\pi^*$  molecular orbitals. Include plots for both an internuclear distance,  $R$ , of  $10a_0$  and  $3a_0$ ,

where  $a_0=52.9$  pm. Interpret the graphs, and explain why this graphical information is useful.

**10C.3** Show, if overlap is ignored, (a) that any molecular orbital expressed as a linear combination of two atomic orbitals may be written in the form  $\psi=\psi_A \cos \theta+\psi_B \sin \theta$ , where  $\theta$  is a parameter that varies between 0 and  $\pi$ , and (b) that if  $\psi_A$  and  $\psi_B$  are orthogonal and normalized to 1, then  $\psi$  is also normalized to 1. (c) To what values of  $\theta$  do the bonding and antibonding orbitals in a homonuclear diatomic molecule correspond?

**10C.4** In a particular photoelectron spectrum using 21.21 eV photons, electrons were ejected with kinetic energies of 11.01 eV, 8.23 eV, and 5.22 eV. Sketch the molecular orbital energy level diagram for the species, showing the ionization energies of the three identifiable orbitals.

## TOPIC 10D Heteronuclear diatomic molecules

### Discussion questions

**10D.1** Describe the Pauling and Mulliken electronegativity scales. Why should they be approximately in step?

**10D.2** Why do both ionization energy and electron affinity play a role in estimating the energy of an atomic orbital to use in a molecular structure calculation?

**10D.3** Discuss the steps involved in the calculation of the energy of a system by using the variation principle. Are any assumptions involved?

**10D.4** What is the physical significance of the Coulomb and resonance integrals?

**10D.5** Discuss how the properties of carbon explain the bonding features that make it an ideal biological building block.

### Exercises

**10D.1(a)** Give the ground-state electron configurations of (i) CO, (ii) NO, and (iii)  $\text{CN}^-$ .

**10D.1(b)** Give the ground-state electron configurations of (i)  $\text{XeF}$ , (ii) PN, and (iii)  $\text{SO}^-$ .

**10D.2(a)** Sketch the molecular orbital energy level diagram for XeF and deduce its ground-state electron configuration. Is XeF likely to have a shorter bond length than  $\text{XeF}^+$ ?

**10D.2(b)** Sketch the molecular orbital energy level diagram for IF and deduce its ground-state electron configuration. Is IF likely to have a shorter bond length than  $\text{IF}^-$  or  $\text{IF}^+$ ?

**10D.3(a)** Use the electron configurations of  $\text{NO}^-$  and  $\text{NO}^+$  to predict which is likely to have the shorter bond length.

**10D.3(b)** Use the electron configurations of  $\text{SO}^-$  and  $\text{SO}^+$  to predict which is likely to have the shorter bond length.

**10D.4(a)** A reasonably reliable conversion between the Mulliken and Pauling electronegativity scales is given by eqn 10D.4. Use Table 10D.1 in the *Resource section* to assess how good the conversion formula is for Period 2 elements.

**10D.4(b)** A reasonably reliable conversion between the Mulliken and Pauling electronegativity scales is given by eqn 10D.4. Use Table 10D.1 in the *Resource section* to assess how good the conversion formula is for Period 3 elements.

**10D.5(a)** Estimate the orbital energies to use in a calculation of the molecular orbitals of HCl. For data, see Tables 9B.2 and 9B.3.

**10D.5(b)** Estimate the orbital energies to use in a calculation of the molecular orbitals of HBr. For data, see Tables 9B.2 and 9B.3.

**10D.6(a)** Use the values derived in Exercise 10D.5(a) to estimate the molecular orbital energies in HCl; Use  $S=0$ .

**10D.6(b)** Use the values derived in Exercise 10D.5(b) to estimate the molecular orbital energies in HBr; Use  $S=0$ .

**10D.7(a)** Now repeat Exercise 10D.6(a), but with  $S=0.20$ .

**10D.7(b)** Now repeat Exercise 10D.6(b), but with  $S=0.20$ .

## Problems

**10D.1** Equation 10D.9 follows from eqn 10D.8a by making the approximation  $|\alpha_B - \alpha_A| \gg 2|\beta|$  and setting  $S=0$ . Explore the consequences of not setting  $S=0$ .

**10D.2** Suppose that a molecular orbital of a heteronuclear diatomic molecule is built from the orbital basis  $A$ ,  $B$ , and  $C$ , where  $B$  and  $C$  are both on one atom (they can be envisaged as  $F2s$  and  $F2p$  in HF, for instance). Set up the secular equations for the optimum values of the coefficients and the corresponding secular determinant.

**10D.3** Continue the preceding problem by setting  $\alpha_A = -7.2$  eV,  $\alpha_B = -10.4$  eV,  $\alpha_C = -8.4$  eV,  $\beta_{AB} = -1.0$  eV,  $\beta_{AC} = -0.8$  eV, and calculate the orbital energies and coefficients with (i) both  $S=0$ , (ii) both  $S=0.2$ .

**10D.4** As a variation of the preceding problem explore the consequences of increasing the energy separation of the  $B$  and  $C$  orbitals (use  $S=0$  for this stage of the calculation). Are you justified in ignoring orbital  $C$  at any stage?

## TOPIC 10E Polyatomic molecules

### Discussion questions

**10E.1** Discuss the scope, consequences, and limitations of the approximations on which the Hückel method is based.

**10E.2** Distinguish between delocalization energy,  $\pi$ -electron binding energy, and  $\pi$ -bond formation energy. Explain how each concept is employed.

**10E.3** Outline the computational steps used in the self-consistent field approach to electronic structure calculations.

**10E.4** Explain why the use of Gaussian-type orbitals is generally preferred over the use of hydrogenic (exponential) orbitals in basis sets.

**10E.5** Distinguish between semi-empirical, *ab initio*, and density functional theory methods of electronic structure determination.

### Exercises

**10E.1(a)** Write down the secular determinants for (i) linear  $H_3$ , (ii) cyclic  $H_3$  within the Hückel approximation.

**10E.1(b)** Write down the secular determinants for (i) linear  $H_4$ , (ii) cyclic  $H_4$  within the Hückel approximation.

**10E.2(a)** Predict the electron configurations of (i) the benzene anion, (ii) the benzene cation. Estimate the  $\pi$ -electron binding energy in each case.

**10E.2(b)** Predict the electron configurations of (i) the allyl radical, (ii) the cyclobutadiene cation. Estimate the  $\pi$ -electron binding energy in each case.

**10E.3(a)** Compute the delocalization energy and  $\pi$ -bond formation energy of (i) the benzene anion, (ii) the benzene cation.

**10E.3(b)** Compute the delocalization energy and  $\pi$ -bond formation energy of (i) the allyl radical, (ii) the cyclobutadiene cation.

**10E.4(a)** Write down the secular determinants for (i) anthracene (1), (ii) phenanthrene (2) within the Hückel approximation and using the  $C2p$  orbitals as the basis set.

1 Anthracene

2 Phenanthrene

**10E.4(b)** Write down the secular determinants for (i) azulene (3), (ii) acenaphthalene (4) within the Hückel approximation and using the  $C2p$  orbitals as the basis set.

3 Azulene

4 Acenaphthalene

**10E.5(a)** Use mathematical software to estimate the  $\pi$ -electron binding energy of (i) anthracene (1), (ii) phenanthrene (2) within the Hückel approximation.

**10E.5(b)** Use mathematical software to estimate the  $\pi$ -electron binding energy of (i) azulene (3), (ii) acenaphthalene (4) within the Hückel approximation.

**10E.6(a)** Write the electronic hamiltonian for  $HeH^+$ .

**10E.6(b)** Write the electronic hamiltonian for  $LiH^{2+}$ .

## Problems

**10E.1** Set up and solve the Hückel secular equations for the  $\pi$  electrons of  $CO_3^{2-}$ . Express the energies in terms of the Coulomb integrals  $\alpha_O$  and  $\alpha_C$

and the resonance integral  $\beta$ . Determine the delocalization energy of the ion.

**10E.2** For monocyclic conjugated polyenes (such as cyclobutadiene and benzene) with each of  $N$  carbon atoms contributing an electron in a  $2p$  orbital, simple Hückel theory gives the following expression for the energies  $E_k$  of the resulting  $\pi$  molecular orbitals:

$$E_k = \alpha + 2\beta \cos \frac{2k\pi}{N} \quad \begin{array}{l} k=0, \pm 1, \dots, \pm N/2 \text{ for } N \text{ even} \\ k=0, \pm 1, \dots, \pm (N-1)/2 \text{ for } N \text{ odd} \end{array}$$

(a) Calculate the energies of the  $\pi$  molecular orbitals of benzene and cyclooctatetraene (5). Comment on the presence or absence of degenerate energy levels. (b) Calculate and compare the delocalization energies of benzene (using the expression above) and hexatriene. What do you conclude from your results? (c) Calculate and compare the delocalization energies of cyclooctatetraene and octatetraene. Are your conclusions for this pair of molecules the same as for the pair of molecules investigated in part (b)?

5 Cyclooctatetraene

**10E.3** Set up the secular determinants for the homologous series consisting of ethene, butadiene, hexatriene, and octatetraene and diagonalize them by using mathematical software. Use your results to show that the  $\pi$  molecular orbitals of linear polyenes obey the following rules:

- The  $\pi$  molecular orbital with lowest energy is delocalized over all carbon atoms in the chain.
- The number of nodal planes between  $C2p$  orbitals increases with the energy of the  $\pi$  molecular orbital.

**10E.4** Set up the secular determinants for cyclobutadiene, benzene, and cyclooctatetraene and diagonalize them by using mathematical software. Use your results to show that the  $\pi$  molecular orbitals of monocyclic polyenes with an even number of carbon atoms follow a pattern in which:

- The  $\pi$  molecular orbitals of lowest and highest energy are non-degenerate.
- The remaining  $\pi$  molecular orbitals exist as degenerate pairs.

**10E.5** Electronic excitation of a molecule may weaken or strengthen some bonds because bonding and antibonding characteristics differ between the HOMO and the LUMO. For example, a carbon-carbon bond in a linear polyene may have bonding character in the HOMO and antibonding character in the LUMO. Therefore, promotion of an electron from the HOMO to the LUMO weakens this carbon-carbon bond in the excited electronic state, relative to the ground electronic state. Consult Figs. 10E.2 and 10E.4 and discuss in detail any changes in bond order that accompany the  $\pi^* \leftarrow \pi$  ultraviolet absorptions in butadiene and benzene.

**10E.6†** Prove that for an open chain of  $N$  conjugated carbons the characteristic polynomial of the secular determinant (the polynomial obtained by expanding the determinant),  $P_N(x)$ , where  $x = (\alpha - \beta)/\beta$ , obeys the recurrence relation  $P_N = xP_{N-1} - P_{N-2}$ , with  $P_1 = x$  and  $P_0 = 1$ .

**10E.7** The standard potential of a redox couple is a measure of the thermodynamic tendency of an atom, ion, or molecule to accept an electron (Topic 6D). Studies indicate that there is a correlation between the LUMO energy and the standard potential of aromatic hydrocarbons. Do you expect the standard potential to increase or decrease as the LUMO energy decreases? Explain your answer.

**10E.8†** In Exercise 10E.1(a) you are invited to set up the Hückel secular determinant for linear and cyclic  $H_3$ . The same secular determinant applies

to the molecular ions  $H_3^+$  and  $D_3^+$ . The molecular ion  $H_3^+$  was discovered as long ago as 1912 by J.J. Thomson but the equilateral triangular structure was confirmed by M.J. Gaillard et al. much more recently (*Phys. Rev. A* 17, 1797 (1978)). The molecular ion  $H_3^+$  is the simplest polyatomic species with a confirmed existence and plays an important role in chemical reactions occurring in interstellar clouds that may lead to the formation of water, carbon monoxide, and ethyl alcohol. The  $H_3^+$  ion has also been found in the atmospheres of Jupiter, Saturn, and Uranus. (a) Solve the Hückel secular equations for the energies of the  $H_3$  system in terms of the parameters  $\alpha$  and  $\beta$ , draw an energy level diagram for the orbitals, and determine the binding energies of  $H_3^+$ ,  $H_3$ , and  $H_3^-$ . (b) Accurate quantum mechanical calculations by G.D. Carney and R.N. Porter (*J. Chem. Phys.* 65, 3547 (1976)) give the dissociation energy for the process  $H_3^+ \rightarrow H + H + H^+$  as  $849 \text{ kJ mol}^{-1}$ . From this information and data in Table 10C.2, calculate the enthalpy of the reaction  $H^+(g) + H_2(g) \rightarrow H_3^+(g)$ . (c) From your equations and the information given, calculate a value for the resonance integral  $\beta$  in  $H_3^+$ . Then go on to calculate the binding energies of the other  $H_3$  species in (a).

**10E.9†** There is some indication that other hydrogen ring compounds and ions in addition to  $H_3$  and  $D_3$  species may play a role in interstellar chemistry. According to J.S. Wright and G.A. DiLabio (*J. Phys. Chem.* 96, 10793 (1992)),  $H_5^-$ ,  $H_6^+$ , and  $H_7^+$  are particularly stable whereas  $H_4$  and  $H_5^+$  are not. Confirm these statements by Hückel calculations.

**10E.10** Use appropriate electronic structure software and basis sets of your or your instructor's choosing, perform self-consistent field calculations for the ground electronic states of  $H_2$  and  $F_2$ . Determine ground-state energies and equilibrium geometries. Compare computed equilibrium bond lengths to experimental values.

**10E.11** Use an appropriate semi-empirical method to compute the equilibrium bond lengths and standard enthalpies of formation of (a) ethanol,  $C_2H_5OH$ , (b) 1,4-dichlorobenzene,  $C_6H_4Cl_2$ . Compare to experimental values and suggest reasons for any discrepancies.

**10E.12** Molecular electronic structure methods may be used to estimate the standard enthalpy of formation of molecules in the gas phase. (a) Use a semi-empirical method of your choice or your instructor's suggestion to calculate the standard enthalpy of formation of ethene, butadiene, hexatriene, and octatetraene in the gas phase. (b) Consult a database of thermochemical data, and, for each molecule in part (a), calculate the difference between the calculated and experimental values of the standard enthalpy of formation. (c) A good thermochemical database will also report the uncertainty in the experimental value of the standard enthalpy of formation. Compare experimental uncertainties with the relative errors calculated in part (b) and discuss the reliability of your chosen semi-empirical method for the estimation of thermochemical properties of linear polyenes.

**10E.13** Molecular orbital calculations based on semi-empirical, *ab initio*, and DFT methods describe the spectroscopic properties of conjugated molecules better than simple Hückel theory. (a) Use the computational method of your choice (semi-empirical, *ab initio*, or density functional methods) or your instructor's suggestion to calculate the energy separation between the HOMO and LUMO of ethene, butadiene, hexatriene, and octatetraene. (b) Plot the HOMO-LUMO energy separations against the experimental frequencies for  $\pi^* \leftarrow \pi$  ultraviolet absorptions for these molecules ( $61\,500$ ,  $46\,080$ ,  $39\,750$ , and  $32\,900 \text{ cm}^{-1}$ , respectively). Use mathematical software to find the polynomial equation that best fits the data. (c) Use your polynomial fit from part (b) to estimate the wavenumber and wavelength of the  $\pi^* \leftarrow \pi$  ultraviolet absorption of decapentaene from the calculated HOMO-LUMO energy separation. (d) Discuss why the calibration procedure of part (b) is necessary.

## Integrated activities

**10.1** The languages of valence-bond theory and molecular orbital theory are commonly combined when discussing unsaturated organic compounds. Construct the molecular orbital energy level diagrams of ethene on the basis that the molecule is formed from the appropriately hybridized  $\text{CH}_2$  or  $\text{CH}$  fragments.

**10.2** Here we develop a molecular orbital theory treatment of the peptide group (6), which links amino acids in proteins, and establish the features that stabilize its planar conformation. (a) It will be familiar from introductory chemistry that valence bond theory explains the planar conformation by invoking delocalization of the  $\pi$  bond over the oxygen, carbon, and nitrogen atoms by resonance:

6 Peptide group

It follows that we can model the peptide group using molecular orbital theory by making LCAO-MOs from 2p orbitals perpendicular to the plane defined by the O, C, and N atoms. The three combinations have the form:

$$\psi_1 = a\psi_{\text{O}} + b\psi_{\text{C}} + c\psi_{\text{N}} \quad \psi_2 = d\psi_{\text{O}} - e\psi_{\text{N}} \quad \psi_3 = f\psi_{\text{O}} - g\psi_{\text{C}} + h\psi_{\text{N}}$$

where the coefficients  $a$  to  $h$  are all positive. Sketch the orbitals  $\psi_1$ ,  $\psi_2$ , and  $\psi_3$  and characterize them as bonding, non-bonding, or antibonding molecular orbitals. In a non-bonding molecular orbital, a pair of electrons resides in an orbital confined largely to one atom and not appreciably involved in bond formation. (b) Show that this treatment is consistent only with a planar conformation of the peptide link. (c) Draw a diagram showing the relative energies of these molecular orbitals and determine the occupancy of the orbitals. *Hint:* Convince yourself that there are four electrons to be distributed among the molecular orbitals. (d) Now consider a non-planar conformation of the peptide link, in which the O2p and C2p orbitals are perpendicular to the plane defined by the O, C, and N atoms, but the N2p orbital lies on that plane. The LCAO-MOs are given by

$$\psi_4 = a\psi_{\text{O}} + b\psi_{\text{C}} \quad \psi_5 = e\psi_{\text{N}} \quad \psi_6 = f\psi_{\text{O}} - g\psi_{\text{C}}$$

Just as before, sketch these molecular orbitals and characterize them as bonding, non-bonding, or antibonding. Also, draw an energy level diagram and determine the occupancy of the orbitals. (e) Why is this arrangement of atomic orbitals consistent with a non-planar conformation for the peptide link? (f) Does the bonding MO associated with the planar conformation have the same energy as the bonding MO associated with the non-planar conformation? If not, which bonding MO is lower in energy? Repeat the analysis for the non-bonding and antibonding molecular orbitals. (g) Use your results from parts (a)–(f) to construct arguments that support the planar model for the peptide link.

**10.3** Molecular orbital calculations may be used to predict trends in the standard potentials of conjugated molecules, such as the quinones and flavins, that are involved in biological electron transfer reactions. It is commonly assumed that decreasing the energy of the LUMO enhances the ability of a molecule to accept an electron into the LUMO, with an accompanying increase in the value of the molecule's standard potential. Furthermore, a number of studies indicate that there is a linear correlation between the LUMO energy and the reduction potential of aromatic hydrocarbons. (a) The standard potentials at  $\text{pH}=7$  for the one-electron reduction of methyl-substituted 1,4-benzoquinones (7) to their respective semiquinone radical anions are:

$R_2$	$R_3$	$R_5$	$R_6$	$E^\ominus/\text{V}$
H	H	H	H	0.078
$\text{CH}_3$	H	H	H	0.023
$\text{CH}_3$	H	$\text{CH}_3$	H	-0.067
$\text{CH}_3$	$\text{CH}_3$	$\text{CH}_3$	H	-0.165
$\text{CH}_3$	$\text{CH}_3$	$\text{CH}_3$	$\text{CH}_3$	-0.260

Using the computational method of your choice (semi-empirical, *ab initio*, or density functional theory methods), calculate  $E_{\text{LUMO}}$ , the energy of the LUMO of each substituted 1,4-benzoquinone, and plot  $E_{\text{LUMO}}$  against  $E^\ominus$ . Do your calculations support a linear relation between  $E_{\text{LUMO}}$  and  $E^\ominus$ ? (b) The 1,4-benzoquinone for which  $R_2=R_3=\text{CH}_3$  and  $R_5=R_6=\text{OCH}_3$  is a suitable model of ubiquinone, a component of the respiratory electron transport chain (*Impact* I17.3). Determine  $E_{\text{LUMO}}$  of this quinone and then use your results from part (a) to estimate its standard potential. (c) The 1,4-benzoquinone for which  $R_2=R_3=R_5=\text{CH}_3$  and  $R_6=\text{H}$  is a suitable model of plastoquinone, an electron carrier in photosynthesis. Determine  $E_{\text{LUMO}}$  of this quinone and then use your results from part (a) to estimate its standard potential. Is plastoquinone expected to be a better or worse oxidizing agent than ubiquinone?

**10.4** The variation principle can be used to formulate the wavefunctions of electrons in atoms as well as molecules. Suppose that the function  $\psi_{\text{trial}} = N(\alpha)e^{-\alpha r^2}$  with  $N(\alpha)$  the normalization constant and  $\alpha$  an adjustable parameter, is used as a trial wavefunction for the 1s orbital of the hydrogen atom. Show that

$$E(\alpha) = \frac{3\alpha\hbar^2}{2\mu} - 2e^2 \left( \frac{2\alpha}{\pi} \right)^{1/2}$$

where  $e$  is the fundamental charge and  $\mu$  is the reduced mass for the H atom. What is the minimum energy associated with this trial wavefunction?

**10.5** The particle-in-a-box wavefunctions can be used as a crude approximation to the molecular orbitals of conjugated polyenes, when it is known as the *free-electron molecular orbital* (FEMO) method. (a) For a linear conjugated polyene with each of  $N$  carbon atoms contributing an electron in a 2p orbital, the energies  $E_k$  of the resulting  $\pi$  molecular orbitals are given by:

$$E_k = \alpha + 2\beta \cos \frac{k\pi}{N+1} \quad k=1, 2, \dots, N$$

Use this expression to determine a reasonable empirical estimate of the resonance integral  $\beta$  for the homologous series consisting of ethene, butadiene, hexatriene, and octatetraene given that  $\pi^* \leftarrow \pi$  ultraviolet absorptions from the HOMO to the LUMO occur at 61 500, 46 080, 39 750, and 32 900  $\text{cm}^{-1}$ , respectively. (b) Calculate the  $\pi$ -electron delocalization energy,  $E_{\text{deloc}} = E_\pi - n(\alpha + \beta)$ , of octatetraene, where  $E_\pi$  is the total  $\pi$ -electron binding energy and  $n$  is the total number of  $\pi$ -electrons. (c) In the context of this Hückel model, the  $\pi$  molecular orbitals are written as linear combinations of the carbon 2p orbitals. The coefficient of the  $j$ th atomic orbital in the  $k$ th molecular orbital is given by:

$$c_{kj} = \left( \frac{2}{N+1} \right)^{1/2} \sin \frac{jk\pi}{N+1} \quad j=1,2,\dots,N$$

Determine the values of the coefficients of each of the six 2p orbitals in each of the six  $\pi$  molecular orbitals of hexatriene. Match each set of coefficients (that is, each molecular orbital) with a value of the energy calculated with the expression given in part (a) of the molecular orbital. Comment on trends that relate the energy of a molecular orbital with its 'shape', which can be inferred from the magnitudes and signs of the coefficients in the linear combination that describes the molecular orbital.

**10.6** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to:

- Plot the  $1\sigma$  orbital (eqn 10B.2, with the atomic orbitals given in *Brief illustration* 10B.1) for different values of the internuclear distance. Point to the features of the  $1\sigma$  orbital that lead to bonding.
- Plot the  $2\sigma$  orbital (eqn 10B.2, with the atomic orbitals given in *Brief illustration* 10B.1) for different values of the internuclear distance. Point to the features of the  $2\sigma$  orbital that lead to antibonding.

## Mathematical background 6 Matrices

A **matrix** is an array of numbers. We shall consider only square matrices, which have the numbers arranged in the same number of rows and columns. By using matrices, we can manipulate large numbers of ordinary numbers simultaneously. A **determinant** is a particular combination of the numbers that appear in a matrix and is used to manipulate the matrix.

Matrices may be combined together by addition or multiplication according to generalizations of the rules for ordinary numbers. Although we describe below the key algebraic procedures involving matrices, it is important to note that most numerical matrix manipulations are now carried out with mathematical software. You are encouraged to use such software, if it is available to you.

### MB6.1 Definitions

Consider a square matrix  $M$  of  $n^2$  numbers arranged in  $n$  columns and  $n$  rows. These  $n^2$  numbers are the **elements** of the matrix, and may be specified by stating the row,  $r$ , and column,  $c$ , at which they occur. Each element is therefore denoted  $M_{rc}$ . A **diagonal matrix** is a matrix in which the only nonzero elements lie on the major diagonal (the diagonal from  $M_{11}$  to  $M_{nn}$ ). Thus, the matrix

$$D = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

is a  $3 \times 3$  diagonal square matrix. The condition may be written

$$M_{rc} = m_r \delta_{rc} \quad (\text{MB6.1})$$

where  $\delta_{rc}$  is the **Kronecker delta**, which is equal to 1 for  $r=c$  and to 0 for  $r \neq c$ . In the above example,  $m_1=1$ ,  $m_2=2$ , and  $m_3=1$ . The **unit matrix**,  $\mathbf{1}$  (and occasionally  $\mathbf{I}$ ), is a special case of a diagonal matrix in which all on the major diagonal are 1.

The **transpose** of a matrix  $M$  is denoted  $M^T$  and is defined by

$$M_{mn}^T = M_{nm} \quad \text{Transpose} \quad (\text{MB6.2})$$

That is, the element in row  $n$ , column  $m$  of the original matrix becomes the element in row  $m$ , column  $n$  of the transpose (in effect, the elements are reflected across the diagonal). The **determinant**,  $|M|$ , of the matrix  $M$  is a real number arising from a specific procedure for taking sums and differences of products of matrix elements, as described in *The chemist's toolkit* 9B.1. For convenience, that discussion is repeated here. Thus, a  $2 \times 2$  determinant is evaluated as

$$\begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc \quad \text{2} \times \text{2 Determinant} \quad (\text{MB6.3a})$$

and a  $3 \times 3$  determinant is evaluated by expanding it as a sum of  $2 \times 2$  determinants:

$$\begin{vmatrix} a & b & c \\ d & e & f \\ g & h & i \end{vmatrix} = a \begin{vmatrix} e & f \\ h & i \end{vmatrix} - b \begin{vmatrix} d & f \\ g & i \end{vmatrix} + c \begin{vmatrix} d & e \\ g & h \end{vmatrix} \\ = a(ei - fh) - b(di - fg) + c(dh - eg) \quad \text{3} \times \text{3 Determinant} \quad (\text{MB6.3b})$$

Note the sign change in alternate columns ( $b$  occurs with a negative sign in the expansion). An important property of a determinant is that if any two rows or any two columns are interchanged, then the determinant changes sign.

### Brief illustration MB6.1 Matrix manipulations

The following grid illustrates the features so far:

Matrix	Transpose	Determinant
$M$	$M^T$	$ M $
$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$	$\begin{pmatrix} 1 & 3 \\ 2 & 4 \end{pmatrix}$	$\begin{vmatrix} 1 & 2 \\ 3 & 4 \end{vmatrix} = 1 \times 4 - 2 \times 3 = -2$

### MB6.2 Matrix addition and multiplication

Two matrices  $M$  and  $N$  may be added to give the sum  $S=M+N$ , according to the rule

$$S_{rc} = M_{rc} + N_{rc} \quad \text{Matrix addition} \quad (\text{MB6.4})$$

That is, corresponding elements are added. Two matrices may also be multiplied to give the product  $P=MN$  according to the rule

$$P_{rc} = \sum_n M_{rn} N_{nc} \quad \text{Matrix multiplication} \quad (\text{MB6.5})$$

These procedures are illustrated in Fig. MB6.1. It should be noticed that in general  $MN \neq NM$ , and matrix multiplication is in general non-commutative (that is, the result depends on the order of multiplication).

### Brief illustration MB6.2 Matrix addition and multiplication

Consider the matrices

$$M = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \quad \text{and} \quad N = \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix}$$

Their sum is

$$S = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} + \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 6 & 8 \\ 10 & 12 \end{pmatrix}$$

and their product is

$$P = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} 5 & 6 \\ 7 & 8 \end{pmatrix} = \begin{pmatrix} 1 \times 5 + 2 \times 7 & 1 \times 6 + 2 \times 8 \\ 3 \times 5 + 4 \times 7 & 3 \times 6 + 4 \times 8 \end{pmatrix} = \begin{pmatrix} 19 & 22 \\ 43 & 50 \end{pmatrix}$$

Figure MB6.1 A diagrammatic representation of (a) matrix addition, (b) matrix multiplication.

The **inverse** of a matrix  $M$  is denoted  $M^{-1}$ , and is defined so that

$$MM^{-1} = M^{-1}M = 1 \quad \text{Inverse} \quad (\text{MB6.6})$$

The inverse of a matrix is best constructed by using mathematical software and the tedious analytical approach is rarely necessary.

**Brief illustration MB6.3** Inversion

Mathematical software gives the following inversion of  $M$ :

Matrix	Inverse
$M$	$M^{-1}$
$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$	$\begin{pmatrix} -2 & 1 \\ 3 & -1 \\ 2 & -2 \end{pmatrix}$

**MB6.3 Eigenvalue equations**

An **eigenvalue equation** is an equation of the form

$$Mx = \lambda x \quad \text{Eigenvalue equation} \quad (\text{MB6.7a})$$

where  $M$  is a square matrix with  $n$  rows and  $n$  columns,  $\lambda$  is a constant, the **eigenvalue**, and  $x$  is the **eigenvector**, an  $n \times 1$

(column) matrix that satisfies the conditions of the eigenvalue equation and has the form:

$$x = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix}$$

In general, there are  $n$  eigenvalues  $\lambda^{(i)}$ ,  $i=1, 2, \dots, n$ , and  $n$  corresponding eigenvectors  $x^{(i)}$ . We write eqn MB6.8a as (noting that  $1x=x$ )

$$(M - \lambda 1)x = 0 \quad (\text{MB6.7b})$$

Equation MB6.7b has a solution only if the determinant  $|M - \lambda 1|$  of the coefficients of the matrix  $M - \lambda 1$  is zero. It follows that the  $n$  eigenvalues may be found from the solution of the **secular equation**:

$$|M - \lambda 1| = 0 \quad (\text{MB6.8})$$

If the inverse of the matrix  $M - \lambda 1$  exists, then, from eqn MB6.7b,  $(M - \lambda 1)^{-1}(M - \lambda 1)x = x = 0$ , a trivial solution. For a nontrivial solution,  $(M - \lambda 1)^{-1}$  must not exist, which is the case if eqn MB6.9 holds.

**Brief illustration MB6.4** Simultaneous equations

Once again we use the matrix  $M$  in *Brief illustration* MB6.1, and write eqn MB6.7a as

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \lambda \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \text{ rearranged into } \begin{pmatrix} 1-\lambda & 2 \\ 3 & 4-\lambda \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = 0$$

From the rules of matrix multiplication, the latter form expands into

$$\begin{pmatrix} (1-\lambda)x_1 + 2x_2 \\ 3x_1 + (4-\lambda)x_2 \end{pmatrix} = 0$$

which is simply a statement of the two simultaneous equations

$$(1-\lambda)x_1 + 2x_2 = 0 \text{ and } 3x_1 + (4-\lambda)x_2 = 0$$

The condition for these two equations to have solutions is

$$|M - \lambda 1| = \begin{vmatrix} 1-\lambda & 2 \\ 3 & 4-\lambda \end{vmatrix} = (1-\lambda)(4-\lambda) - 6 = 0$$

This condition corresponds to the quadratic equation

$$\lambda^2 - 5\lambda - 2 = 0$$

with solutions  $\lambda = +5.372$  and  $\lambda = -0.372$ , the two eigenvalues of the original equation.

The  $n$  eigenvalues found by solving the secular equations are used to find the corresponding eigenvectors. To do so, we begin by considering an  $n \times n$  matrix  $X$  which will be formed from the eigenvectors corresponding to all the eigenvalues. Thus, if the eigenvalues are  $\lambda_1, \lambda_2, \dots$ , and the corresponding eigenvectors are

$$\mathbf{x}^{(1)} = \begin{pmatrix} x_1^{(1)} \\ x_2^{(1)} \\ \vdots \\ x_n^{(1)} \end{pmatrix} \quad \mathbf{x}^{(2)} = \begin{pmatrix} x_1^{(2)} \\ x_2^{(2)} \\ \vdots \\ x_n^{(2)} \end{pmatrix} \quad \dots \quad \mathbf{x}^{(n)} = \begin{pmatrix} x_1^{(n)} \\ x_2^{(n)} \\ \vdots \\ x_n^{(n)} \end{pmatrix} \quad (\text{MB6.9a})$$

the matrix  $X$  is

$$X = (\mathbf{x}^{(1)} \mathbf{x}^{(2)} \dots \mathbf{x}^{(n)}) = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} & \dots & x_1^{(n)} \\ x_2^{(1)} & x_2^{(2)} & \dots & x_2^{(n)} \\ \vdots & \vdots & \dots & \vdots \\ x_n^{(1)} & x_n^{(2)} & \dots & x_n^{(n)} \end{pmatrix} \quad (\text{MB6.9b})$$

Similarly, we form an  $n \times n$  matrix  $A$  with the eigenvalues  $\lambda$  along the diagonal and zeroes elsewhere:

$$A = \begin{pmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & \lambda_n \end{pmatrix} \quad (\text{MB6.10})$$

Now all the eigenvalue equations  $M\mathbf{x}^{(i)} = \lambda_i \mathbf{x}^{(i)}$  may be combined into the single matrix equation

$$MX = XA \quad (\text{MB6.11})$$

**Brief illustration MB6.5 Eigenvalue equations**

In *Brief illustration MB6.4* we established that if  $M = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$  then  $\lambda_1 = +5.372$  and  $\lambda_2 = -0.372$ , with eigenvectors  $\mathbf{x}^{(1)} = \begin{pmatrix} x_1^{(1)} \\ x_2^{(1)} \end{pmatrix}$  and  $\mathbf{x}^{(2)} = \begin{pmatrix} x_1^{(2)} \\ x_2^{(2)} \end{pmatrix}$ . We form

$$X = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} \quad A = \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix}$$

The expression  $MX = XA$  becomes

$$\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} = \begin{pmatrix} x_1^{(1)} & x_1^{(2)} \\ x_2^{(1)} & x_2^{(2)} \end{pmatrix} \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix}$$

which expands to

$$\begin{pmatrix} x_1^{(1)} + 2x_2^{(1)} & x_1^{(2)} + 2x_2^{(2)} \\ 3x_1^{(1)} + 4x_2^{(1)} & 3x_1^{(2)} + 4x_2^{(2)} \end{pmatrix} = \begin{pmatrix} 5.372x_1^{(1)} & -0.372x_1^{(2)} \\ 5.372x_2^{(1)} & -0.372x_2^{(2)} \end{pmatrix}$$

This is a compact way of writing the four equations

$$\begin{aligned} x_1^{(1)} + 2x_2^{(1)} &= 5.372x_1^{(1)} & x_1^{(2)} + 2x_2^{(2)} &= -0.372x_1^{(2)} \\ 3x_1^{(1)} + 4x_2^{(1)} &= 5.372x_2^{(1)} & 3x_1^{(2)} + 4x_2^{(2)} &= -0.372x_2^{(2)} \end{aligned}$$

corresponding to the two original simultaneous equations and their two roots.

Finally, we form  $X^{-1}$  from  $X$  and multiply eqn MB6.13 by it from the left:

$$X^{-1}MX = X^{-1}XA = A \quad (\text{MB6.12})$$

A structure of the form  $X^{-1}MX$  is called a **similarity transformation**. In this case the similarity transformation  $X^{-1}MX$  makes  $M$  diagonal (because  $A$  is diagonal). It follows that if the matrix  $X$  that causes  $X^{-1}MX$  to be diagonal is known, then the problem is solved: the diagonal matrix so produced has the eigenvalues as its only nonzero elements, and the matrix  $X$  used to bring about the transformation has the corresponding eigenvectors as its columns. As will be appreciated once again, the solutions of eigenvalue equations are best found by using mathematical software.

**Brief illustration MB6.6 Similarity transformation**

To apply the similarity transformation, eqn MB6.12, to the matrix  $\begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$  from *Brief illustration MB6.1* it is best to use mathematical software to find the form of  $X$ . The result is

$$X = \begin{pmatrix} 0.416 & 0.825 \\ 0.909 & -0.566 \end{pmatrix} \quad X^{-1} = \begin{pmatrix} 0.574 & 0.837 \\ 0.922 & -0.422 \end{pmatrix}$$

This result can be verified by carrying out the multiplication

$$\begin{aligned} X^{-1}MX &= \begin{pmatrix} 0.574 & 0.837 \\ 0.922 & -0.422 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \begin{pmatrix} 0.416 & 0.825 \\ 0.909 & -0.566 \end{pmatrix} \\ &= \begin{pmatrix} 5.372 & 0 \\ 0 & -0.372 \end{pmatrix} \end{aligned}$$

The result is indeed the diagonal matrix  $A$  calculated in *Brief illustration MB6.4*. It follows that the eigenvectors  $\mathbf{x}^{(1)}$  and  $\mathbf{x}^{(2)}$  are

$$\mathbf{x}^{(1)} = \begin{pmatrix} 0.416 \\ 0.909 \end{pmatrix} \quad \mathbf{x}^{(2)} = \begin{pmatrix} 0.825 \\ -0.566 \end{pmatrix}$$

# CHAPTER 11

## Molecular symmetry

In this chapter we sharpen the concept of 'shape' into a precise definition of 'symmetry', and show that symmetry may be discussed systematically.

### 11A Symmetry elements

We see how to classify any molecule according to its symmetry and how to use this classification to discuss the polarity and chirality of molecules.

### 11B Group theory

The systematic treatment of symmetry is 'group theory'. We show that it is possible to represent the outcome of symmetry operations (such as rotations and reflections) by matrices. That step allows us to express symmetry operations numerically and therefore to perform numerical manipulations. One

important outcome is the ability to classify various combinations of atomic orbitals according to their symmetries. It also introduces the hugely important concept of a 'character table', which is the concept most widely employed in chemical applications of group theory.

### 11C Applications of symmetry

The symmetry analysis described in the preceding two Topics is now put to use. We see that it provides simple criteria for deciding whether certain integrals necessarily vanish. One important integral is the overlap integral between two orbitals. By knowing which atomic orbitals may have nonzero overlap, we can decide which ones can contribute to molecular orbitals. We also see how to select linear combinations of atomic orbitals that match the symmetry of the nuclear framework. Finally, by considering the symmetry properties of integrals, we see that it is possible to derive the selection rules that govern spectroscopic transitions.

### ► Why do you need to know this material?

Symmetry arguments can be used to make immediate assessments of the properties of molecules, and when expressed quantitatively (Topic 11B) can be used to save a great deal of calculation.

### ► What is the key idea?

Molecules can be classified into groups according to their symmetry elements.

### ► What do you need to know already?

This Topic does not draw on others directly, but it will be useful to be aware of the shapes of a variety of simple molecules and ions encountered in introductory chemistry courses.

Some objects are ‘more symmetrical’ than others. A sphere is more symmetrical than a cube because it looks the same after it has been rotated through any angle about any diameter. A cube looks the same only if it is rotated through certain angles about specific axes, such as  $90^\circ$ ,  $180^\circ$ , or  $270^\circ$  about an axis passing through the centres of any of its opposite faces (Fig. 11A.1), or by  $120^\circ$  or  $240^\circ$  about an axis passing through any of its opposite corners. Similarly, an  $\text{NH}_3$  molecule is ‘more symmetrical’ than an  $\text{H}_2\text{O}$  molecule because  $\text{NH}_3$  looks the same after rotations of  $120^\circ$  or  $240^\circ$  about the axis shown in Fig. 11A.2, whereas  $\text{H}_2\text{O}$  looks the same only after a rotation of  $180^\circ$ .

This Topic puts these intuitive notions on a more formal foundation. In it, we see that molecules can be grouped together according to their symmetry, with the tetrahedral species  $\text{CH}_4$  and  $\text{SO}_4^{2-}$  in one group and the pyramidal species  $\text{NH}_3$  and  $\text{SO}_3^{2-}$  in another. It turns out that molecules in the same group share certain physical properties, so powerful predictions can be made about whole series of molecules once we know the group to which they belong.

Figure 11A.1 Some of the symmetry elements of a cube. The twofold, threefold, and fourfold axes are labelled with the conventional symbols.

Figure 11A.2 (a) An  $\text{NH}_3$  molecule has a threefold ( $C_3$ ) axis and (b) an  $\text{H}_2\text{O}$  molecule has a twofold ( $C_2$ ) axis. Both have other symmetry elements too.

We have slipped in the term ‘group’ in its conventional sense. In fact, a group in mathematics has a precise formal significance and considerable power and gives rise to the name ‘group theory’ for the quantitative study of symmetry. This power is revealed in Topic 11B.

## 11A.1 Symmetry operations and symmetry elements

An action that leaves an object looking the same after it has been carried out is called a **symmetry operation**. Typical symmetry operations include rotations, reflections, and inversions. There is a corresponding **symmetry element** for each symmetry operation, which is the point, line, or plane with respect to which the symmetry operation is performed. For instance, a rotation (a symmetry operation) is carried out around an axis (the corresponding symmetry element). We shall see that we can classify molecules by identifying all their symmetry elements, and grouping together molecules that possess the same set of symmetry elements. This procedure, for example, puts the trigonal pyramidal species  $\text{NH}_3$  and  $\text{SO}_3^{2-}$  into one group and the angular species  $\text{H}_2\text{O}$  and  $\text{SO}_2$  into another group.

An  **$n$ -fold rotation** (the operation) about an  **$n$ -fold axis of symmetry**,  $C_n$  (the corresponding element), is a rotation through  $360^\circ/n$ . An  $\text{H}_2\text{O}$  molecule has one twofold axis,  $C_2$ . An  $\text{NH}_3$  molecule has one threefold axis,  $C_3$ , with which is associated two symmetry operations, one being  $120^\circ$  rotation in a clockwise sense and the other  $120^\circ$  rotation in an anticlockwise sense. There is only one twofold rotation associated with a  $C_2$  axis because clockwise and anticlockwise  $180^\circ$  rotations are identical. A pentagon has a  $C_5$  axis, with two rotations (one clockwise, the other anticlockwise) through  $72^\circ$  associated with it. It also has an axis denoted  $C_5^2$ , corresponding to two successive  $C_5$  rotations; there are two such operations, one through  $144^\circ$  in a clockwise sense and the other through  $144^\circ$  in an anticlockwise sense. A cube has three  $C_4$  axes, four  $C_3$  axes, and six  $C_2$  axes. However, even this high symmetry is exceeded by a sphere, which possesses an infinite number of symmetry axes (along any diameter) of all possible integral values of  $n$ . If a molecule possesses several rotation axes, then the one (or more) with the greatest value of  $n$  is called the **principal axis**. The principal axis of a benzene molecule is the sixfold axis perpendicular to the hexagonal ring (1).

1 Benzene,  $\text{C}_6\text{H}_6$

A **reflection** (the operation) in a **mirror plane**,  $\sigma$  (the element), may contain the principal axis of a molecule or be perpendicular to it. If the plane contains the principal axis, it is called ‘vertical’ and denoted  $\sigma_v$ . An  $\text{H}_2\text{O}$  molecule has two vertical planes of symmetry (Fig. 11A.3) and an  $\text{NH}_3$  molecule has three. A vertical mirror plane that bisects the angle between two  $C_2$  axes is called a ‘dihedral plane’ and is denoted  $\sigma_d$  (Fig. 11A.4). When the plane of symmetry is perpendicular to the principal axis it is called ‘horizontal’ and denoted  $\sigma_h$ . A  $\text{C}_6\text{H}_6$  molecule has a  $C_6$  principal axis and a horizontal mirror plane (as well as several other symmetry elements).

In an **inversion** (the operation) through a **centre of symmetry**,  $i$  (the element), we imagine taking each point in a molecule, moving it to the centre of the molecule, and then moving it out the same distance on the other side; that is, the point  $(x, y, z)$  is taken into the point  $(-x, -y, -z)$ . Neither an  $\text{H}_2\text{O}$  molecule nor an  $\text{NH}_3$  molecule has a centre of inversion, but a sphere and a cube do have one. A  $\text{C}_6\text{H}_6$  molecule does have a centre of inversion, so does a regular octahedron (Fig. 11A.5); a regular tetrahedron and a  $\text{CH}_4$  molecule do not.

An  **$n$ -fold improper rotation** (the operation) about an  **$n$ -fold axis of improper rotation** or an  **$n$ -fold improper rotation axis**,  $S_n$ , (the symmetry element) is composed of two successive transformations. The first component is a rotation through  $360^\circ/n$ , and the second is a reflection through a plane perpendicular to the axis of that rotation; neither operation alone needs to be a symmetry operation. A  $\text{CH}_4$  molecule has three  $S_4$  axes (Fig. 11A.6).

Figure 11A.3 An  $\text{H}_2\text{O}$  molecule has two mirror planes. They are both vertical (that is, contain the principal axis), so are denoted  $\sigma_v$  and  $\sigma'_v$ .

Figure 11A.4 Dihedral mirror planes ( $\sigma_d$ ) bisect the  $C_2$  axes perpendicular to the principal axis.

Figure 11A.5 A regular octahedron has a centre of inversion ( $i$ ).

Figure 11A.6 (a) A  $\text{CH}_4$  molecule has a fourfold improper rotation axis ( $S_4$ ): the molecule is indistinguishable after a  $90^\circ$  rotation followed by a reflection across the horizontal plane, but neither operation alone is a symmetry operation. (b) The staggered form of ethane has an  $S_6$  axis composed of a  $60^\circ$  rotation followed by a reflection.

The **identity**,  $E$ , consists of doing nothing; the corresponding symmetry element is the entire object. Because every molecule is indistinguishable from itself if nothing is done to it, every object possesses at least the identity element. One reason for including the identity is that some molecules have only this symmetry element (2).

#### Brief illustration 11A.1 Symmetry elements

To identify the symmetry elements of a naphthalene molecule (3) we first note that, like all molecules, it has the identity element,  $E$ . There is one twofold axis of rotation,  $C_2$ , perpendicular to the plane and two others,  $C_2'$ , lying in the plane. There is a mirror plane in the plane of the molecule,  $\sigma_h$ , and two perpendicular planes,  $\sigma_v$ , containing the  $C_2$  rotation axis. There is also a centre of inversion,  $i$ , through the mid-point of

the molecule. Note that some of these elements are implied by others: the centre of inversion, for instance, is implied by a  $\sigma_v$  plane and a  $C_2'$  axis.

3 Naphthalene,  $\text{C}_{10}\text{H}_8$

**Self-test 11A.1** Identify the symmetry elements of an  $\text{SF}_6$  molecule.

Answer:  $E, 3S_4, 3C_4, 6C_2, 4S_6, 4C_3, 3\sigma_h, 6\sigma_d, i$

## 11A.2 The symmetry classification of molecules

The classification of objects according to symmetry elements corresponding to operations that leave at least one common point unchanged gives rise to the **point groups**. There are five kinds of symmetry operation (and five kinds of symmetry element) of this kind. When we consider crystals (Topic 18A), we meet symmetries arising from translation through space. These more extensive groups are called **space groups**.

To classify molecules according to their symmetries, we list their symmetry elements and collect together molecules with the same list of elements. The name of the group to which a molecule belongs is determined by the symmetry elements it possesses. There are two systems of notation (Table 11A.1). The **Schoenflies system** (in which a name looks like  $C_{4v}$ ) is more common for the discussion of individual molecules, and the **Hermann–Mauguin system**, or **International system** (in which a name looks like  $4mm$ ), is used almost exclusively in the discussion of crystal symmetry. The identification of a molecule's point group according to the Schoenflies system is simplified by referring to the flow diagram in Fig. 11A.7 and the shapes shown in Fig. 11A.8.

#### Brief illustration 11A.2 Symmetry classification

To identify the point group to which a ruthenocene molecule (4) belongs we use the flow diagram in Fig. 11A.7. The path to trace is shown by a blue line; it ends at  $D_{nh}$ . Because

the molecule has a fivefold axis, it belongs to the group  $D_{5h}$ . If the rings were staggered, as they are in an excited state of ferrocene that lies  $4 \text{ kJ mol}^{-1}$  above the ground state (5), the horizontal reflection plane would be absent, but dihedral planes would be present.

4 Ruthenocene,  $\text{Ru}(\text{Cp})_2$

5 Ferrocene,  $\text{Fe}(\text{Cp})_2$   
(excited state)

**Self-test 11A.2** Classify the pentagonal antiprismatic excited state of ferrocene (5).

Answer:  $D_{5d}$

**Table 11A.1** The notations for point groups\*

$C_i$	$\bar{1}$				
$C_s$	$m$				
$C_1$	1	$C_2$	2	$C_3$	3
		$C_4$	4	$C_6$	6
		$C_{2v}$	$2mm$	$C_{3v}$	$3m$
		$C_{4v}$	$4mm$	$C_{6v}$	$6mm$
		$C_{2h}$	$2/m$	$C_{3h}$	$\bar{6}$
		$C_{4h}$	$4/m$	$C_{6h}$	$6/m$
		$D_2$	$222$	$D_3$	32
		$D_4$	$422$	$D_6$	$622$

$O$	432	$O_h$	$m\bar{3}m$		

\* Schoenflies notation in black, Hermann–Mauguin (International system) in blue. In the Hermann–Mauguin system, a number  $n$  denotes the presence of an  $n$ -fold axis and  $m$  denotes a mirror plane. A slash (/) indicates that the mirror plane is perpendicular to the symmetry axis. It is important to distinguish symmetry elements of the same type but of different classes, as in  $4/mmm$ , in which there are three classes of mirror plane. A bar over a number indicates that the element is combined with an inversion. The only groups listed here are the so-called ‘crystallographic point groups’.

**Figure 11A.7** A flow diagram for determining the point group of a molecule. Start at the top and answer the question posed in each diamond (Y=yes, N=no).

### (a) The groups $C_1$ , $C_i$ , and $C_s$

Name	Elements
$C_1$	$E$
$C_i$	$E, i$
$C_s$	$E, \sigma$

A molecule belongs to the group  $C_1$  if it has no element other than the identity. It belongs to  $C_i$  if it has the identity and the inversion alone, and to  $C_s$  if it has the identity and a mirror plane alone.

### Brief illustration 11A.3 $C_1$ , $C_i$ , and $C_s$

The  $\text{CBrClFI}$  molecule (2) has only the identity element, and so belongs to the group  $C_1$ . Meso-tartaric acid (6) has the identity and inversion elements, and so belongs to the group  $C_i$ . Quinoline (7) has the elements ( $E, \sigma$ ), and so belongs to the group  $C_s$ .

$n =$	2	3	4	5	6	$\infty$
$C_n$						
$D_n$						
$C_{nv}$	 Pyramid					 Cone
$C_{nh}$						
$D_{nh}$	 Plane or bipyramid					
$D_{nd}$						
$S_{2n}$						

Figure 11A.8 A summary of the shapes corresponding to different point groups. The group to which a molecule belongs can often be identified from this diagram without going through the formal procedure in Fig. 11A.7.

### (b) The groups $C_n$ , $C_{nv}$ , and $C_{nh}$

A molecule belongs to the group  $C_n$  if it possesses an  $n$ -fold axis. Note that symbol  $C_n$  is now playing a triple role: as the label of a symmetry element, a symmetry operation, and a group. If in addition to the identity and a  $C_n$  axis a molecule has  $n$  vertical mirror planes  $\sigma_v$ , then it belongs to the group  $C_{nv}$ . Objects that in addition to the identity and an  $n$ -fold principal axis also have a horizontal mirror plane  $\sigma_h$  belong to the groups  $C_{nh}$ . The presence of certain symmetry elements may be implied by the presence of others: thus, in  $C_{2h}$  the elements  $C_2$  and  $\sigma_h$  jointly imply the presence of a centre of inversion (Fig. 11A.9). Note also that the tables specify the *elements*, not the *operations*: for instance, there are two operations associated with a single  $C_3$  axis (rotations by  $+120^\circ$  and  $-120^\circ$ ).

Name	Elements
$C_n$	$E, C_n$
$C_{nv}$	$E, C_n, n\sigma_v$
$C_{nh}$	$E, C_n, \sigma_h$

Figure 11A.9 The presence of a twofold axis and a horizontal mirror plane jointly imply the presence of a centre of inversion in the molecule.

#### Brief illustration 11A.4 $C_n$ , $C_{nv}$ , and $C_{nh}$

An  $\text{H}_2\text{O}_2$  molecule (9) has the symmetry elements  $E$  and  $C_2$ , so belongs to the group  $C_2$ . An  $\text{H}_2\text{O}$  molecule has the symmetry elements  $E$ ,  $C_2$ , and  $2\sigma_v$ , so it belongs to the group  $C_{2v}$ . An  $\text{NH}_3$  molecule has the elements  $E$ ,  $C_3$ , and  $3\sigma_v$ , so it belongs to the group  $C_{3v}$ . A heteronuclear diatomic molecule such as  $\text{HCl}$  belongs to the group  $C_{\infty v}$  because rotations around the axis by any angle and reflections in all the infinite number of planes that contain the axis are symmetry operations. Other members of the group  $C_{\infty v}$  include the linear  $\text{OCS}$  molecule and a cone. The molecule *trans*- $\text{CHCl}=\text{CHCl}$  (10) has the elements  $E$ ,  $C_2$ , and  $\sigma_h$ , so belongs to the group  $C_{2h}$ .

9 Hydrogen peroxide,  $\text{H}_2\text{O}_2$

10 *trans*- $\text{CHCl}=\text{CHCl}$

**Self-test 11A.4** Identify the group to which the molecule  $\text{B}(\text{OH})_3$  in the conformation shown in (11) belongs.

11  $\text{B}(\text{OH})_3$

Answer:  $C_{3h}$

### (c) The groups $D_n$ , $D_{nh}$ , and $D_{nd}$

We see from Fig. 11A.7 that a molecule that has an  $n$ -fold principal axis and  $n$  twofold axes perpendicular to  $C_n$  belongs to the group  $D_n$ . A molecule belongs to  $D_{nh}$  if it also possesses a horizontal mirror plane.  $D_{\infty h}$  is also the group of the linear  $\text{OCO}$  and  $\text{HCCH}$  molecules, and of a uniform cylinder. A molecule belongs to the group  $D_{nd}$  if in addition to the elements of  $D_n$  it possesses  $n$  dihedral mirror planes  $\sigma_d$ .

Name	Elements
$D_n$	$E, C_n, nC_2'$
$D_{nh}$	$E, C_n, nC_2', \sigma_h$
$D_{nd}$	$E, C_n, nC_2', n\sigma_d$

#### Brief illustration 11A.5 $D_n$ , $D_{nh}$ , and $D_{nd}$

The planar trigonal  $\text{BF}_3$  molecule has the elements  $E$ ,  $C_3$ ,  $3C_2$ , and  $\sigma_h$  (with one  $C_2$  axis along each  $\text{B}-\text{F}$  bond), so belongs to  $D_{3h}$  (12). The  $\text{C}_6\text{H}_6$  molecule has the elements  $E$ ,  $C_6$ ,  $3C_2$ ,  $3C_2'$ , and  $\sigma_h$  together with some others that these elements imply, so it belongs to  $D_{6h}$ . Three of the  $C_2$  axes bisect  $\text{C}-\text{C}$  bonds and the other three pass through vertices of the hexagon formed by the carbon framework of the molecule. The prime on  $3C_2'$  indicates that the three  $C_2$  axes are different from the other three  $C_2$  axes. All homonuclear diatomic molecules, such as  $\text{N}_2$ , belong to the group  $D_{\infty h}$  because all rotations around the axis are symmetry operations, as are end-to-end rotation and end-to-end reflection. Another example of a  $D_{nh}$  species is (13). The twisted,  $90^\circ$  allene (14) belongs to  $D_{2d}$ .

12 Boron trifluoride,  $\text{BF}_3$

13 Phosphorus pentachloride,  $\text{PCl}_5$  ( $D_{3h}$ )

14 Allene,  $\text{C}_3\text{H}_4$  ( $D_{2d}$ )

**Self-test 11A.5** Identify the groups to which (a) the tetrachloroaurate(III) ion (15) and (b) the staggered conformation of ethane (16) belong.

15 Tetrachloroaurate(III) ion,  $[\text{AuCl}_4]^-$

16 Ethane,  $\text{C}_2\text{H}_6$  ( $D_{3d}$ )

Answer: (a)  $D_{4h}$ , (b)  $D_{3d}$

### (d) The groups $S_n$

Molecules that have not been classified into one of the groups mentioned so far, but which possess one  $S_n$  axis, belong to the group  $S_n$ . Note that the group  $S_2$  is the same as  $C_i$ , so such a molecule will already have been classified as  $C_i$ .

Name	Elements
$S_n$	$E, S_n$ and not previously classified

Brief illustration 11A.6  $S_n$ 

Tetraphenylmethane (17) belongs to the point group  $S_4$ . Molecules belonging to  $S_n$  with  $n > 4$  are rare.

17 Tetraphenylmethane,  $C(C_6H_5)_4$  ( $S_4$ )

**Self-test 11A.6** Identify the group to which the ion in (18) belongs.

18  $N(CH_2CH(CH_3)CH(CH_3)CH_2)_2^+$

Answer:  $S_4$

## (e) The cubic groups

A number of very important molecules possess more than one principal axis. Most belong to the **cubic groups**, and in particular to the **tetrahedral groups**  $T$ ,  $T_d$ , and  $T_h$  (Fig. 11A.10a) or to the **octahedral groups**  $O$  and  $O_h$  (Fig. 11A.10b). A few icosahedral (20-faced) molecules belonging to the **icosahedral group**,  $I$  (Fig. 11A.10c), are also known. The groups  $T_d$  and  $O_h$  are the groups of the regular tetrahedron and the regular octahedron, respectively. If the object possesses the rotational symmetry of the tetrahedron or the octahedron, but none of their planes of reflection, then it belongs to the simpler groups  $T$  or  $O$  (Fig. 11A.11). The group  $T_h$  is based on  $T$  but also contains a centre of inversion (Fig. 11A.12).

Name	Elements
$T$	$E, 4C_3, 3C_2$
$T_d$	$E, 3C_2, 4C_3, 3S_4, 6\sigma_d$
$T_h$	$E, 3C_2, 4C_3, i, 4S_6, 3\sigma_h$

Name	Elements
$O$	$E, 3C_4, 4C_3, 6C_2$
$O_h$	$E, 3S_4, 3C_4, 6C_2, 4S_6, 4C_3, 3\sigma_h, 6\sigma_d, i$
$I$	$E, 6C_5, 10C_3, 15C_2$
$I_h$	$E, 6S_{10}, 10S_6, 6C_5, 10C_3, 15C_2, 15\sigma, i$

## Brief illustration 11A.7 The cubic groups

The molecules  $CH_4$  and  $SF_6$  belong, respectively, to the groups  $T_d$  and  $O_h$ . Molecules belonging to the icosahedral group  $I$  include some of the boranes and buckminsterfullerene,  $C_{60}$  (19). The molecules shown in Fig. 11A.11 belong to the groups  $T$  and  $O$ , respectively.

19 Buckminsterfullerene,  $C_{60}$  ( $I$ )

**Self-test 11A.7** Identify the group to which the object shown in 20 belongs.

20

Answer:  $T_h$

**Figure 11A.10** (a) Tetrahedral, (b) octahedral, and (c) icosahedral molecules are drawn in a way that shows their relation to a cube: they belong to the cubic groups  $T_d$ ,  $O_h$ , and  $I_h$ , respectively.

Figure 11A.11 Shapes corresponding to the point groups (a)  $T$  and (b)  $O$ . The presence of the decorated slabs reduces the symmetry of the object from  $T_d$  and  $O_h$ , respectively.

Figure 11A.12 The shape of an object belonging to the group  $T_h$ .

### (f) The full rotation group

The **full rotation group**,  $R_3$  (the 3 refers to rotation in three dimensions), consists of an infinite number of rotation axes with all possible values of  $n$ . A sphere and an atom belong to  $R_3$ , but no molecule does. Exploring the consequences of  $R_3$  is a very important way of applying symmetry arguments to atoms, and is an alternative approach to the theory of orbital angular momentum.

Name	Elements
$R_3$	$E, \infty C_2, \infty C_3, \dots$

## 11A.3 Some immediate consequences of symmetry

Some statements about the properties of a molecule can be made as soon as its point group has been identified.

### (a) Polarity

A **polar molecule** is one with a permanent electric dipole moment (HCl,  $O_3$ , and  $NH_3$  are examples). If the molecule

belongs to the group  $C_n$  with  $n > 1$ , it cannot possess a charge distribution with a dipole moment perpendicular to the symmetry axis because the symmetry of the molecule implies that any dipole that exists in one direction perpendicular to the axis is cancelled by an opposing dipole (Fig. 11A.13a). For example, the perpendicular component of the dipole associated with one O–H bond in  $H_2O$  is cancelled by an equal but opposite component of the dipole of the second O–H bond, so any dipole that the molecule has must be parallel to the twofold symmetry axis. However, as the group makes no reference to operations relating the two ends of the molecule, a charge distribution may exist that results in a dipole along the axis (Fig. 11A.13b), and  $H_2O$  has a dipole moment parallel to its twofold symmetry axis.

The same remarks apply generally to the group  $C_{nv}$ , so molecules belonging to any of the  $C_{nv}$  groups may be polar. In all the other groups, such as  $C_{3h}$ ,  $D$ , etc., there are symmetry operations that take one end of the molecule into the other. Therefore, as well as having no dipole perpendicular to the axis, such molecules can have none along the axis, for otherwise these additional operations would not be symmetry operations. We can conclude that *only molecules belonging to the groups  $C_n$ ,  $C_{nv}$ , and  $C_s$  may have a permanent electric dipole moment*. For  $C_n$  and  $C_{nv}$ , that dipole moment must lie along the symmetry axis.

#### Brief illustration 11A.8 Polar molecules

Ozone,  $O_3$ , which is angular and belongs to the group  $C_{2v}$ , may be polar (and is), but carbon dioxide,  $CO_2$ , which is linear and belongs to the group  $D_{\infty h}$ , is not.

**Self-test 11A.8** Is tetraphenylmethane polar?

Answer: No ( $S_4$ )

Figure 11A.13 (a) A molecule with a  $C_n$  axis cannot have a dipole perpendicular to the axis, but (b) it may have one parallel to the axis. The arrows represent local contributions to the overall electric dipole, such as may arise from bonds between pairs of neighbouring atoms with different electronegativities.

**(b) Chirality**

A **chiral molecule** (from the Greek word for 'hand') is a molecule that cannot be superimposed on its mirror image. An **achiral molecule** is a molecule that can be superimposed on its mirror image. Chiral molecules are **optically active** in the sense that they rotate the plane of polarized light. A chiral molecule and its mirror-image partner constitute an **enantiomeric pair** of isomers and rotate the plane of polarization in equal but opposite directions.

A molecule may be chiral, and therefore optically active, only if it does not possess an axis of improper rotation,  $S_n$ . We need to be aware that an  $S_n$  improper rotation axis may be present under a different name, and be implied by other symmetry elements that are present. For example, molecules belonging to the groups  $C_{nh}$  possess an  $S_n$  axis implicitly because they possess both  $C_n$  and  $\sigma_h$ , which are the two components of an improper rotation axis. Any molecule containing a centre of inversion,  $i$ , also possesses an  $S_2$  axis, because  $i$  is equivalent to  $C_2$  in conjunction with  $\sigma_h$ , and that combination of elements is  $S_2$  (Fig. 11A.14). It follows that all molecules with centres of inversion are achiral and hence optically inactive. Similarly, because  $S_1 = \sigma$ , it follows that any molecule with a mirror plane is achiral.

**Figure 11A.14** Some symmetry elements are implied by the other symmetry elements in a group. Any molecule containing an inversion also possesses at least an  $S_2$  element because  $i$  and  $S_2$  are equivalent.

**Brief illustration 11A.9** Chiral molecules

A molecule may be chiral if it does not have a centre of inversion or a mirror plane, which is the case with the amino acid alanine (21), but not with glycine (22). However, a molecule may be achiral even though it does not have a centre of inversion. For example, the  $S_4$  species (18) is achiral and optically inactive: though it lacks  $i$  (that is,  $S_2$ ) it does have an  $S_4$  axis.

**21** L-Alanine,  $\text{NH}_2\text{CH}(\text{CH}_3)\text{COOH}$

**22** Glycine,  $\text{NH}_2\text{CH}_2\text{COOH}$

**Self-test 11A.9** Is tetraphenylmethane chiral?

Answer: No ( $S_4$ )

**Checklist of concepts**

- 1. A **symmetry operation** is an action that leaves an object looking the same after it has been carried out.
- 2. A **symmetry element** is a point, line, or plane with respect to which a symmetry operation is performed.
- 3. The **notation** for point groups commonly used for molecules and solids is summarized in Table 11A1.
- 4. To be **polar** a molecule must belong to  $C_n$ ,  $C_{nv}$  or  $C_s$  (and have no higher symmetry).
- 5. A molecule may be **chiral** only if it does not possess an axis of improper rotation,  $S_n$ .

## Checklist of operations and elements

Symmetry operation	Symbol	Symmetry element
$n$ -Fold rotation	$C_n$	$n$ -fold axis of rotation
Reflection	$\sigma$	mirror plane
Inversion	$i$	centre of symmetry
$n$ -Fold improper rotation	$S_n$	$n$ -fold improper axis of rotation
Identity	$E$	entire object

### ► Why do you need to know this material?

Group theory puts qualitative ideas about symmetry on to a systematic basis that can be applied to a wide variety of calculations; it is used to draw conclusions that might not be immediately obvious and as a result can greatly simplify calculations. It is also the basis of the labelling of atomic and molecular orbitals that is used throughout chemistry.

### ► What is the key idea?

Symmetry operations may be represented by the effect of matrices on a basis.

### ► What do you need to know already?

You need to know about the types of symmetry operation and element introduced in Topic 11A. This discussion draws heavily on matrix algebra, especially matrix multiplication, as set out in *Mathematical background 6*.

The systematic discussion of symmetry is called **group theory**. Much of group theory is a summary of common sense about the symmetries of objects. However, because group theory is systematic, its rules can be applied in a straightforward, mechanical way. In most cases the theory gives a simple, direct method for arriving at useful conclusions with the minimum of calculation, and this is the aspect we stress here. In some cases, though, they lead to unexpected results.

## 11B.1 The elements of group theory

A **group** in mathematics is a collection of transformations that satisfy four criteria. Thus, if we write the transformations as  $R$ ,  $R'$ , ... (which we can think of as reflections, rotations, and so on, of the kind introduced in Topic 11A), then they form a group if:

1. One of the transformations is the identity (that is: 'do nothing').
2. For every transformation  $R$ , the inverse transformation  $R^{-1}$  is included in the collection so that the combination  $RR^{-1}$  (the transformation  $R^{-1}$  followed by  $R$ ) is equivalent to the identity.
3. The combination  $RR'$  (the transformation  $R'$  followed by  $R$ ) is equivalent to a single member of the collection of transformations.
4. The combination  $R(R'R'')$ , the transformation  $(R'R'')$  followed by  $R$ , is equivalent to  $(RR')R''$ , the transformation  $R''$  followed by  $(RR')$ .

### Example 11B.1 Showing that symmetry operations form a group

Show that  $C_{2v} = \{E, C_2, 2\sigma_v\}$  (specified by its elements) and consisting of the operations  $\{E, C_2, \sigma_v, \sigma_v'\}$  is indeed a group in the mathematical sense.

**Method** We need to show that combinations of the operations match the criteria set out above. The operations are specified in Topic 11A.

**Answer** Criterion 1 is fulfilled because the collection of symmetry operations includes the identity  $E$ . Criterion 2 is fulfilled because in each case the inverse of an operation is the operation itself. Thus, two successive twofold rotations is equivalent to the identity:  $C_2C_2=E$  and likewise for the two reflections and the identity itself. Criterion 3 is fulfilled, because in each case one operation followed by another is the same as one of the four symmetry operations. For instance, a twofold rotation  $C_2$  followed by the reflection  $\sigma'_v$  is the same as the single reflection  $\sigma_v$  (Fig. 11B.1). Thus:  $\sigma'_v C_2 = \sigma_v$ . Criterion 4 is fulfilled, as it is immaterial how the operations are grouped together. The following group multiplication table for the point group can be constructed similarly, where the entries are the product symmetry operations  $RR'$ :

$R \downarrow R' \rightarrow$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$
$E$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$
$C_2$	$C_2$	$E$	$\sigma'_v$	$\sigma_v$
$\sigma_v$	$\sigma_v$	$\sigma'_v$	$E$	$C_2$
$\sigma'_v$	$\sigma'_v$	$\sigma_v$	$C_2$	$E$

**Figure 11B.1** A twofold rotation  $C_2$  followed by the reflection  $\sigma'_v$  is the same as the single reflection  $\sigma_v$ .

**Self-test 11B.1** Confirm that  $C_{3v} = \{E, C_3, 3\sigma_v\}$  and consisting of the operations  $\{E, 2C_3, 3\sigma_v\}$  is a group.

Answer: Criteria are fulfilled

There is one potentially very confusing point that needs to be clarified at the outset. The entities that make up a group are its 'elements'. In chemistry, these elements are almost always symmetry operations. However, as explained in Topic 11A, we distinguish 'symmetry operations' from 'symmetry elements', the axes, planes, and so on with respect to which the operation is carried out. Finally, there is a third use of the word 'element', to denote the number lying in a particular location in a matrix. Be

**Figure 11B.2** Symmetry operations in the same class are related to one another by the symmetry operations of the group. Thus, the three mirror planes shown here are related by threefold rotations, and the two rotations shown here are related by reflection in  $\sigma_v$ .

very careful to distinguish *element* (of a group), *symmetry element*, and *matrix element*.

Symmetry operations fall into the same **class** if they are of the same type (for example, rotations) and can be transformed into one another by a symmetry operation of the group. The two threefold rotations in  $C_{3v}$  belong to the same class because one can be converted into the other by a reflection (Fig. 11B.2); the three reflections all belong to the same class because each can be rotated into another by a threefold rotation. The formal definition of a class is that two operations  $R$  and  $R'$  belong to the same class if there is a member  $S$  of the group such that

$$R' = S^{-1}RS \quad \text{Membership of a class} \quad (11B.1)$$

where  $S^{-1}$  is the inverse of  $S$ .

### Brief illustration 11B.1 Classes

To show that  $C_3^+$  and  $C_3^-$  belong to the same class in  $C_{3v}$  (which intuitively we know to be the case as they are both rotations around the same axis), take  $S = \sigma_v$ . The reciprocal of a reflection is the reflection itself, so  $\sigma_v^{-1} = \sigma_v$ . It follows by using the relations derived to confirm the result of *Self-test* 11B.1 that

$$\underbrace{\sigma_v^{-1}}_{\sigma_v} C_3^+ \sigma_v = \sigma_v \underbrace{C_3^+}_{\sigma'_v} \sigma_v = \underbrace{\sigma_v C_3^+ \sigma_v}_{C_3^-} = C_3^-$$

Therefore,  $C_3^+$  and  $C_3^-$  are related by an equation of the form of eqn 11B.1 and hence belong to the same class.

**Self-test 11B.2** Show that the two reflections of the group  $C_{2v}$  fall into different classes.

Answer: No operation of the group takes  $\sigma_v \rightarrow \sigma'_v$

## 11B.2 Matrix representations

Group theory takes on great power when the notional ideas presented so far are expressed in terms of collections of numbers in the form of matrices.

### (a) Representatives of operations

Consider the set of three p orbitals shown on the  $C_{2v}$   $\text{SO}_2$  molecule in Fig. 11B.3. Under the reflection operation  $\sigma_v$ , the change  $(p_S, p_B, p_A) \leftarrow (p_S, p_A, p_B)$  takes place. We can express this transformation by using matrix multiplication (*Mathematics background 6*):

$$(p_S, p_B, p_A) = (p_S, p_A, p_B) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} = (p_S, p_A, p_B) D(\sigma_v) \quad (11B.2a)$$

The matrix  $D(\sigma_v)$  is called a **representative** of the operation  $\sigma_v$ . Representatives take different forms according to the **basis**, the set of orbitals that has been adopted. In this case, the basis is  $(p_S, p_A, p_B)$ .

#### Brief illustration 11B.2 Representatives

We use the same technique to find matrices that reproduce the other symmetry operations. For instance,  $C_2$  has the effect  $(-p_S, -p_B, -p_A) \leftarrow (p_S, p_A, p_B)$ , and its representative is

$$D(C_2) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix} \quad (11B.2b)$$

The effect of  $\sigma'_v$  is  $(-p_S, -p_A, -p_B) \leftarrow (p_S, p_A, p_B)$ , and its representative is

$$D(\sigma'_v) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix} \quad (11B.2c)$$

The identity operation has no effect on the basis, so its representative is the  $3 \times 3$  unit matrix:

$$D(E) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (11B.2d)$$

**Self-test 11B.3** Find the representative of the one remaining operation of the group, the reflection  $\sigma_v$ .

$$\text{Answer: } D(\sigma_v) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

### (b) The representation of a group

The set of matrices that represents *all* the operations of the group is called a **matrix representation**,  $\Gamma$  (uppercase gamma),

**Figure 11B.3** The three  $p_x$  orbitals that are used to illustrate the construction of a matrix representation in a  $C_{2v}$  molecule ( $\text{SO}_2$ ).

of the group for the basis that has been chosen. We denote this 'three-dimensional' representation (a representation consisting of  $3 \times 3$  matrices) by  $\Gamma^{(3)}$ . The matrices of a representation multiply together in the same way as the operations they represent. Thus, if for any two operations  $R$  and  $R'$  we know that  $RR' = R''$ , then  $D(R)D(R') = D(R'')$  for a given basis.

#### Brief illustration 11B.3 Matrix representations

In the group  $C_{2v}$  a twofold rotation followed by a reflection in a mirror plane is equivalent to a reflection in the second mirror plane: specifically,  $\sigma'_v C_2 = \sigma_v$ . When we use the representatives specified above, we find

$$D(\sigma'_v)D(C_2) = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} = D(\sigma_v)$$

This multiplication reproduces the group multiplication. The same is true of all pairs of representative multiplications, so the four matrices form a representation of the group.

**Self-test 11B.4** Confirm the result that  $\sigma_v \sigma'_v = C_2$  by using the matrix representations developed here.

The discovery of a matrix representation of the group means that we have found a link between symbolic manipulations of operations and algebraic manipulations of numbers.

### (c) Irreducible representations

Inspection of the representatives shows that they are all of **block-diagonal form**:

$$D = \begin{pmatrix} \blacksquare & 0 & 0 \\ 0 & \blacksquare & \blacksquare \\ 0 & \blacksquare & \blacksquare \end{pmatrix} \quad \text{Block-diagonal form} \quad (11B.3)$$

The block-diagonal form of the representatives shows us that the symmetry operations of  $C_{2v}$  never mix  $p_S$  with the other two

functions. Consequently, the basis can be cut into two parts, one consisting of  $p_S$  alone and the other of  $(p_A, p_B)$ . It is readily verified that the  $p_S$  orbital itself is a basis for the one-dimensional representation

$$D(E)=1 \quad D(C_2)=-1 \quad D(\sigma_v)=1 \quad D(\sigma'_v)=-1$$

which we shall call  $\Gamma^{(1)}$ . The remaining two functions  $(p_A, p_B)$  are a basis for the two-dimensional representation  $\Gamma^{(2)}$ :

$$D(E)=\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2)=\begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}$$

$$D(\sigma_v)=\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad D(\sigma'_v)=\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$

These matrices are the same as those of the original three-dimensional representation, except for the loss of the first row and column. We say that the original three-dimensional representation has been **reduced** to the 'direct sum' of a one-dimensional representation 'spanned' by  $p_S$ , and a two-dimensional representation spanned by  $(p_A, p_B)$ . This reduction is consistent with the common sense view that the central orbital plays a role different from the other two. We denote the reduction symbolically by writing<sup>1</sup>

$$\Gamma^{(3)} = \Gamma^{(1)} + \Gamma^{(2)} \quad \text{Direct sum} \quad (11B.4)$$

The one-dimensional representation  $\Gamma^{(1)}$  cannot be reduced any further, and is called an **irreducible representation** of the group (an 'irrep'). We can demonstrate that the two-dimensional representation  $\Gamma^{(2)}$  is reducible (for this basis in this group) by switching attention to the linear combinations  $p_1 = p_A + p_B$  and  $p_2 = p_A - p_B$ . These combinations are sketched in Fig. 11B.4. The representatives in the new basis can be constructed from the old by noting, for example, that under  $\sigma_v$ ,  $(p_B, p_A) \leftarrow (p_A, p_B)$ . In this way we find the following representation in the new basis:

**Figure 11B.4** Two symmetry-adapted linear combinations of the basis orbitals shown in Fig. 11B.3. The two combinations each span a one-dimensional irreducible representation, and their symmetry species are different.

<sup>1</sup> The symbol  $\oplus$  is sometimes used to denote a direct sum to distinguish it from an ordinary sum, in which case eqn 11B.4 would be written  $\Gamma^{(3)} = \Gamma^{(1)} \oplus \Gamma^{(2)}$ .

$$D(E)=\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad D(C_2)=\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$$

$$D(\sigma_v)=\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad D(\sigma'_v)=\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$$
