The new representatives are all in block-diagonal form, in this case  $\begin{pmatrix} \blacksquare & 0 \\ 0 & \blacksquare \end{pmatrix}$ , and the two combinations are not mixed with each other by any operation of the group. We have therefore achieved the reduction of  $\Gamma^{(2)}$  to the sum of two one-dimensional representations. Thus,  $p_1$  spans

$$D(E)=1 \quad D(C_2)=-1 \quad D(\sigma_v)=1 \quad D(\sigma'_v)=-1$$

which is the same one-dimensional representation as that spanned by  $p_S$ , and  $p_2$  spans

$$D(E)=1 \quad D(C_2)=1 \quad D(\sigma_v)=-1 \quad D(\sigma'_v)=-1$$

which is a different one-dimensional representation; we shall denote these two representations  $\Gamma^{(1)'}$  and  $\Gamma^{(1)''}$ , respectively. At this stage we have reduced the original representation as follows:

$$\Gamma^{(3)} = \Gamma^{(1)} + \Gamma^{(1)'} + \Gamma^{(1)''}$$

## (d) Characters and symmetry species

The **character**,  $\chi$  (chi), of an operation in a particular matrix representation is the sum of the diagonal elements of the representative of that operation. Thus, in the original basis we are using, the characters of the representatives are

$R$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$
$D(R)$	$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$	$\begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$	$\begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$
$\chi(R)$	3	-1	1	-3

The characters of one-dimensional representatives are just the representatives themselves. The sum of the characters of the reduced representation is unchanged by the reduction:

$R$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$
$\chi(R)$ for $\Gamma^{(1)}$	1	-1	1	-1
$\chi(R)$ for $\Gamma^{(1)'}$	1	-1	1	-1
$\chi(R)$ for $\Gamma^{(1)''}$	1	1	-1	-1
Sum:	3	-1	1	-3

Although the notation  $\Gamma^{(n)}$  can be used for general representations, it is common in chemical applications of group theory

to use the labels A, B, E, and T to denote the **symmetry species** of the representation:

A: one-dimensional representation, character +1 under the principal rotation

B: one-dimensional representation, character -1 under the principal rotation

E: two-dimensional irreducible representation

T: three-dimensional irreducible representation

Subscripts are used to distinguish the irreducible representations if there is more than one of the same type:  $A_1$  is reserved for the representation with character +1 for all operations;  $A_2$  has +1 for the principal rotation but -1 for reflections. All the irreducible representations of  $C_{2v}$  are one-dimensional, and the table above is labelled as follows:

Symmetry species	$E$	$C_2$	$\sigma_v$	$\sigma'_v$
$B_2$	1	-1	1	-1
$B_1$	1	-1	1	-1
$A_2$	1	1	-1	-1

At this point we have found three irreducible representations of the group  $C_{2v}$ . Are these the only irreducible representations of the group  $C_{2v}$ ? There is in fact only one more species of irreducible representations of this group, for a surprising theorem of group theory states that

$$\text{Number of symmetry species} = \text{number of classes} \quad \text{Number of species} \quad (11B.5)$$

In  $C_{2v}$ , for instance, there are four classes of operation (four columns in the character table), so there are only four species of irreducible representation. The character table therefore shows the characters of all the irreducible representations of this group. Another powerful result relates the sum of the dimensions,  $d_i$ , of all the symmetry species  $\Gamma^{(i)}$  to the **order** of the group, the total number of symmetry operations,  $h$ :

$$\sum_{\text{Species } i} d_i^2 = h \quad \text{Dimensionality and order} \quad (11B.6)$$

#### Brief illustration 11B.4 Symmetry species

There are three classes of operation in the group  $C_{3v}$  with operations  $\{E, 2C_3, 3\sigma_v\}$ , so there are three symmetry species (they turn out to be  $A_1$ ,  $A_2$ , and E). The order of the group is 6, so if we already knew that two of the symmetry species are one dimensional, we could infer that the remaining irreducible representation is two-dimensional (E) from  $1^2 + 1^2 + d^2 = 6$ .

**Self-test 11B.5** How many symmetry species are there for the group  $T_d$ , with operations  $\{E, 8C_3, 3C_2, 6\sigma_d, 6S_4\}$ ? Can you infer their dimensionalities?

Answer: 5 species;  $2A + E + 2T$  for  $h=24$

## 11B.3 Character tables

The tables we have been constructing are called **character tables** and from now on move to the centre of the discussion. The columns of a character table are labelled with the symmetry operations of the group. For instance, for the group  $C_{3v}$  the columns are headed  $E$ ,  $2C_3$ , and  $3\sigma_v$  (Table 11B.1). The numbers multiplying each operation are the numbers of members of each class. The rows under the labels for the operations summarize the symmetry properties of the orbitals. They are labelled with the symmetry species.

### (a) Character tables and orbital degeneracy

The character of the identity operation  $E$  tells us the degeneracy of the orbitals. Thus, in a  $C_{3v}$  molecule, any orbital with a symmetry label  $A_1$  or  $A_2$  is non-degenerate. Any doubly degenerate pair of orbitals in  $C_{3v}$  must be labelled E because, in this group, only E symmetry species have characters greater than 1. (Take care to distinguish the identity operation  $E$  (italic, a column heading) from the symmetry label E (roman, a row label).)

Because there are no characters greater than 2 in the column headed  $E$  in  $C_{3v}$ , we know that there can be no triply degenerate orbitals in a  $C_{3v}$  molecule. This last point is a powerful result of group theory, for it means that with a glance at the character table of a molecule, we can state the maximum possible degeneracy of its orbitals.

Table 11B.1\* The  $C_{3v}$  character table

$C_{3v}, 3m$	$E$	$2C_3$	$3\sigma_v$	$h=6$	
$A_1$	1	1	1	$z$	$z^2, x^2 + y^2$
$A_2$	1	1	-1		
E	2	-1	0	$(x, y)$	$(xy, x^2 - y^2), (yz, zx)$

\* More character tables are given in the Resource section.

### Example 11B.2 Using a character table to judge degeneracy

Can a trigonal planar molecule such as  $BF_3$  have triply degenerate orbitals? What is the minimum number of atoms from which a molecule can be built that does display triple degeneracy?

**Method** First identify the point group, and then refer to the corresponding character table in the *Resource section*. The maximum number in the column headed by the identity  $E$  is the maximum orbital degeneracy possible in a molecule of that point group. For the second part, consider the shapes that can be built from two, three, etc. atoms, and decide which number can be used to form a molecule that can have orbitals of symmetry species  $T$ .

**Answer** Trigonal planar molecules belong to the point group  $D_{3h}$ . Reference to the character table for this group shows that the maximum degeneracy is 2, as no character exceeds 2 in the column headed  $E$ . Therefore, the orbitals cannot be triply degenerate. A tetrahedral molecule (symmetry group  $T$ ) has an irreducible representation with a  $T$  symmetry species. The minimum number of atoms needed to build such a molecule is four (as in  $P_4$ , for instance).

**Self-test 11B.6** A buckminsterfullerene molecule,  $C_{60}$ , belongs to the icosahedral point group. What is the maximum possible degree of degeneracy of its orbitals?

Answer: 5

## (b) The symmetry species of atomic orbitals

The characters in the rows labelled A and B and in the columns headed by symmetry operations other than the identity  $E$  indicate the behaviour of an orbital under the corresponding operations: a +1 indicates that an orbital is unchanged, and a -1 indicates that it changes sign. It follows that we can identify the symmetry label of the orbital by comparing the changes that occur to an orbital under each operation, and then comparing the resulting +1 or -1 with the entries in a row of the character table for the point group concerned. By convention, irreducible representations are labelled with upper case Roman letters (such as  $A_1$  and  $E$ ) and the orbitals to which they apply are labelled with the lower case equivalents (so an orbital of symmetry species  $A_1$  is called an  $a_1$  orbital). Examples of each type of orbital are shown in Fig. 11B.5.

**Figure 11B.5** Typical symmetry-adapted linear combinations of orbitals in a  $C_{3v}$  molecule.

## Brief illustration 11B.5 Symmetry species of atomic orbitals

Consider the  $O2p_x$  orbital in  $H_2O$  (the  $x$ -axis is perpendicular to the molecular plane; the  $y$ -axis is parallel to the  $H-H$  direction; the  $z$ -axis bisects the  $HOH$  angle). Because  $H_2O$  belongs to the point group  $C_{2v}$ , we know by referring to the  $C_{2v}$  character table (Table 11B.2) that the labels available for the orbitals are  $a_1$ ,  $a_2$ ,  $b_1$ , and  $b_2$ . We can decide the appropriate label for  $O2p_x$  by noting that under a  $180^\circ$  rotation ( $C_2$ ) the orbital changes sign (Fig. 11B.6), so it must be either  $B_1$  or  $B_2$ , as only these two symmetry types have character -1 under  $C_2$ . The  $O2p_x$  orbital also changes sign under the reflection  $\sigma'_v$ , which identifies it as  $B_1$ . As we shall see, any molecular orbital built from this atomic orbital will also be a  $b_1$  orbital. Similarly,  $O2p_y$  changes sign under  $C_2$  but not under  $\sigma'_v$ ; therefore, it can contribute to  $b_2$  orbitals.

**Table 11B.2\*** The  $C_{2v}$  character table

$C_{2v}$ $2mm$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$	$h=4$	
$A_1$	1	1	1	1	$z$	$z^2, y^2, x^2$
$A_2$	1	1	-1	-1		$xy$
$B_1$	1	-1	1	-1	$x$	$zx$
$B_2$	1	-1	-1	1	$y$	$yz$

\* More character tables are given in the *Resource section*.

**Figure 11B.6** A  $p_x$  orbital on the central atom of a  $C_{2v}$  molecule and the symmetry elements of the group.

**Self-test 11B.7** Identify the symmetry species of  $d$  orbitals on the central atom of a square-planar ( $D_{4h}$ ) complex.

Answer:  $A_{1g} + B_{1g} + B_{2g} + E_g$

For the rows labelled  $E$  or  $T$  (which refer to the behaviour of sets of doubly and triply degenerate orbitals, respectively), the characters in a row of the table are the sums of the characters summarizing the behaviour of the individual orbitals in the basis. Thus, if one member of a doubly degenerate pair remains unchanged under a symmetry operation but the other changes sign (Fig. 11B.7), then the entry is reported as  $\chi = 1 - 1 = 0$ . Care must be exercised with these characters because the

Figure 11B.7 The two orbitals shown here have different properties under reflection through the mirror plane: one changes sign (character  $-1$ ), the other does not (character  $+1$ ).

transformations of orbitals can be quite complicated; nevertheless, the sums of the individual characters are integers.

The behaviour of s, p, and d orbitals on a central atom under the symmetry operations of the molecule is so important that the symmetry species of these orbitals are generally indicated in a character table. To make these allocations, we look at the symmetry species of  $x$ ,  $y$ , and  $z$ , which appear on the right hand side of the character table. Thus, the position of  $z$  in Table 11B.1 shows that  $p_z$  (which is proportional to  $zf(r)$ ), has symmetry species  $A_1$  in  $C_{3v}$ , whereas  $p_x$  and  $p_y$  (which are proportional to  $xf(r)$  and  $yf(r)$ , respectively) are jointly of E symmetry. In technical terms, we say that  $p_x$  and  $p_y$  jointly **span** an irreducible representation of symmetry species E. An s orbital on the central atom always spans the fully symmetrical irreducible representation (typically labelled  $A_1$  but sometimes  $A_1'$ ) of a group as it is unchanged under all symmetry operations.

The five d orbitals of a shell are represented by  $xy$  for  $d_{xy}$ , etc., and are also listed on the right of the character table. We can see at a glance that in  $C_{3v}$ ,  $d_{xy}$  and  $d_{x^2-y^2}$  on a central atom jointly belong to E and hence form a doubly degenerate pair.

### (c) The symmetry species of linear combinations of orbitals

So far, we have dealt with the symmetry classification of individual orbitals. The same technique may be applied to linear combinations of orbitals on atoms that are related by symmetry transformations of the molecule, such as the combination  $\psi_1 = \psi_A + \psi_B + \psi_C$  of the three H1s orbitals in the  $C_{3v}$  molecule  $\text{NH}_3$  (Fig. 11B.8). This combination remains unchanged under a  $C_3$  rotation and under any of the three vertical reflections of the group, so its characters are

$$\chi(E)=1 \quad \chi(C_3)=1 \quad \chi(\sigma_v)=-1$$

Comparison with the  $C_{3v}$  character table shows that  $\psi_1$  is of symmetry species  $A_1$ , and therefore that it contributes to  $a_1$  molecular orbitals in  $\text{NH}_3$ .

Figure 11B.8 The three H1s orbitals used to construct symmetry-adapted linear combinations in a  $C_{3v}$  molecule such as  $\text{NH}_3$ .

#### Example 11B.3 Identifying the symmetry species of orbitals

Identify the symmetry species of the orbital  $\psi = \psi_A - \psi_B$  in a  $C_{2v}$   $\text{NO}_2$  molecule, where  $\psi_A$  is an  $\text{O}2p_x$  orbital on one O atom and  $\psi_B$  that on the other O atom.

**Method** The negative sign in  $\psi$  indicates that the sign of  $\psi_B$  is opposite to that of  $\psi_A$ . We need to consider how the combination changes under each operation of the group, and then write the character as  $+1$ ,  $-1$ , or  $0$  as specified above. Then we compare the resulting characters with each row in the character table for the point group, and hence identify the symmetry species.

**Answer** The combination is shown in Fig. 11B.9. Under  $C_2$ ,  $\psi$  changes into itself, implying a character of  $+1$ . Under the reflection  $\sigma_v$ , both orbitals change sign, so  $\psi \rightarrow -\psi$ , implying a character of  $-1$ . Under  $\sigma'_v$ ,  $\psi \rightarrow -\psi$ , so the character for this operation is also  $-1$ . The characters are therefore

$$\chi(E)=1 \quad \chi(C_2)=1 \quad \chi(\sigma_v)=-1 \quad \chi(\sigma'_v)=-1$$

These values match the characters of the  $A_2$  symmetry species, so  $\psi$  can contribute to an  $a_2$  orbital.

Figure 11B.9 One symmetry-adapted linear combination of  $\text{O}2p_x$  orbitals in the  $C_{2v}$   $\text{NO}_2$  molecule.

**Self-test 11B.8** Consider  $\text{PtCl}_4$ , in which the Cl ligands form a square planar array of point group  $D_{4h}$  (1). Identify the symmetry type of the combination  $\psi_A - \psi_B + \psi_C - \psi_D$ .

Answer:  $B_{2g}$

## Checklist of concepts

- 1. A **group** in mathematics is a collection of transformations that satisfy the four criteria set out at the start of the Topic.
- 2. A **matrix representative** is a matrix that represents the effect of an operation on a basis.
- 3. The **character** is the sum of the diagonal elements of a matrix representative of an operation.
- 4. A **matrix representation** is the collection of matrix representatives for the operations in the group.
- 5. A **character table** consists of entries showing the characters of all the irreducible representations of a group.
- 6. A **symmetry species** is a label for an irreducible representation of a group.
- 7. The character of the identity operation  $E$  is the degeneracy of the orbitals that form a basis for an irreducible representation of a group.

### ► Why do you need to know this material?

This Topic explains how the concepts introduced in Topics 11A and 11B are put to use. The arguments here are essential for understanding how molecular orbitals are constructed and underlie the whole of spectroscopy.

### ► What is the key idea?

An integral is invariant under symmetry transformations of a molecule.

### ► What do you need to know already?

This Topic develops the material that began in Topic 11A, where the symmetry classification of molecules is introduced on the basis of their symmetry elements, and draws heavily on the properties of characters and character tables described in Topic 11B. You need to be aware that

many quantum-mechanical properties, including transition probabilities (Topic 9C), depend on integrals over pairs of wavefunctions (Topic 7C).

Group theory shows its power when brought to bear on a variety of problems in chemistry, among them the construction of molecular orbitals and the formulation of spectroscopic selection rules. This Topic describes these two applications after establishing a general result relating to integrals. In Topic 7C it is explained how integrals ('matrix elements') are central to the formulation of quantum mechanics, and knowing with very little calculation that various integrals are necessarily zero can save a great deal of calculational effort as well as adding to insight about the origin of properties.

## 11C.1 Vanishing integrals

An integral, which we shall denote  $I$ , in one dimension is equal to the area beneath the curve. In higher dimensions, it is equal to volume and various generalizations of volume. The key point is that the value of the area, volume, etc. is independent of the orientation of the axes used to express the function being integrated, the 'integrand' (Fig. 11C.1). In group theory we express this point by saying that  $I$  is *invariant under any symmetry operation*, and that each symmetry operation brings about the trivial transformation  $I \rightarrow I$ .

**Figure 11C.1** The value of an integral  $I$  (for example, an area) is independent of the coordinate system used to evaluate it. That is,  $I$  is a basis of a representation of symmetry species  $A_1$  (or its equivalent).

### (a) Integrals over the product of two functions

Suppose we had to evaluate the integral

$$I = \int f_1 f_2 d\tau \quad (11C.1)$$

where  $f_1$  and  $f_2$  are functions and the integration is over all space. For example,  $f_1$  might be an atomic orbital  $A$  on one atom and  $f_2$  an atomic orbital  $B$  on another atom, in which case  $I$  would be their overlap integral. If we knew that the integral is zero, we could say at once that a molecular orbital does not result from  $(A,B)$  overlap in that molecule. We shall now see that the character tables introduced in Topic 11B provide a quick way of judging whether an integral is necessarily zero.

The volume element  $d\tau$  is invariant under any symmetry operation. It follows that the integral is nonzero only if the integrand itself, the product  $f_1 f_2$ , is unchanged by any symmetry operation of the molecular point group. If the integrand changed sign under a symmetry operation, the integral would be the sum of equal and opposite contributions, and hence would be zero. It follows that the only contribution to a nonzero integral comes from functions for which under any symmetry operation of the molecular point group  $f_1 f_2 \rightarrow f_1 f_2$ , and hence for which the characters of the operations are all equal to +1. Therefore, for  $I$  not to be zero, the integrand  $f_1 f_2$  must have symmetry species  $A_1$  (or its equivalent in the specific molecular point group).

The following procedure is used to deduce the symmetry species spanned by the product  $f_1 f_2$  and hence to see whether it does indeed span  $A_1$ .

- Identify the symmetry species of the individual functions  $f_1$  and  $f_2$  by reference to the character table for the molecular point group in question and write their characters in two rows in the same order as in the table.
- Multiply the two numbers in each column, writing the results in the same order.
- Inspect the row so produced, and see if it can be expressed as a sum of characters from each column of the group. The integral must be zero if this sum does not use  $A_1$ .

A shortcut that works when  $f_1$  and  $f_2$  are bases for irreducible representations of a group is to note their symmetry species; if they are different ( $B_1$  and  $A_2$ , for instance), then the integral of their product must vanish; if they are the same (both  $B_1$ , for instance), then the integral may be nonzero.

It is important to note that group theory is specific about when an integral must be zero, but integrals that it allows to be nonzero may be zero for reasons unrelated to symmetry. For example, the N–H distance in ammonia may be so great that the  $(s_1, s_N)$  overlap integral is zero simply because the orbitals are so far apart.

#### Example 11C.1 Deciding if an integral must be zero 1

May the integral of the function  $f=xy$  be nonzero when evaluated over a region the shape of an equilateral triangle centred on the origin (Fig. 11C.2)?

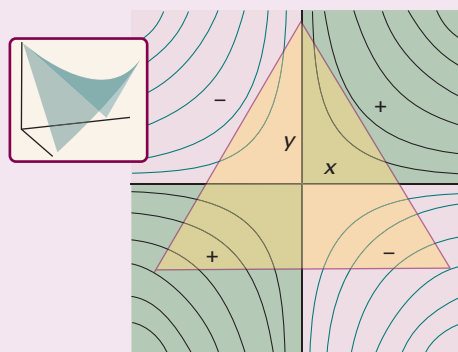

Figure 11C.2 The integral of the function  $f=xy$  over the tinted region is zero. In this case, the result is obvious by inspection, but group theory can be used to establish similar results in less obvious cases. The insert shows the shape of the function in three dimensions.

**Method** First, note that an integral over a single function  $f$  is included in the previous discussion if we take  $f_1=f$  and  $f_2=1$  in eqn 11C.1. Therefore, we need to judge whether  $f$  alone belongs to the symmetry species  $A_1$  (or its equivalent) in the point group of the system. To decide that, we identify the point group and then examine the character table to see whether  $f$  belongs to  $A_1$  (or its equivalent).

**Answer** An equilateral triangle has the point-group symmetry  $D_{3h}$ . If we refer to the character table of the group, we see that  $xy$  is a member of a basis that spans the irreducible representation  $E'$ . Therefore, its integral must be zero, because the integrand has no component that spans  $A_1'$ .

**Self-test 11C.1** Can the function  $x^2+y^2$  have a nonzero integral when integrated over a regular pentagon centred on the origin?

Answer: Yes, see Fig. 11C.3.

Figure 11C.3 The integration of a function over a pentagonal region. The insert shows the shape of the function in three dimensions.

**(b) Decomposition of a direct product**

In many cases, the product of functions  $f_1$  and  $f_2$  spans a sum of irreducible representations. For instance, in  $C_{2v}$  we may find the characters 2,0,0,-2 when we multiply the characters of  $f_1$  and  $f_2$  together. In this case, we note that these characters are the sum of the characters for  $A_2$  and  $B_1$ :

	$E$	$C_{2v}$	$\sigma_v$	$\sigma'_v$
$A_2$	1	1	-1	-1
$B_1$	1	-1	1	-1
$A_2+B_1$	2	0	0	-2

To summarize this result we write the symbolic expression  $A_2 \times B_1 = A_2 + B_1$ , which is called the **decomposition of a direct product**. This expression is symbolic. The  $\times$  and  $+$  signs in this expression are not ordinary multiplication and addition signs: formally, they denote technical procedures with matrices called a 'direct product' and a 'direct sum'.<sup>1</sup> Because the sum on the right does not include a component that is a basis for an irreducible representation of symmetry species  $A_1$ , we can conclude that the integral of  $f_1 f_2$  over all space is zero in a  $C_{2v}$  molecule.

Whereas the decomposition of the characters 2,0,0,-2 can be done by inspection in this simple case, in other cases and more complex groups the decomposition is often far from obvious. For example, if we found the characters 8,-2,-6,4, it might not be obvious that the sum contains  $A_1$ . Group theory, however, provides a systematic way of using the characters of the representation spanned by a product to find the symmetry species of the irreducible representations. The formal recipe is

$$n(\Gamma) = \frac{1}{h} \sum_R \chi^{(\Gamma)}(R) \chi(R) \quad \text{Decomposition of direct product} \quad (11C.2)$$

We implement this expression as follows:

1. Write down a table with columns headed by the symmetry operations,  $R$ , of the group. Include a column for every operation, not just the classes.
2. In the first row write down the characters of the representation we want to analyse; these are the  $\chi(R)$ .
3. In the second row, write down the characters of the irreducible representation  $\Gamma$  we are interested in; these are the  $\chi^{(\Gamma)}(R)$ .
4. Multiply the two rows together, add the products together, and divide by the order of the group,  $h$ .

The resulting number,  $n(\Gamma)$ , is the number of times  $\Gamma$  occurs in the decomposition.

<sup>1</sup> As mentioned in Topic 11B, for this reason a direct sum is sometimes denoted  $\oplus$ ; likewise, a direct product is sometimes denoted  $\otimes$ .

**Brief illustration 11C.1** Decomposition of a direct product

To find whether  $A_1$  does indeed occur in the product with characters 8,-2,-6,4 in  $C_{2v}$ , we draw up the following table:

	$E$	$C_{2v}$	$\sigma_v$	$4\sigma'_v$	$h=4$ (the order of the group)
$f_1 f_2$	8	-2	-6	4	(the characters of the product)
$A_1$	1	1	1	1	(the symmetry species we are interested in)
	8	-2	-6	4	(the product of the two sets of characters)

The sum of the numbers in the last line is 4; when that number is divided by the order of the group, we get 1, so  $A_1$  occurs once in the decomposition. When the procedure is repeated for all four symmetry species, we find that  $f_1 f_2$  spans  $A_1 + 2A_2 + 5B_2$ .

**Self-test 11C.2** Does  $A_2$  occur among the symmetry species of the irreducible representations spanned by a product with characters 7,-3,-1,5 in the group  $C_{2v}$ ?

Answer: No

**(c) Integrals over products of three functions**

Integrals of the form

$$I = \int f_1 f_2 f_3 d\tau \quad (11C.3)$$

are also common in quantum mechanics for they include matrix elements of operators (Topic 7C), and it is important to know when they are necessarily zero. As for integrals over two functions, for  $I$  to be nonzero, *the product  $f_1 f_2 f_3$  must span  $A_1$  (or its equivalent) or contain a component that spans  $A_1$* . To test whether this is so, the characters of all three functions are multiplied together in the same way as in the rules set out earlier.

**Example 11C.2** Deciding if an integral must be zero 2

Does the integral  $\int (d_{z^2})x(d_{xy})d\tau$  vanish in a  $C_{2v}$  molecule?

**Method** We must refer to the  $C_{2v}$  character table (Table 11B.2) and the characters of the irreducible representations spanned by  $3z^2 - r^2$  (the form of the  $d_{z^2}$  orbital),  $x$ , and  $xy$ ; then we can use the procedure set out above (with one more row of multiplication).

**Answer** We draw up the following table:

	$E$	$C_2$	$\sigma_v$	$\sigma'_v$	
$f_3 = d_{xy}$	1	1	-1	-1	$A_2$
$f_2 = x$	1	-1	1	-1	$B_1$
$f_1 = d_{z^2}$	1	1	1	1	$A_1$
$f_1 f_2 f_3$	1	-1	-1	1	

The characters are those of  $B_2$ . Therefore, the integral is necessarily zero.

**Self-test 11C.3** Does the integral  $\int (p_x)y(p_z)d\tau$  necessarily vanish in an octahedral environment?

Answer: No

## 11C.2 Applications to orbitals

The rules we have outlined let us decide which atomic orbitals may have nonzero overlap in a molecule. It is also very useful to have a set of procedures to construct linear combinations of atomic orbitals (LCAOs) to have a certain symmetry, and thus to know in advance whether or not they will have nonzero overlap with other orbitals.

### (a) Orbital overlap

An overlap integral,  $S$ , between two sets of atomic orbitals  $\psi_1$  and  $\psi_2$  is

$$S = \int \psi_2^* \psi_1 d\tau \quad \text{Overlap integral} \quad (11C.4)$$

and clearly has the same form as eqn 11C.1. It follows from that discussion that *only orbitals of the same symmetry species may have nonzero overlap* ( $S \neq 0$ ), so only orbitals of the same symmetry species form bonding and antibonding combinations. It is explained in Topics 10B–10D that the selection of atomic orbitals that had mutual nonzero overlap is the central and initial step in the construction of molecular orbitals by the LCAO procedure. We are therefore at the point of contact between group theory and the material introduced in those Topics.

### Example 11C.3 Determining which orbitals can contribute to bonding

The four H1s orbitals of methane span  $A_1 + T_2$ . With which of the C atom orbitals can they overlap? What bonding pattern would be possible if the C atom had d orbitals available?

**Method** Refer to the  $T_d$  character table (in the *Resource section*) and look for s, p, and d orbitals spanning  $A_1$  or  $T_2$ .

**Answer** An s orbital spans  $A_1$  in the group  $T_d$ , so it may have nonzero overlap with the  $A_1$  combination of H1s orbitals. The C2p orbitals span  $T_2$ , so they may have nonzero overlap with the  $T_2$  combination. The  $d_{xy}$ ,  $d_{yz}$ , and  $d_{zx}$  orbitals span  $T_2$ , so they may overlap the same combination. Neither of the other two d orbitals spans  $A_1$  (they span E), so they remain nonbonding orbitals. It follows that in methane there are

(C2s,H1s)-overlap  $a_1$  orbitals and (C2p,H1s)-overlap  $t_2$  orbitals. The C3d orbitals might contribute to the latter. The lowest energy configuration is probably  $a_1^2 t_2^6$ , with all bonding orbitals occupied.

**Self-test 11C.4** Consider the octahedral  $SF_6$  molecule, with the bonding arising from overlap of S orbitals and a 2p orbital on each fluorine directed towards the central sulfur atom. The latter span  $A_{1g} + E_g + T_{1u}$ . What S orbitals have nonzero overlap? Suggest what the ground-state configuration is likely to be.

Answer:  $3s(A_{1g}), 3p(T_{1u}), 3d(E_g); a_{1g}^2 t_{1u}^6 e_g^4$

### (b) Symmetry-adapted linear combinations

In the discussion of the molecular orbitals of  $NH_3$  (Topic 10C) we encounter molecular orbitals of the form  $\psi = c_1 s_N + c_2(s_1 + s_2 + s_3)$ , where  $s_N$  is an N2s atomic orbital and  $s_1, s_2,$  and  $s_3$  are H1s orbitals. The  $s_N$  orbital has nonzero overlap with the combination of H1s orbitals as the latter has matching symmetry. The combination of H1s orbitals is an example of a **symmetry-adapted linear combination** (SALC), which are orbitals constructed from equivalent atoms and having a specified symmetry. Group theory also provides machinery that takes an arbitrary **basis**, or set of atomic orbitals ( $s_A$ , etc.), as input and generates combinations of the specified symmetry. As illustrated by the example of  $NH_3$ , SALCs are the building blocks of LCAO molecular orbitals and their construction is the first step in any molecular orbital treatment of molecules.

The technique for building SALCs is derived by using the full power of group theory and involves the use of a **projection operator**,  $P^{(\Gamma)}$ , an operator that takes one of the basis orbitals and generates from it—projects from it—an SALC of the symmetry species  $\Gamma$ :

$$P^{(\Gamma)} = \frac{1}{h} \sum_R \chi^{(\Gamma)}(R) R \quad \text{for } \psi_m^{(\Gamma)} = P^{(\Gamma)} \chi_o \quad \text{Projection operator} \quad (11C.5)$$

To implement this rule, do the following:

1. Write each basis orbital at the head of a column and in successive rows show the effect of each operation  $R$  on each orbital. Treat each operation individually.
2. Multiply each member of the column by the character,  $\chi^{(\Gamma)}(R)$ , of the corresponding operation.
3. Add together all the orbitals in each column with the factors as determined in (2).
4. Divide the sum by the order of the group,  $h$ .

**Example 11C.4** Constructing symmetry-adapted orbitals

Construct the  $A_1$  symmetry-adapted linear combination of H1s orbitals for  $\text{NH}_3$ .

**Method** Identify the point group of the molecule and have available its character table. Then apply the projection operator technique.

**Answer** From the  $(s_N, s_A, s_B, s_C)$  basis in  $\text{NH}_3$  we form the following table with each row showing the effect of the operation shown on the left.

	$s_N$	$s_A$	$s_B$	$s_C$
$E$	$s_N$	$s_A$	$s_B$	$s_C$
$C_3^+$	$s_N$	$s_B$	$s_C$	$s_A$
$C_3^-$	$s_N$	$s_C$	$s_A$	$s_B$
$\sigma_v$	$s_N$	$s_A$	$s_C$	$s_B$
$\sigma_v'$	$s_N$	$s_B$	$s_A$	$s_C$
$\sigma_v''$	$s_N$	$s_C$	$s_B$	$s_A$

To generate the  $A_1$  combination, we take the characters for  $A_1$  (1,1,1,1,1); then rules 2 and 3 lead to  $\psi \propto s_N + s_N + \dots = 6s_N$ . The order of the group (the number of elements) is 6, so the combination of  $A_1$  symmetry that can be generated from  $s_N$  is  $s_N$  itself. Applying the same technique to the column under  $s_A$  gives

$$\psi = \frac{1}{6}(s_A + s_B + s_C + s_A + s_B + s_C) = \frac{1}{3}(s_A + s_B + s_C)$$

The same combination is built from the other two columns, so they give no further information. The combination we have just formed is the  $s_1$  combination used in Topic 10D (apart from the numerical factor).

**Self-test 11C.5** Construct the  $A_1$  symmetry-adapted linear combinations of H1s orbitals for  $\text{CH}_4$ .

$$\text{Answer: } \frac{1}{4}(s_A + s_B + s_C + s_D)$$

We now form the overall molecular orbital by forming a linear combination of all the SALCs of the specified symmetry species. In this case, therefore, the  $a_1$  molecular orbital is  $\psi = c_N s_N + c_1 s_1$ , as specified above. This is as far as group theory can take us. The coefficients are found by solving the Schrödinger equation; they do not come directly from the symmetry of the system.

We run into a problem when we try to generate an SALC of symmetry species E, because, for representations of dimension 2 or more, the rules generate sums of SALCs. This problem can be illustrated as follows. In  $C_{3v}$  the E characters are 2, -1, -1, 0, 0, 0, so the column under  $s_N$  gives

$$\psi = \frac{1}{6}(2s_N - s_N - s_N + 0 + 0 + 0) = 0$$

The other columns give

$$\frac{1}{6}(2s_A - s_B - s_C) \quad \frac{1}{6}(2s_B - s_A - s_C) \quad \frac{1}{6}(2s_C - s_B - s_A)$$

However, any one of these three expressions can be expressed as a sum of the other two (they are not 'linearly independent'). The difference of the second and third gives  $\frac{1}{2}(s_B - s_C)$ , and this combination and the first,  $\frac{1}{6}(2s_A - s_B - s_C)$  are the two (now linearly independent) SALCs we have used in the discussion of e orbitals.

**11C.3 Selection rules**

It is explained in Topic 9C and developed further in Topics 12A, 12C–12E, and 13A that the intensity of a spectral line arising from a molecular transition between some initial state with wavefunction  $\psi_i$  and a final state with wavefunction  $\psi_f$  depends on the (electric) transition dipole moment,  $\mu_{fi}$ . The z-component of this vector is defined through

$$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau \quad \text{Transition dipole moment} \quad (11C.6)$$

where  $-e$  is the charge of the electron. The transition moment has the form of the integral in eqn 11C.3; so, once we know the symmetry species of the states, we can use group theory to formulate the selection rules for the transitions.

**Example 11C.5** Deducing a selection rule

Is  $p_x \rightarrow p_y$  an allowed transition in a tetrahedral environment?

**Method** We must decide whether the product  $p_y q p_x$ , with  $q = x, y, \text{ or } z$ , spans  $A_1$  by using the  $T_d$  character table.

**Answer** The procedure works out as follows:

	$E$	$8C_3$	$3C_2$	$6\sigma_d$	$6S_4$	
$f_3(p_y)$	3	0	-1	1	-1	$T_2$
$f_2(q)$	3	0	-1	1	-1	$T_2$
$f_1(p_x)$	3	0	-1	1	-1	$T_2$
$f_1 f_2 f_3$	27	0	-1	1	-1	

We now use the decomposition procedure described to deduce that  $A_1$  occurs (once) in this set of characters, so  $p_x \rightarrow p_y$  is allowed. A more detailed analysis (using the matrix representatives rather than the characters) shows that only  $q = z$  gives an integral that may be nonzero, so the transition is z-polarized. That is, the electromagnetic radiation involved in the transition has a component of its electric vector in the z-direction.

**Self-test 11C.6** What are the allowed transitions, and their polarizations, of an electron in a  $b_1$  orbital in a  $C_{4v}$  molecule?

$$\text{Answer: } b_1 \rightarrow b_1(z); b_1 \rightarrow e(x,y)$$

## Checklist of concepts

- 1. Character tables are used to decide whether an integral is necessarily zero.
- 2. To be nonzero, an integrand must include a component that is a basis for the totally symmetric representation.
- 3. Only orbitals of the same symmetry species may have nonzero overlap.
- 4. A **symmetry-adapted linear combination** (SALC) is a linear combination of atomic orbitals constructed from equivalent atoms and having a specified symmetry.

## Checklist of equations

Property	Equation	Comment	Equation number
Decomposition of direct product	$n(\Gamma) = (1/h) \sum_R \chi^{(\Gamma)}(R) \chi(R)$	Real characters*	11C.2
Overlap integral	$S = \int \psi_2^* \psi_1 d\tau$	Definition	11C.4
Projection operator	$P^{(\Gamma)} = (1/h) \sum_R \chi^{(\Gamma)}(R) R$	To generate $\psi_m^{(\Gamma)} = P^{(\Gamma)} \chi_o$	11C.5
Transition dipole moment	$\mu_{z,fi} = -e \int \psi_f^* z \psi_i d\tau$	z-Component	11C.6

\* In general, characters may have complex values; throughout this text we encounter only real values.

# CHAPTER 11 Molecular symmetry

## TOPIC 11A Symmetry elements

### Discussion questions

**11A.1** Explain how a molecule is assigned to a point group.

**11A.2** List the symmetry operations and the corresponding symmetry elements of the point groups.

### Exercises

**11A.1(a)** The  $\text{CH}_3\text{Cl}$  molecule belongs to the point group  $C_{3v}$ . List the symmetry elements of the group and locate them in a drawing of the molecule.

**11A.1(b)** The  $\text{CCl}_4$  molecule belongs to the point group  $T_d$ . List the symmetry elements of the group and locate them in a drawing of the molecule.

**11A.2(a)** Identify the group to which the naphthalene molecule belongs and locate the symmetry elements in a drawing of the molecule.

**11A.2(b)** Identify the group to which the anthracene molecule belongs and locate the symmetry elements in a drawing of the molecule.

**11A.3(a)** Identify the point groups to which the following objects belong: (i) a sphere, (ii) an isosceles triangle, (iii) an equilateral triangle, (iv) an unsharpened cylindrical pencil.

**11A.3(b)** Identify the point groups to which the following objects belong: (i) a sharpened cylindrical pencil, (ii) a three-bladed propeller, (iii) a four-legged table, (iv) yourself (approximately).

**11A.4(a)** List the symmetry elements of the following molecules and name the point groups to which they belong: (i)  $\text{NO}_2$ , (ii)  $\text{N}_2\text{O}$ , (iii)  $\text{CHCl}_3$ , (iv)  $\text{CH}_2=\text{CH}_2$ .

**11A.4(b)** List the symmetry elements of the following molecules and name the point groups to which they belong: (i) furan (**1**), (ii)  $\gamma$ -pyran (**2**), (iii) 1,2,5-trichlorobenzene.

### Problems

**11A.1** List the symmetry elements of the following molecules and name the point groups to which they belong: (a) staggered  $\text{CH}_3\text{CH}_3$ , (b) chair and boat cyclohexane, (c)  $\text{B}_2\text{H}_6$ , (d)  $[\text{Co}(\text{en})_3]^{3+}$ , where en is ethylenediamine (1,2-diaminoethane; ignore its detailed structure), (e) crown-shaped  $\text{S}_8$ . Which of these molecules can be (i) polar, (ii) chiral?

**11A.2\*** In the square-planar complex anion  $[\text{trans-Ag}(\text{CF}_3)_2(\text{CN})_2]^-$ , the Ag–CN groups are collinear. (a) Assume free rotation of the  $\text{CF}_3$  groups (that is, disregarding the AgCF and AgCH angles) and name the point group of this complex ion. (b) Now suppose the  $\text{CF}_3$  groups cannot rotate freely (because the ion was in a solid, for example). Structure (**5**) shows a plane which bisects the NC–Ag–CN axis and is perpendicular to it. Name the point group of the complex if each  $\text{CF}_3$  group has a CF bond in that plane (so the  $\text{CF}_3$  groups do

**11A.3** State and explain the symmetry criteria that allow a molecule to be polar.

**11A.4** State the symmetry criteria that allow a molecule to be optically active.

**11A.5(a)** Assign (i) *cis*-dichloroethene and (ii) *trans*-dichloroethene to point groups.

**11A.5(b)** Assign the following molecules to point groups: (i) HF, (ii)  $\text{IF}_7$  (pentagonal bipyramid), (iii)  $\text{XeO}_2\text{F}_2$  (see-saw), (iv)  $\text{Fe}_2(\text{CO})_9$  (**3**), (v) cubane,  $\text{C}_8\text{H}_8$ , (vi) tetrafluorocubane,  $\text{C}_8\text{H}_4\text{F}_4$  (**4**).

**11A.6(a)** Which of the following molecules may be polar? (i) pyridine, (ii) nitroethane, (iii) gas-phase  $\text{HgBr}_2$ , (iv)  $\text{B}_3\text{N}_3\text{H}_6$ .

**11A.6(b)** Which of the following molecules may be polar? (i)  $\text{CH}_3\text{Cl}$ , (ii)  $\text{HW}_2(\text{CO})_{10}$ , (iii)  $\text{SnCl}_4$ .

**11A.7(a)** Identify the point groups to which all isomers of dichloronaphthalene belong.

**11A.7(b)** Identify the point groups to which all isomers of dichloroanthracene belong.

**11A.8(a)** Can molecules belonging to the point groups  $D_{2h}$  or  $C_{3h}$  be chiral? Explain your answer.

**11A.8(b)** Can molecules belonging to the point groups  $T_h$  or  $T_d$  be chiral? Explain your answer.

not point to either CN group preferentially) and the  $\text{CF}_3$  groups are (i) staggered, (ii) eclipsed.

**11A.3\*** B.A. Bovenzi and G.A. Pearce, Jr. (*J. Chem. Soc. Dalton Trans.*, 2763 (1997)) synthesized coordination compounds of the tridentate ligand pyridine-2,6-diamidoxime ( $C_7H_9N_5O_2$ , **6**). Reaction with  $NiSO_4$  produced a complex in which two of the essentially planar ligands are bonded at right angles to a single Ni atom. Name the point group and the symmetry operations of the resulting  $[Ni(C_7H_9N_5O_2)_2]^{2+}$  complex cation.

## TOPIC 11B Group theory

### Discussion questions

- 11B.1** Explain what is meant by a 'group'.
- 11B.2** Explain what is meant by (a) a representative and (b) a representation in the context of group theory.
- 11B.3** Explain the construction and content of a character table.

### Exercises

- 11B.1(a)** Use as a basis the valence  $p_z$  orbitals on each atom in  $BF_3$  to find the representative of the operation  $\sigma_h$ . Take  $z$  as perpendicular to the molecular plane.
- 11B.1(b)** Use as a basis the valence  $p_z$  orbitals on each atom in  $BF_3$  to find the representative of the operation  $C_3$ . Take  $z$  as perpendicular to the molecular plane.
- 11B.2(a)** Use the matrix representatives of the operations  $\sigma_h$  and  $C_3$  in a basis of valence  $p_z$  orbitals on each atom in  $BF_3$  to find the operation and its representative resulting from  $\sigma_h C_3$ . Take  $z$  as perpendicular to the molecular plane.
- 11B.2(b)** Use the matrix representatives of the operations  $\sigma_h$  and  $C_3$  in a basis of valence  $p_z$  orbitals on each atom in  $BF_3$  to find the operation and its representative resulting from  $C_3 \sigma_h$ . Take  $z$  as perpendicular to the molecular plane.

### Problems

- 11B.1** The group  $C_{2h}$  consists of the elements  $E$ ,  $C_2$ ,  $\sigma_h$ ,  $i$ . Construct the group multiplication table and find an example of a molecule that belongs to the group.
- 11B.2** The group  $D_{2h}$  has a  $C_2$  axis perpendicular to the principal axis and a horizontal mirror plane. Show that the group must therefore have a centre of inversion.
- 11B.3** Consider the  $H_2O$  molecule, which belongs to the group  $C_{2v}$ . Take as a basis the two  $1s$  orbitals and the four valence orbitals of the O atom and set up the  $6 \times 6$  matrices that represent the group in this basis. Confirm by explicit matrix multiplication that the group multiplications (a)  $C_2 \sigma_v = \sigma'_v$  and (b)  $\sigma_v \sigma'_v = C_2$ . Confirm, by calculating the traces of the matrices, (a) that symmetry elements in the same class have the same character, (b) that the representation is reducible, and (c) that the basis spans  $3A_1 + B_1 + 2B_2$ .
- 11B.4** Confirm that the  $z$ -component of orbital angular momentum is a basis for an irreducible representation of  $A_2$  symmetry in  $C_{3v}$ .
- 11B.5** Find the representatives of the operations of the group  $T_d$  in a basis of four  $1s$  orbitals, one at each apex of a regular tetrahedron (as in  $CH_4$ ).

\* These problems were provided by Charles Trapp and Carmen Giunta.

- 11B.4** Explain what is meant by the reduction of a representation to a direct sum of representations.
- 11B.5** Discuss the significance of the letters and subscripts used to denote the symmetry species of a representation.

- 11B.3(a)** Show that all three  $C_2$  operations in the group  $D_{3h}$  belong to the same class.
- 11B.3(b)** Show that all three  $\sigma_v$  operations in the group  $D_{3h}$  belong to the same class.
- 11B.4(a)** What is the maximum degeneracy of a particle confined to the interior of an octahedral hole in a crystal?
- 11B.4(b)** What is the maximum degeneracy of a particle confined to the interior of an icosahedral nanoparticle?
- 11B.5(a)** What is the maximum possible degree of degeneracy of the orbitals in benzene?
- 11B.5(b)** What is the maximum possible degree of degeneracy of the orbitals in 1,4-dichlorobenzene?

- 11B.6** Confirm that the representatives constructed in Problem 11B.5 reproduce the group multiplications  $C_3^+ C_3^- = E$ ,  $S_4 C_3 = S_4$ , and  $S_4 C_3 = \sigma_d$ .
- 11B.7** The (one-dimensional) matrices  $D(C_3) = 1$  and  $D(C_2) = 1$ , and  $D(C_3) = 1$  and  $D(C_2) = -1$  both represent the group multiplication  $C_3 C_2 = C_6$  in the group  $C_{6v}$ , with  $D(C_6) = +1$  and  $-1$ , respectively. Use the character table to confirm these remarks. What are the representatives of  $\sigma_v$  and  $\sigma_d$  in each case?
- 11B.8** Construct the multiplication table of the Pauli spin matrices,  $\sigma$ , and the  $2 \times 2$  unit matrix:

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

Do the four matrices form a group under multiplication?

- 11B.9** The algebraic forms of the  $f$  orbitals are a radial function multiplied by one of the factors (a)  $z(5z^2 - 3r^2)$ , (b)  $y(5y^2 - 3r^2)$ , (c)  $x(5x^2 - 3r^2)$ , (d)  $z(x^2 - y^2)$ , (e)  $y(x^2 - z^2)$ , (f)  $x(z^2 - y^2)$ , (g)  $xyz$ . Identify the irreducible representations spanned by these orbitals in (a)  $C_{2v}$ , (b)  $C_{3v}$ , (c)  $T_d$ , (d)  $O_h$ . Consider a lanthanoid ion at the centre of (a) a tetrahedral complex, (b) an octahedral complex. What sets of orbitals do the seven  $f$  orbitals split into?

## TOPIC 11C Applications of symmetry

### Discussion questions

11C.1 Identify and list four applications of character tables.

11C.2 Explain how symmetry arguments are used to construct molecular orbitals.

### Exercises

11C.1(a) Use symmetry properties to determine whether or not the integral  $\int p_x z p_z d\tau$  is necessarily zero in a molecule with symmetry  $C_{2v}$ .

11C.1(b) Use symmetry properties to determine whether or not the integral  $\int p_x z p_z d\tau$  is necessarily zero in a molecule with symmetry  $D_{3h}$ .

11C.2(a) Is the transition  $A_1 \rightarrow A_2$  forbidden for electric dipole transitions in a  $C_{3v}$  molecule?

11C.2(b) Is the transition  $A_{1g} \rightarrow E_{2u}$  forbidden for electric dipole transitions in a  $D_{6h}$  molecule?

11C.3(a) Show that the function  $xy$  has symmetry species  $B_2$  in the group  $C_{4v}$ .

11C.3(b) Show that the function  $xyz$  has symmetry species  $A_1$  in the group  $D_2$ .

11C.4(a) Consider the  $C_{2v}$  molecule  $\text{NO}_2$ . The combination  $p_x(\text{A}) - p_x(\text{B})$  of the two O atoms (with  $x$  perpendicular to the plane) spans  $A_2$ . Is there any orbital of the central N atom that can have a nonzero overlap with that combination of O orbitals? What would be the case in  $\text{SO}_2$ , where 3d orbitals might be available?

11C.4(b) Consider the  $C_{3v}$  ion  $\text{NO}_3^-$ . Is there any orbital of the central N atom that can have a nonzero overlap with the combination  $2p_z(\text{A}) - p_z(\text{B}) - p_z(\text{C})$  of the three O atoms (with  $z$  perpendicular to the plane). What would be the case in  $\text{SO}_3$ , where 3d orbitals might be available?

11C.5(a) The ground state of  $\text{NO}_2$  is  $A_1$  in the group  $C_{2v}$ . To what excited states may it be excited by electric dipole transitions, and what polarization of light is it necessary to use?

11C.5(b) The  $\text{ClO}_2$  molecule (which belongs to the group  $C_{2v}$ ) was trapped in a solid. Its ground state is known to be  $B_1$ . Light polarized parallel to the  $y$ -axis (parallel to the OO separation) excited the molecule to an upper state. What is the symmetry species of that state?

11C.6(a) A set of basis functions is found to span a reducible representation of the group  $C_{4v}$  with characters 4, 1, 1, 3, 1 (in the order of operations in the character table in the *Resource section*). What irreducible representations does it span?

11C.6(b) A set of basis functions is found to span a reducible representation of the group  $D_2$  with characters 6, -2, 0, 0 (in the order of operations in the character table in the *Resource section*). What irreducible representations does it span?

11C.7(a) What states of (i) benzene, (ii) naphthalene may be reached by electric dipole transitions from their (totally symmetrical) ground states?

11C.7(b) What states of (i) anthracene, (ii) coronene (7) may be reached by electric dipole transitions from their (totally symmetrical) ground states?

7 Coronene

11C.8(a) Write  $f_1 = \sin \theta$  and  $f_2 = \cos \theta$ , and show by symmetry arguments using the group  $C_s$  that the integral of their product over a symmetrical range around  $\theta=0$  is zero.

11C.8(b) Write  $f_1 = x$  and  $f_2 = 3x^2 - 1$ , and show by symmetry arguments using the group  $C_s$  that the integral of their product over a symmetrical range around  $x=0$  is zero.

### Problems

11C.1 What irreducible representations do the four H1s orbitals of  $\text{CH}_4$  span? Are there s and p orbitals of the central C atom that may form molecular orbitals with them? Could d orbitals, even if they were present on the C atom, play a role in orbital formation in  $\text{CH}_4$ ?

11C.2 Suppose that a methane molecule became distorted to (a)  $C_{3v}$  symmetry by the lengthening of one bond, (b)  $C_{2v}$  symmetry, by a kind of scissors action in which one bond angle opened and another closed slightly. Would more d orbitals become available for bonding?

11C.3 Does the product  $3x^2 - 1$  necessarily vanish when integrated over (a) a cube, (b) a tetrahedron, (c) a hexagonal prism, each centred on the origin?

11C.4<sup>†</sup> In a spectroscopic study of  $C_{60}$ , Negri et al. (*J. Phys. Chem.* **100**, 10849 (1996)) assigned peaks in the fluorescence spectrum. The molecule has icosahedral symmetry ( $I_h$ ). The ground electronic state is  $A_{1g}$ , and the lowest-lying excited states are  $T_{1g}$  and  $G_g$ . (a) Are photon-induced transitions allowed from the ground state to either of these excited states? Explain your answer. (b) What if the molecule is distorted slightly so as to remove its centre of inversion?

11C.5 In the square planar  $\text{XeF}_4$  molecule, consider the symmetry-adapted linear combination  $p_1 = p_A - p_B + p_C - p_D$  where  $p_A, p_B, p_C,$  and  $p_D$  are  $2p_z$

atomic orbitals on the fluorine atoms (clockwise labelling of the F atoms). Using the reduced point group  $D_4$  rather than the full symmetry point group of the molecule, determine which of the various s, p, and d atomic orbitals on the central Xe atom can form molecular orbitals with  $p_1$ .

11C.6 The chlorophylls that participate in photosynthesis and the haem groups of cytochromes are derived from the porphine dianion group (8), which belongs to the  $D_{4h}$  point group. The ground electronic state is  $A_{1g}$  and the lowest-lying excited state is  $E_u$ . Is a photon-induced transition allowed from the ground state to the excited state? Explain your answer.

# CHAPTER 12

## Rotational and vibrational spectra

The origin of spectral lines in molecular spectroscopy is the absorption, emission, or scattering of a photon when the energy of a molecule changes. The difference from atomic spectroscopy (Topic 9C) is that the energy of a molecule can change not only as a result of electronic transitions but also because it can undergo changes of rotational and vibrational state. Molecular spectra are therefore more complex than atomic spectra. However, they also contain information relating to more properties, and their analysis leads to values of bond strengths, lengths, and angles. They also provide a way of determining a variety of molecular properties, such as dipole moments.

The general strategy we adopt in this chapter is to set up expressions for the energy levels of molecules and then infer the form of rotational and vibrational spectra. Electronic spectra are considered in Chapter 13.

### 12A General features of molecular spectroscopy

This Topic begins with a discussion of the theory of absorption and emission of radiation, leading to the factors that determine the intensities and widths of spectral lines. Then we describe features of instrumentation used to monitor the absorption, emission, and scattering of radiation spanning a wide range of frequencies.

### 12B Molecular rotation

In this Topic we see how to derive expressions for the values of the rotational energy levels of diatomic and polyatomic molecules. The most direct procedure, which we adopt, is to identify the expressions for the energy and angular momentum obtained in classical physics, and then to transform these expressions into their quantum mechanical counterparts.

### 12C Rotational spectroscopy

This Topic focuses on the interpretation of pure rotational and rotational Raman spectra, in which only the rotational state of a molecule changes. We explain in terms of nuclear spin and the Pauli principle the observation that not all molecules can occupy all rotational states.

### 12D Vibrational spectroscopy of diatomic molecules

In this Topic we consider the vibrational energy levels of diatomic molecules and see that we can use the properties of harmonic oscillators developed in Topic 8B, but must also take into account deviations from harmonic oscillation. We also see that vibrational spectra of gaseous samples show features that arise from the rotational transitions that accompany the excitation of vibrations.

### 12E Vibrational spectroscopy of polyatomic molecules

The vibrational spectra of polyatomic molecules may be discussed as though they consisted of a set of independent harmonic oscillators, so the same approach as employed for diatomic molecules may be used. We also see that the symmetry properties of the atomic displacements of polyatomic molecules are helpful for deciding which modes of vibration can be studied spectroscopically.

### What is the impact of this material?

Molecular spectroscopy is also useful to astrophysicists and environmental scientists. In *Impact* I12.1 we see how the

identities of molecules found in interstellar space can be inferred from their rotational and vibrational spectra. In *Impact* I12.2 we turn our attention back towards the Earth and see how the vibrational properties of its atmospheric constituents can affect its climate.

### ► Why do you need to know this material?

To interpret data from the wide range of varieties of molecular spectroscopy you need to understand the experimental and theoretical features that all types of spectra share.

### ► What is the key idea?

A transition from a low energy state to one of higher energy can be stimulated by absorption of electromagnetic radiation; a transition from a higher to a lower state may be either spontaneous (resulting in emission of radiation) or stimulated by radiation.

### ► What do you need to know already?

You need to be familiar with quantization of energy in molecules (Topics 8A–8C), and the concept of selection rules in spectroscopy (Topic 9C).

In **emission spectroscopy**, a molecule undergoes a transition from a state of high energy  $E_1$  to a state of lower energy  $E_2$  and emits the excess energy as a photon. In **absorption spectroscopy**, the net absorption of incident radiation is monitored as its frequency is varied. We say *net* absorption, because, when a sample is irradiated, both absorption and emission at a given frequency are stimulated, and the detector measures the difference, the net absorption. In **Raman spectroscopy**, changes in molecular state are explored by examining the frequencies present in the radiation scattered by molecules.

The energy,  $h\nu$ , of the photon emitted or absorbed, and therefore the frequency  $\nu$  of the radiation emitted or absorbed, is given by the Bohr frequency condition (eqn 7A.12 of Topic 7A,  $h\nu = |E_1 - E_2|$ ). Emission and absorption spectroscopy give the same information about electronic, vibrational, or rotational energy level separations, but practical considerations generally determine which technique is employed.

In Raman spectroscopy the difference between the frequencies of the scattered and incident radiation is determined by the transitions that take place within the molecule as a result of the impact of the incoming photon; this technique is used to study molecular vibrations and rotations. About 1 in  $10^7$  of the incident photons that collide with the molecules, give up some of their energy, and emerge with a lower energy. These scattered photons constitute the lower-frequency **Stokes radiation** from the sample (Fig. 12A.1). Other incident photons may collect energy from the molecules (if they are already excited), and emerge as higher-frequency **anti-Stokes radiation**. The component scattered without change of frequency is called **Rayleigh radiation**.

Atomic spectroscopy is discussed in Topic 9C. Here we set the stage for detailed discussion of rotational (Topics 12B

**Figure 12A.1** In Raman spectroscopy, an incident photon is scattered from a molecule with either an increase in frequency (if the radiation collects energy from the molecule) or with a lower frequency (if it loses energy to the molecule) to give the anti-Stokes and Stokes lines, respectively. Scattering without change of frequency results in the Rayleigh lines. The process can be regarded as taking place by an excitation of the molecule to a wide range of states (represented by the shaded band), and the subsequent return of the molecule to a lower state; the net energy change is then carried away by the photon.

and 12C), vibrational (Topics 12D and 12E), and electronic (the several Topics of Chapter 13) transitions in molecules. Techniques that probe transitions between spin states of electrons and nuclei are also useful. They rely on special experimental approaches and theoretical considerations described in Chapter 14.

## 12A.1 The absorption and emission of radiation

As mentioned in *Foundations B*, the separation of rotational energy levels (in small molecules,  $\Delta E \approx 0.01$  zJ, corresponding to about  $0.01$  kJ mol<sup>-1</sup>) is smaller than that of vibrational energy levels ( $\Delta E \approx 10$  zJ, corresponding to  $10$  kJ mol<sup>-1</sup>), which itself is smaller than that of electronic energy levels ( $\Delta E \approx 0.1$ – $1$  aJ, corresponding to about  $10^2$ – $10^3$  kJ mol<sup>-1</sup>). From  $\nu = \Delta E/h$ , it follows that rotational, vibrational, and electronic transitions result from the absorption or emission of microwave, infrared, and ultraviolet/visible/far infrared radiation, respectively (see also Chapter 8). Here we turn our attention to the origins of spectroscopic transitions, focusing on concepts that apply generally to all varieties of spectroscopy.

### (a) Stimulated and spontaneous radiative processes

Albert Einstein identified three contributions to the transitions between states. First, he recognized the transition from a low

energy state to one of higher energy that is driven by the electromagnetic field oscillating at the transition frequency. This process is called **stimulated absorption**. The rate of this type of transition is proportional to the intensity of the incident radiation: the more intense the incident radiation, the greater is the rate of the transition and the stronger is the absorption by the sample. Einstein wrote this transition rate as

$$w_{f \leftarrow i} = B_{fi} \rho \quad \text{Stimulated absorption} \quad \text{Transition rate} \quad (12A.1)$$

The constant  $B_{fi}$  is the **Einstein coefficient of stimulated absorption** and  $\rho d\nu$  is the energy density of radiation in the frequency range from  $\nu$  to  $\nu + d\nu$ , where  $\nu$  is the frequency of the transition. For instance, when the atom or molecule is exposed to black-body radiation from a source of temperature  $T$ ,  $\rho$  is given by the Planck distribution (eqn 7A.6 of Topic 7A):

$$\rho = \frac{8\pi h \nu^3 / c^3}{e^{h\nu/kT} - 1} \quad \text{Planck distribution} \quad (12A.2)$$

At this stage  $B_{fi}$  is an empirical parameter that characterizes the transition: if it is large, then a given intensity of incident radiation will induce transitions strongly and the sample will be strongly absorbing. The **total rate of absorption**,  $W_{f \leftarrow i}$ , is the transition rate of a single molecule multiplied by the number of molecules  $N_i$  in the lower state:

$$W_{f \leftarrow i} = N_i w_{f \leftarrow i} = N_i B_{fi} \rho \quad \text{Total absorption rate} \quad (12A.3)$$

Einstein considered that the radiation was also able to induce the molecule in the upper state to undergo a transition to the lower state, and hence to generate a photon of frequency  $\nu$ . Thus, he wrote the rate of this **stimulated emission** as

$$w_{f \rightarrow i} = B_{if} \rho \quad \text{Stimulated emission} \quad \text{Transition rate} \quad (12A.4)$$

where  $B_{if}$  is the **Einstein coefficient of stimulated emission**. This coefficient is in fact equal to the coefficient of stimulated absorption as we shall see below. Moreover, only radiation of the same frequency as the transition can stimulate an excited state to fall to a lower state. At this point, it is tempting to suppose that the total rate of emission is this individual rate multiplied by the number of molecules in the upper state,  $N_f$ , and therefore to write  $W_{f \rightarrow i} = N_f B_{if} \rho$ . But here we encounter a problem: at equilibrium (as in a black-body container), the rate of emission is equal to the rate of absorption, so  $N_i B_{fi} \rho = N_f B_{if} \rho$  and therefore, since  $B_{if} = B_{fi}$ ,  $N_i = N_f$ . The conclusion that the populations must be equal at equilibrium is in conflict with another very fundamental conclusion, that the ratio of populations is given by the Boltzmann distribution (*Foundations B* and Topic 15A) which implies that  $N_i \neq N_f$ .

Einstein realized that to bring the analysis of transition rates into alignment with the Boltzmann distribution there must be

another route for the upper state to decay into the lower state, and wrote

$$w_{f \rightarrow i} = A + B_{if}\rho \quad \text{Emission rate} \quad (12A.5)$$

The constant  $A$  is the **Einstein coefficient of spontaneous emission**. The **total rate of emission**,  $W_{f \rightarrow i}$ , is therefore

$$W_{f \rightarrow i} = N_f w_{f \rightarrow i} = N_f (A + B_{if}\rho) \quad \text{Total emission rate} \quad (12A.6)$$

At thermal equilibrium,  $N_i$  and  $N_f$  do not change over time. This condition is reached when the total rates of emission and absorption are equal:

$$N_i B_{if}\rho = N_f (A + B_{if}\rho) \quad \text{Thermal equilibrium} \quad (12A.7)$$

and therefore

$$\rho = \frac{N_f A}{N_i B_{if} - N_f B_{if}} \stackrel{\text{divide by } N_f B_{if}}{=} \frac{A/B_{if}}{N_i/N_f - B_{if}/B_{if}} = \frac{A/B_{if}}{e^{h\nu/kT} - B_{if}/B_{if}} \quad (12A.8)$$

We have used the Boltzmann expression (*Foundations* B and Topic 15A) for the ratio of populations of the upper state (of energy  $E_f$ ) and lower state (of energy  $E_i$ ):

$$\frac{N_f}{N_i} = e^{-\frac{h\nu}{(E_f - E_i)/kT}}$$

This result has the same form as the Planck distribution (eqn 12A.2), which describes the radiation density at thermal equilibrium. Indeed when we compare eqns 12A.2 and 12A.8, we can conclude that  $B_{if} = B_{fi}$  (as we promised to show) and that

$$A = \left( \frac{8\pi h\nu^3}{c^3} \right) B \quad (12A.9)$$

The important point about eqn 12A.9 is that it shows that the relative importance of spontaneous emission increases as the cube of the transition frequency and therefore that it is therefore potentially of great importance at very high frequencies. Conversely, spontaneous emission can be ignored at low transition frequencies, in which case intensities of those transitions can be discussed in terms of stimulated emission and absorption alone.

#### Brief illustration 12A.1 The Einstein coefficients

For a transition in the microwave region of the electromagnetic spectrum (corresponding to an excitation of a molecular rotation), a typical frequency is 600 GHz (1 GHz =  $10^9$  Hz), or

$6.00 \times 10^{11} \text{ s}^{-1}$ . To assess the relative significance of spontaneous emission, with rate  $A$ , and stimulated emission, with rate  $B\rho$ , at 298 K, we rearrange eqn 12A.8, with  $B = B_{fi} = B_{if}$ , when it becomes

$$\rho = \frac{A/B}{e^{h\nu/kT} - 1}$$

to form the ratio

$$\frac{A}{B\rho} = e^{h\nu/kT} - 1 = e^{(6.626 \times 10^{-34} \text{ J s}) \times (6.00 \times 10^{11} \text{ s}^{-1}) / (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} - 1 = 0.101$$

and both spontaneous and stimulated emission are significant at this wavelength.

**Self-test 12A.1** Calculate the ratio  $A/B\rho$  at 298 K for a transition in the infrared region of the electromagnetic spectrum, corresponding to excitation of a molecular vibration, with wavenumber  $2000 \text{ cm}^{-1}$ . What conclusion can you draw?

Answer:  $A/B\rho = 1.6 \times 10^4$ ; for vibrational transitions spontaneous emission is more significant than stimulated emission

## (b) Selection rules and transition moments

We first met the concept of a ‘selection rule’ in Topic 9C as a statement about whether a transition is forbidden or allowed. Selection rules also apply to molecular spectra, and the form they take depends on the type of transition. The underlying classical idea is that, for the molecule to be able to interact with the electromagnetic field and absorb or create a photon of frequency  $\nu$ , it must possess, at least transiently, a dipole oscillating at that frequency. In Topic 9C it is shown that this transient dipole is expressed quantum mechanically in terms of the transition dipole moment,  $\mu_{fi}$ , between states  $\psi_i$  and  $\psi_f$ :

$$\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i \, d\tau \quad \text{Definition} \quad \text{Transition dipole moment} \quad (12A.10)$$

where  $\hat{\mu}$  is the electric dipole moment operator. The size of the transition dipole can be regarded as a measure of the charge redistribution that accompanies a transition: a transition is active (and generates or absorbs photons) only if the accompanying charge redistribution is dipolar (Fig. 12A.2). Only if the transition dipole moment is nonzero does the transition contribute to the spectrum. It follows that, to identify the selection rules, we must establish the conditions for which  $\mu_{fi} \neq 0$ .

A **gross selection rule** specifies the general features that a molecule must have if it is to have a spectrum of a given kind. For instance, in Topic 12C it is shown that a molecule gives a rotational spectrum only if it has a permanent electric dipole moment. This rule and others like it for other types of transition

**Figure 12A.2** (a) When a 1s electron becomes a 2s electron, there is a spherical migration of charge. There is no dipole moment associated with this migration of charge, so this transition is electric-dipole forbidden. (b) In contrast, when a 1s electron becomes a 2p electron, there is a dipole associated with the charge migration; this transition is allowed.

are explained in relevant Topics. A detailed study of the transition moment leads to the **specific selection rules** that express the allowed transitions in terms of the changes in quantum numbers.

### (c) The Beer–Lambert law

Consider the absorption of radiation by a sample. It is found empirically that the transmitted intensity  $I$  varies with the length,  $L$ , of the sample and the molar concentration,  $[J]$ , of the absorbing species  $J$  in accord with the **Beer–Lambert law**:

$$I = I_0 10^{-\varepsilon [J] L} \quad \text{Beer–Lambert law} \quad (12A.11)$$

where  $I_0$  is the incident intensity. The quantity  $\varepsilon$  (epsilon) is called the **molar absorption coefficient** (formerly, and still widely, the ‘extinction coefficient’). The molar absorption coefficient depends on the frequency of the incident radiation and is greatest where the absorption is most intense. Its dimensions are  $1/(\text{concentration} \times \text{length})$ , and it is normally convenient to express it in cubic decimetres per mole per centimetre ( $\text{dm}^3 \text{mol}^{-1} \text{cm}^{-1}$ ); in SI base units it is expressed in metres-squared per mole ( $\text{m}^2 \text{mol}^{-1}$ ). The latter units imply that  $\varepsilon$  may be regarded as a (molar) cross-section for absorption and that the greater the cross-sectional area of the molecule for absorption, the greater is its ability to block the passage of the incident radiation at a given frequency. The Beer–Lambert law is an empirical result. However, it is simple to account for its form as we show in the following *Justification*.

#### Justification 12A.1 The Beer–Lambert law

We think of the sample as consisting of a stack of infinitesimal slices, like sliced bread (Fig. 12A.3). The thickness of each layer is  $dx$ . The change in intensity,  $dI$ , that occurs when electromagnetic radiation passes through one particular slice is

**Figure 12A.3** To establish the Beer–Lambert law, the sample is supposed to be sliced into a large number of planes. The reduction in intensity caused by one plane is proportional to the intensity incident on it (after passing through the preceding planes), the thickness of the plane, and the concentration of absorbing species.

proportional to the thickness of the slice, the concentration of the absorber  $J$ , and the intensity of the incident radiation at that slice of the sample, so  $dI \propto [J]I dx$ . Because  $dI$  is negative (the intensity is reduced by absorption), we can write

$$dI = -\kappa [J] I dx$$

where  $\kappa$  (kappa) is the proportionality coefficient. Division of both sides by  $I$  gives

$$\frac{dI}{I} = -\kappa [J] dx$$

This expression applies to each successive slice.

To obtain the intensity that emerges from a sample of thickness  $L$  when the intensity incident on one face of the sample is  $I_0$ , we sum all the successive changes. Because a sum over infinitesimally small increments is an integral, we write:

$$\int_{I_0}^I \frac{dI}{I} = -\kappa \int_0^L [J] dx \stackrel{\text{Integral A.2}}{\equiv} -\kappa [J] \int_0^L dx \stackrel{\text{Integral A.1}}{\equiv} -\kappa [J] L$$

in the second step we have supposed that the concentration is uniform, so  $[J]$  is independent of  $x$  and can be taken outside the integral. Therefore

$$\ln \frac{I}{I_0} = -\kappa [J] L$$

Because  $\ln x = (\ln 10) \log x$ , we can write  $\varepsilon = \kappa / \ln 10$  and obtain

$$\log \frac{I}{I_0} = -\varepsilon [J] L$$

which, on taking (common) antilogarithms, is the Beer–Lambert law (eqn 12A.11).

The spectral characteristics of a sample are commonly reported as the **transmittance**,  $T$ , of the sample at a given frequency:

$$T = \frac{I}{I_0} \quad \text{Definition Transmittance (12A.12)}$$

and the **absorbance**,  $A$ , of the sample:

$$A = \log \frac{I_0}{I} \quad \text{Definition Absorbance (12A.13)}$$

The two quantities are related by  $A = -\log T$  (note the common logarithm) and the Beer–Lambert law becomes

$$A = \epsilon[J]L \quad (12A.14)$$

The product  $\epsilon[J]L$  was known formerly as the *optical density* of the sample.

#### Example 12A.1 Determining a molar absorption coefficient

Radiation of wavelength 280 nm passed through 1.0 mm of a solution that contained an aqueous solution of the amino acid tryptophan at a concentration of  $0.50 \text{ mol dm}^{-3}$ . The light intensity is reduced to 54 per cent of its initial value (so  $T=0.54$ ). Calculate the absorbance and the molar absorption coefficient of tryptophan at 280 nm. What would be the transmittance through a cell of thickness 2.0 mm?

**Method** From  $A = -\log T = \epsilon[J]L$ , it follows that  $\epsilon = -(\log T)/[J]L$ . For the transmittance through the thicker cell, we use  $T=10^{-A}$  and the value of  $\epsilon$  calculated here.

**Solution** The molar absorption coefficient is

$$\epsilon = \frac{-\log 0.54}{(5.0 \times 10^{-4} \text{ mol dm}^{-3}) \times (1.0 \text{ mm})} = 5.4 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ mm}^{-1}$$

These units are convenient for the rest of the calculation (but the outcome could be reported as  $5.4 \times 10^3 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$  if desired). The absorbance is

$$A = -\log 0.54 = 0.27$$

The absorbance of a sample of length 2.0 mm is

$$A = (5.4 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ mm}^{-1}) \times (5.0 \times 10^{-4} \text{ mol dm}^{-3}) \times (2.0 \text{ mm}) = 0.54$$

It follows that the transmittance is now

$$T = 10^{-A} = 10^{-0.54} = 0.29$$

That is, the emergent light is reduced to 29 per cent of its incident intensity.

**Self-test 12A.2** The transmittance of an aqueous solution that contained the amino acid tyrosine at a molar concentration of  $0.10 \text{ mol dm}^{-3}$  was measured as 0.14 at 240 nm in a cell of length 5.0 mm. Calculate the molar absorption coefficient of tyrosine at that wavelength and the absorbance of the solution. What would be the transmittance through a cell of length 1.0 mm?

Answer:  $1.1 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ ,  $A=0.17$ ,  $T=0.68$

The maximum value of the molar absorption coefficient,  $\epsilon_{\text{max}}$ , is an indication of the intensity of a transition. However, as absorption bands generally spread over a range of wavenumbers, quoting the absorption coefficient at a single wavenumber might not give a true indication of the intensity of a transition. The **integrated absorption coefficient**,  $\mathcal{A}$ , is the sum of the absorption coefficients over the entire band (Fig. 12A.4), and corresponds to the area under the plot of the molar absorption coefficient against wavenumber:

$$\mathcal{A} = \int_{\text{band}} \epsilon(\tilde{\nu}) d\tilde{\nu} \quad \text{Definition Integrated absorption coefficient (12A.15)}$$

For lines of similar widths, the integrated absorption coefficients are proportional to the heights of the lines.

## 12A.2 Spectral linewidths

A number of effects contribute to the widths of spectroscopic lines. Some contributions to linewidths can be modified by changing the conditions, and to achieve high resolutions we need to know how to minimize these contributions. Other contributions cannot be changed, and represent an inherent limitation on resolution.

**Figure 12A.4** The integrated absorption coefficient of a transition is the area under a plot of the molar absorption coefficient against the wavenumber of the incident radiation.

**(a) Doppler broadening**

One important broadening process in gaseous samples is the **Doppler effect**, in which radiation is shifted in frequency when the source is moving towards or away from the observer. When a source emitting electromagnetic radiation of frequency  $\nu$  moves with a speed  $s$  relative to an observer, the observer detects radiation of frequency

$$\nu_{\text{receding}} = \left( \frac{1-s/c}{1+s/c} \right)^{1/2} \nu \quad \nu_{\text{approaching}} = \left( \frac{1+s/c}{1-s/c} \right)^{1/2} \nu$$

Doppler shifts (12A.16a)

where  $c$  is the speed of light. For nonrelativistic speeds ( $s \ll c$ ), these expressions simplify to

$$\nu_{\text{receding}} \approx \frac{\nu}{1+s/c} \quad \nu_{\text{approaching}} \approx \frac{\nu}{1-s/c}$$

(12A.16b)

Atoms and molecules reach high speeds in all directions in a gas, and a stationary observer detects the corresponding Doppler-shifted range of frequencies. Some molecules approach the observer, some move away; some move quickly, others slowly. The detected spectral 'line' is the absorption or emission profile arising from all the resulting Doppler shifts. As shown in the following *Justification*, the profile reflects the distribution of velocities parallel to the line of sight, which is a bell-shaped Gaussian curve. The Doppler line shape is therefore also a Gaussian (Fig. 12A.5), and we show in the *Justification* that, when the temperature is  $T$  and the mass of the atom or molecule is  $m$ , then the observed width of the line at half-height (in terms of frequency or wavelength) is

$$\delta\nu_{\text{obs}} = \frac{2\nu}{c} \left( \frac{2kT \ln 2}{m} \right)^{1/2} \quad \delta\lambda_{\text{obs}} = \frac{2\lambda}{c} \left( \frac{2kT \ln 2}{m} \right)^{1/2}$$

Doppler broadening (12A.17)

**Figure 12A.5** The Gaussian shape of a Doppler-broadened spectral line reflects the Maxwell distribution of speeds in the sample at the temperature of the experiment. Notice that the line broadens as the temperature is increased.

Doppler broadening increases with temperature because the molecules acquire a wider range of speeds. Therefore, to obtain spectra of maximum sharpness, it is best to work with cool samples.

**Brief illustration 12A.2 Doppler broadening**

For a molecule like  $\text{N}_2$  at  $T=300\text{ K}$ ,

$$\frac{\delta\nu_{\text{obs}}}{\nu} = \frac{2}{c} \left( \frac{2kT \ln 2}{m_{\text{N}_2}} \right)^{1/2} = \frac{2}{2.998 \times 10^8 \text{ m s}^{-1}} \times \left( \frac{2 \times \left( 1.380 \times 10^{-23} \text{ kg m}^2 \text{ s}^{-2} \text{ K}^{-1} \right) \times (300 \text{ K}) \times \ln 2}{4.653 \times 10^{-26} \text{ kg}} \right)^{1/2} = 2.34 \times 10^{-6}$$

For a transition wavenumber of  $2331\text{ cm}^{-1}$  (from the Raman spectrum of  $\text{N}_2$ ), corresponding to a frequency of  $69.9\text{ THz}$  ( $1\text{ THz} = 10^{12}\text{ Hz}$ ), the linewidth is  $164\text{ MHz}$ .

**Self-test 12A.3** What is the Doppler-broadened linewidth of the transition at  $821\text{ nm}$  in atomic hydrogen at  $300\text{ K}$ ?

Answer:  $4.38\text{ GHz}$

**Justification 12A.2 Doppler broadening**

It follows from the Boltzmann distribution (*Foundations B* and Topic 15A) that the probability that an atom or molecule of mass  $m$  and speed  $s$  in a gas phase sample at a temperature  $T$  has kinetic energy  $E_k = \frac{1}{2}ms^2$  is proportional to  $e^{-ms^2/2kT}$ . The observed frequencies,  $\nu_{\text{obs}}$ , emitted or absorbed by the molecule are related to its speed by eqn 12A.16b. When  $s \ll c$ , the Doppler shift in the frequency is

$$\nu_{\text{obs}} - \nu \approx \pm \nu s / c$$

More specifically, the intensity  $I$  of a transition at  $\nu_{\text{obs}}$  is proportional to the probability of there being an atom that emits or absorbs at  $\nu_{\text{obs}}$ , so it follows from the Boltzmann distribution and the expression for the Doppler shift in the form  $s = (\nu_{\text{obs}} - \nu)c/\nu$  that

$$I(\nu_{\text{obs}}) \propto e^{-mc^2(\nu_{\text{obs}} - \nu)^2 / 2\nu^2 kT}$$

(12A.18)

which has the form of a Gaussian function. Because the width at half-height of a Gaussian function  $ae^{-(x-b)^2/2\sigma^2}$  (where  $a$ ,  $b$ , and  $\sigma$  are constants) is  $\delta x = 2\sigma(2 \ln 2)^{1/2}$ ,  $\delta\nu_{\text{obs}}$  can be inferred directly from the exponent of eqn 12A.18 to give eqn 12A.17.

### (b) Lifetime broadening

It is found that spectroscopic lines from gas-phase samples are not infinitely sharp even when Doppler broadening has been largely eliminated by working at low temperatures. This residual broadening is due to quantum mechanical effects. Specifically, when the Schrödinger equation is solved for a system that is changing with time, it is found that it is impossible to specify the energy levels exactly. If on average a system survives in a state for a time  $\tau$ , the lifetime of the state, then its energy levels are blurred to an extent of order  $\delta E \approx \hbar/\tau$ . With the energy spread expressed as a wavenumber through  $\delta E = hc\delta\tilde{\nu}$ , and the values of the fundamental constants introduced, this relation becomes

$$\delta\tilde{\nu} \approx \frac{5.3 \text{ cm}^{-1}}{\tau/\text{ps}} \quad \text{Lifetime broadening} \quad (12A.19)$$

and given an indication of **lifetime broadening** of spectral lines. No excited state has an infinite lifetime; therefore, all states are subject to some lifetime broadening and the shorter the lifetimes of the states involved in a transition the broader are the corresponding spectral lines.

#### Brief illustration 12A.3 Lifetime broadening

A typical electronic excited state natural lifetime is about  $\tau = 10^{-8} \text{ s} = 1.0 \times 10^4 \text{ ps}$ , corresponding to a linewidth of

$$\delta\tilde{\nu} \approx \frac{5.3 \text{ cm}^{-1}}{1.0 \times 10^4} = 5.3 \times 10^{-4} \text{ cm}^{-1}$$

which corresponds to 16 MHz.

**Self-test 12A.4** Consider a molecular rotation with a lifetime of about  $10^3 \text{ s}$ . What is the linewidth of the spectral line?

Answer:  $5 \times 10^{-15} \text{ cm}^{-1}$  (of the order of  $10^{-4} \text{ Hz}$ )

Two processes are responsible for the finite lifetimes of excited states. The dominant one for low frequency transitions is **collisional deactivation**, which arises from collisions between atoms or with the walls of the container. If the **collisional lifetime**, the mean time between collisions, is  $\tau_{\text{col}}$ , the resulting collisional linewidth is  $\delta E_{\text{col}} \approx \hbar/\tau_{\text{col}}$ . Because  $\tau_{\text{col}} = 1/z$ , where  $z$  is the collision frequency, and from the kinetic model of gases (Topic 1B), which implies that  $z$  is proportional to the pressure, we conclude that the collisional linewidth is proportional to the pressure. The collisional linewidth can therefore be minimized by working at low pressures.

The rate of spontaneous emission cannot be changed. It is a natural limit to the lifetime of an excited state which cannot be changed by modifying the conditions, and the resulting lifetime broadening is the **natural linewidth** of the transition. Because the rate of spontaneous emission increases as  $\nu^3$ , the

lifetime of the excited state decreases as  $\nu^3$ , and the natural linewidth increases with the transition frequency. Thus, rotational (microwave) transitions occur at much lower frequencies than vibrational (infrared) transitions and consequently have much longer lifetimes and hence much smaller natural linewidths: at low pressures rotational linewidths are due principally to Doppler broadening.

## 12A.3 Experimental techniques

We now turn to practical aspects of molecular spectroscopy. Common to all spectroscopic techniques is a **spectrometer**, an instrument that detects the characteristics of radiation scattered, emitted, or absorbed by atoms and molecules. As an example, Fig. 12A.6 shows the general layout of an absorption spectrometer. Radiation from an appropriate source is directed toward a sample and the radiation transmitted strikes a device that separates it into different frequencies. The intensity of radiation at each frequency is then analysed by a suitable detector.

### (a) Sources of radiation

Sources of radiation are either *monochromatic*, those spanning a very narrow range of frequencies around a central value, or *polychromatic*, those spanning a wide range of frequencies. Monochromatic sources that can be tuned over a range of frequencies include the *klystron* and the *Gunn diode*, which operate in the microwave range, and lasers (Topic 13C).

Polychromatic sources that take advantage of black-body radiation from hot materials (Topic 7A) can be used from the infrared to the ultraviolet regions of the electromagnetic spectrum. Examples include mercury arcs inside a quartz envelope ( $35 \text{ cm}^{-1} < \tilde{\nu} < 200 \text{ cm}^{-1}$ ), *Nernst filaments* and *globars* ( $200 \text{ cm}^{-1} < \tilde{\nu} < 4000 \text{ cm}^{-1}$ ), and *quartz-tungsten-halogen lamps* ( $320 \text{ nm} < \lambda < 2500 \text{ nm}$ ).

**Figure 12A.6** The layout of a typical absorption spectrometer, in which the exciting beams of radiation pass alternately through a sample and a reference cell, and the detector is synchronized with them so that the relative absorption can be determined.

**Figure 12A.7** A simple synchrotron storage ring. The electrons injected into the ring from the linear accelerator and booster synchrotron are accelerated to high speed in the main ring. An electron in a curved path is subject to constant acceleration, and an accelerated charge radiates electromagnetic energy. Different versions of synchrotrons use different strategies for generating radiation across a wide spectral range, so that experiments at different frequencies can be conducted simultaneously.

A *gas discharge lamp* is a common source of ultraviolet and visible radiation. In a *xenon discharge lamp*, an electrical discharge excites xenon atoms to excited states, which then emit ultraviolet radiation. In a *deuterium lamp*, excited  $D_2$  molecules dissociate into electronically excited D atoms, which emit intense radiation in the range 200–400 nm.

For certain applications, radiation is generated in a *synchrotron storage ring*, which consists of an electron beam travelling in a circular path with circumferences of up to several hundred metres. As electrons travelling in a circle are constantly accelerated by the forces that constrain them to their path, they generate radiation (Fig. 12A.7). This **synchrotron radiation** spans a wide range of frequencies, including the infrared and X-rays. Except in the microwave region, synchrotron radiation is much more intense than can be obtained by most conventional sources.

### (b) Spectral analysis

A common device for the analysis of the wavelengths (or wave-numbers) in a beam of radiation is a *diffraction grating*, which consists of a glass or ceramic plate into which fine grooves have been cut and covered with a reflective aluminium coating. For work in the visible region of the spectrum, the grooves are cut about 1000 nm apart (a spacing comparable to the wavelength of visible light). The grating causes interference between waves reflected from its surface, and constructive interference occurs at specific angles that depend on the frequency of the radiation being used. Thus, each wavelength of light is directed into a specific direction (Fig. 12A.8). In a *monochromator*, a narrow exit slit allows only a narrow range of wavelengths to reach the

**Figure 12A.8** A polychromatic beam is dispersed by a diffraction grating into three component wavelengths  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda_3$ . In the configuration shown, only radiation with  $\lambda_2$  passes through a narrow slit and reaches the detector. Rotating the diffraction grating (as shown by the arrows on the dotted circle) allows  $\lambda_1$  or  $\lambda_3$  to reach the detector.

detector. Turning the grating around an axis perpendicular to the incident and diffracted beams allows different wavelengths to be analysed; in this way, the absorption spectrum is built up one narrow wavelength range at a time. In a *polychromator*, there is no slit and a broad range of wavelengths can be analysed simultaneously by *array detectors*, such as those discussed below.

Many spectrometers, particularly those operating in the infrared and near-infrared, now almost always use **Fourier transform techniques** of spectral detection and analysis. The heart of a Fourier transform spectrometer is a *Michelson interferometer*, a device for analysing the frequencies present in a composite signal. The total signal from a sample is like a chord played on a piano, and the Fourier transform of the signal is equivalent to the separation of the chord into its individual notes, its spectrum.

The Michelson interferometer works by splitting the beam from the sample into two and introducing a varying path difference,  $p$ , into one of them (Fig. 12A.9). When the two components recombine, there is a phase difference between them, and

**Figure 12A.9** A Michelson interferometer. The beam-splitting element divides the incident beam into two beams with a path difference that depends on the location of the mirror  $M_1$ . The compensator ensures that both beams pass through the same thickness of material.

**Figure 12A.10** An interferogram produced as the path length  $p$  is changed in the interferometer shown in Fig. 12A.9. Only a single frequency component is present in the signal, so the graph is a plot of the function  $I(p) = I_0(1 + \cos 2\pi\tilde{\nu}p)$ , where  $I_0$  is the intensity of the radiation.

they interfere either constructively or destructively depending on the difference in path lengths. The detected signal oscillates as the two components alternately come into and out of phase as the path difference is changed (Fig. 12A.10). If the radiation has wavenumber  $\tilde{\nu}$ , the intensity of the detected signal due to radiation in the range of wavenumbers  $\tilde{\nu}$  to  $\tilde{\nu} + d\tilde{\nu}$ , which we denote  $I(p, \tilde{\nu})d\tilde{\nu}$ , varies with  $p$  as

$$I(p, \tilde{\nu})d\tilde{\nu} = I(\tilde{\nu})(1 + \cos 2\pi\tilde{\nu}p)d\tilde{\nu} \quad (12A.20)$$

Hence, the interferometer converts the presence of a particular wavenumber component in the signal into a variation in intensity of the radiation reaching the detector. An actual signal consists of radiation spanning a large number of wavenumbers, and the total intensity at the detector, which we write  $I(p)$ , is the sum of contributions from all the wavenumbers present in the signal:

$$I(p) = \int_0^\infty I(p, \tilde{\nu})d\tilde{\nu} = \int_0^\infty I(\tilde{\nu})(1 + \cos 2\pi\tilde{\nu}p)d\tilde{\nu} \quad (12A.21)$$

A plot of  $I(p)$  against  $p$  is called an **interferogram**. The problem is to find  $I(\tilde{\nu})$ , the variation of intensity with wavenumber, which is the spectrum we require, from the record of values of  $I(p)$ . This step is a standard technique of mathematics, and is the ‘Fourier transformation’ step from which this form of spectroscopy takes its name (see *Mathematical background 7* following Chapter 18). Specifically:

$$I(\tilde{\nu}) = 4 \int_0^\infty \{I(p) - \frac{1}{2}I(0)\} \cos 2\pi\tilde{\nu}p \, dp \quad \text{Fourier transformation} \quad (12A.22)$$

where  $I(0)$  is given by eqn 12A.21 with  $p=0$ . This integration is carried out numerically in a computer connected to the spectrometer, and the output,  $I(\tilde{\nu})$ , is the transmission spectrum of the sample.

### Example 12A.2 Calculating a Fourier transform

Consider a signal consisting of three monochromatic beams with the following characteristics:

$\tilde{\nu}_i / \text{cm}^{-1}$	150	250	450
$I(\tilde{\nu}_i)$	1	3	6

where the intensities are relative to the first value listed. Plot the interferogram associated with this signal. Then calculate and plot the Fourier transform of the interferogram.

**Method** For a signal consisting of only a few monochromatic beams, the integral in eqn 12A.21 can be replaced by a sum over the finite number of wavenumbers. It follows that the interferogram is

$$I(p) = \sum_i I(\tilde{\nu}_i)(1 + \cos 2\pi\tilde{\nu}_i p)$$

In practice, the path difference  $p$  does not vary continuously, so the integral over  $p$  in eqn 12A.22 must be replaced by a sum over discrete path lengths  $p_j$ , in which case the equation to use to generate the Fourier transform of  $I(p)$  is

$$I(\tilde{\nu}) = 4 \sum_j \{I(p_j) - \frac{1}{2}I(0)\} \cos 2\pi\tilde{\nu}p_j$$

It is best to sum over a large number  $N$  of data points spanning a relatively large overall path difference  $P$ , with  $p_j = jP/N$  (see Problem 12A.13). For example, let  $j$  range from 0 to 1000 with  $P = 1.0$  cm, so that the path length difference increases in steps of  $(1.0/1000)$  cm =  $10 \mu\text{m}$ .

**Answer** From the data, the interferogram is

$$\begin{aligned} I(p) &= (1 + \cos 2\pi\tilde{\nu}_1 p) + 3(1 + \cos 2\pi\tilde{\nu}_2 p) + 6(1 + \cos 2\pi\tilde{\nu}_3 p) \\ &= 10 + \cos 2\pi\tilde{\nu}_1 p + 3 \cos 2\pi\tilde{\nu}_2 p + 6 \cos 2\pi\tilde{\nu}_3 p \end{aligned}$$

This function is plotted in Fig. 12A.11. The calculation of the Fourier transform  $I(\tilde{\nu})$  is made easier by the use of mathematical software. The result is shown in Fig. 12A.12.

**Figure 12A.11** The interferogram calculated from data in Example 12A.2.

**Self-test 12A.5** Explore the effect of varying the wavenumbers of the three components of the radiation on the shape of the interferogram by changing the value of  $\tilde{\nu}_3$  to  $550\text{ cm}^{-1}$ .

Answer: See Fig. 12A.13.

Figure 12A.13 The interferogram calculated from data in Self-test 12A.5.

### (c) Detectors

A **detector** is a device that converts radiation into an electric signal for appropriate processing and display. Detectors may consist of a single radiation sensing element or of several small elements arranged in one- or two-dimensional arrays.

A microwave detector is typically a *crystal diode* consisting of a tungsten tip in contact with a semiconductor. The most common detectors found in commercial infrared spectrometers are sensitive in the mid-infrared region. In a *photovoltaic device* the potential difference changes upon exposure to infrared radiation. In a *pyroelectric device* the capacitance is sensitive to temperature and hence the presence of infrared radiation.

A common detector for work in the ultraviolet and visible ranges is the *photomultiplier tube* (PMT), in which the

photoelectric effect (Topic 7A) is used to generate an electrical signal proportional to the intensity of light that strikes the detector. A common, but less sensitive, alternative to the PMT is the *photodiode*, a solid-state device that conducts electricity when struck by photons because light-induced electron transfer reactions in the detector material create mobile charge carriers (negatively charged electrons and positively charged ‘holes’).

The *charge-coupled device* (CCD) is a two-dimensional array of several million small photodiode detectors. With a CCD, a wide range of wavelengths that emerge from a polychromator are detected simultaneously, thus eliminating the need to measure light intensity one narrow wavelength range at a time. CCD detectors are the imaging devices in digital cameras, but are also used widely in spectroscopy to measure absorption, emission, and Raman scattering.

### (d) Examples of spectrometers

With a proper choice of spectrometer, absorption spectroscopy can probe electronic, vibrational, and rotational transitions in molecules. It is often necessary to modify the general design of Fig. 12A.6 in order to detect weak signals. For example, to detect rotational transitions with a microwave spectrometer it is useful to modulate the transmitted intensity by varying the energy levels with an oscillating electric field. In this **Stark modulation**, an electric field of about  $10^5\text{ V m}^{-1}$  ( $1\text{ kV cm}^{-1}$ ) and a frequency of between 10 and 100 kHz is applied to the sample.

Virtually every commercial absorption spectrometer operating in the infrared region and designed for the study of vibrational transitions uses Fourier transform techniques. Their major advantage is that all the radiation emitted by the source is monitored continuously, in contrast to a spectrometer in which a monochromator discards most of the generated radiation. As a result, Fourier transform spectrometers have a higher sensitivity than conventional spectrometers.

Rotational, vibrational, and electronic transitions can be explored by monitoring the spectrum of radiation emitted by a sample. Emission by electronic excited states of molecules has two forms: **fluorescence**, which ceases within a few nanoseconds of the exciting radiation being extinguished, and **phosphorescence**, which may persist for long periods (Topic 13B). In a conventional fluorescence experiment, the source is tuned, often with the use of a monochromator, to a wavelength that causes electronic excitation of the molecule. Typically, the emitted radiation is detected perpendicular to the direction of the exciting beam of radiation, and analysed with a second monochromator (Fig. 12A.14).

In a typical Raman spectroscopy experiment, a monochromatic incident laser beam is passed through the sample and the radiation scattered from the front face of sample is monitored (Fig. 12A.15). Lasers are used as the source of the incident

**Figure 12A.14** A simple emission spectrometer for monitoring fluorescence, where light emitted by the sample is detected at right angles to the direction of propagation of an incident beam of radiation.

radiation because an intense beam increases the intensity of scattered radiation. The monochromaticity of laser radiation makes possible the observation of frequencies of scattered light that differs only slightly from that of the incident radiation. Such high resolution is particularly useful for observing rotational transitions by Raman spectroscopy. The monochromaticity of laser radiation also allows observations to be made very close to absorption frequencies. Fourier transform instruments are common, as are spectrometers using polychromators connected to CCD detectors.

**Figure 12A.15** A common arrangement adopted in Raman spectroscopy. A laser beam first passes through a lens and then through a small hole in a mirror with a curved reflecting surface. The focused beam strikes the sample and scattered light is both deflected and focused by the mirror. The spectrum is analysed by a monochromator or an interferometer.

Raman spectroscopy can be used to study rotational and vibrational transitions in molecules. Most commercial instruments are designed for vibrational studies, which lead to applications in biochemistry, art restoration, and monitoring of industrial processes. Raman spectrometers can also be coupled to microscopes, resulting in spectra of very small regions of a sample.

## Checklist of concepts

- 1. In **Raman spectroscopy**, changes in molecular states are explored by examining the frequencies present in the radiation scattered by molecules.
- 2. **Stokes radiation** is the result of Raman scattering of photons that give up some of their energy during (and emerge with lower frequency after) collisions with molecules.
- 3. **Anti-Stokes radiation** is the result of Raman scattering of photons that collect some energy during (and emerge with higher frequency after) collisions with molecules.
- 4. The component of radiation scattered without change of frequency is called **Rayleigh radiation**.
- 5. A transition from a low energy state to one of higher energy that is driven by an oscillating electromagnetic field is called **stimulated absorption**.
- 6. A transition driven from high energy to low energy is called **stimulated emission**.
- 7. A transition from a high energy state to a low energy state occurs by the process of **spontaneous emission** at a rate independent of any radiation also present.
- 8. The relative importance of spontaneous emission increases as the cube of the transition frequency.
- 9. A **gross selection rule** specifies the general features a molecule must have if it is to have a spectrum of a given kind.
- 10. A **specific selection rule** expresses the allowed transitions in terms of the changes in quantum numbers.
- 11. **Doppler broadening** of a spectral line is caused by the distribution of molecular and atomic speeds in a sample.
- 12. **Lifetime broadening** arises from the finite lifetime of an excited state and a consequent blurring of energy levels.
- 13. Collisions between atoms can affect excited state lifetimes and spectral linewidths.
- 14. The **natural linewidth** of a transition is an intrinsic property that depends on the rate of spontaneous emission at the transition frequency.
- 15. A **spectrometer** is an instrument that detects the characteristics of radiation scattered, emitted, or absorbed by atoms and molecules.

### ► Why do you need to know this material?

To understand the origin of rotational spectra and to derive structural information, such as bond lengths, about molecules from them, you need to understand the quantum mechanical treatment of rotation of polyatomic molecules.

### ► What is the key idea?

The energy levels of a molecule modelled as a rigid rotor may be expressed in terms of quantum numbers and parameters related to its moments of inertia.

### ► What do you need to know already?

You need to be familiar with the classical description of rotational motion (*Foundations B*). You also need to be familiar with the particle on a ring and particle on a sphere as quantum mechanical models of rotational motion (Topic 8C).

Topic 8C explores the rotational states of diatomic molecules by using the particle on a ring and particle on a sphere, respectively, as models. Here we use a related but more sophisticated model that can be applied to the rotation of polyatomic molecules.

## 12B.1 Moments of inertia

The key molecular parameter we need for the description of molecular rotation is the **moment of inertia**,  $I$ , of the molecule. The moment of inertia of a molecule is defined as the mass of each atom multiplied by the square of its distance from the rotational axis passing through the centre of mass of the molecule (Fig. 12B.1):

$$I = \sum_i m_i x_i^2 \quad \text{Definition} \quad \text{Moment of inertia} \quad (12B.1)$$

where  $x_i$  is the perpendicular distance of the atom  $i$  from the axis of rotation. The moment of inertia depends on the masses of the atoms present and the molecular geometry, so we can suspect (and see explicitly in Topic 12C) that microwave spectroscopy will give information about bond lengths and bond angles.

In general, the rotational properties of any molecule can be expressed in terms of the moments of inertia about three perpendicular axes set in the molecule (Fig. 12B.2). The convention is to label the moments of inertia  $I_a$ ,  $I_b$ , and  $I_c$ , with the axes chosen so that  $I_c \geq I_b \geq I_a$ . For linear molecules, the moment of inertia around the internuclear axis is zero (because  $x_i = 0$  for all the atoms) and the two remaining moments of inertia, which are equal, are denoted simply  $I$ . The explicit expressions for the moments of inertia of some symmetrical molecules are given in Table 12B.1.

**Figure 12B.1** The definition of moment of inertia. In this molecule there are three identical atoms attached to the B atom and three different but mutually identical atoms attached to the C atom. In this example, the centre of mass lies on an axis passing through the B and C atoms, and the perpendicular distances are measured from this axis.

Figure 12B.2 An asymmetric rotor has three different moments of inertia; all three rotation axes coincide at the centre of mass of the molecule.

Table 12B.1 Moments of inertia\*

1. Diatomic molecules

$$I = \mu R^2 \quad \mu = \frac{m_A m_B}{m}$$

2. Triatomic linear rotors

$$I = m_A R^2 + m_C R'^2 - \frac{(m_A R - m_C R')^2}{m}$$

$$I = 2m_A R^2$$

3. Symmetric rotors

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A}{m} \times (m_B + m_A) (1 + 2 \cos \theta) R^2 + \frac{m_C}{m} \{ (3m_A + m_B) R' + 6m_A R \left[ \frac{1}{3} (1 + 2 \cos \theta) \right]^{1/2} \} R'$$

$$I_{\parallel} = 2m_A (1 - \cos \theta) R^2$$

$$I_{\perp} = m_A (1 - \cos \theta) R^2 + \frac{m_A m_B}{m} (1 + 2 \cos \theta) R^2$$

$$I_{\parallel} = 4m_A R^2$$

$$I_{\perp} = 2m_A R^2 + 2m_C R'^2$$

4. Spherical rotors

$$I = \frac{8}{3} m_A R^2$$

$$I = 4m_A R^2$$

\* In each case,  $m$  is the total mass of the molecule.

Example 12B.1 Calculating the moment of inertia of a molecule

Calculate the moment of inertia of an  $\text{H}_2\text{O}$  molecule around the axis defined by the bisector of the HOH angle (1). The HOH bond angle is  $104.5^\circ$  and the bond length is  $95.7 \text{ pm}$ . Use  $m(^1\text{H}) = 1.0078 m_u$ .

**Method** According to eqn 12B.1, the moment of inertia is the sum of the masses multiplied by the squares of their distances from the axis of rotation. The latter can be expressed by using trigonometry and the bond angle and bond length.

**A note on good practice** The mass to use in the calculation of the moment of inertia is the actual atomic mass, not the element's molar mass; don't forget to convert from relative masses to actual masses by using the atomic mass constant  $m_u$ .

**Answer** From eqn 12B.1,

$$I = \sum_i m_i x_i^2 = m_{\text{H}} x_{\text{H}}^2 + 0 + m_{\text{H}} x_{\text{H}}^2 = 2m_{\text{H}} x_{\text{H}}^2$$

If the bond angle of the molecule is denoted  $\phi$  and the bond length is  $R$ , trigonometry gives  $x_{\text{H}} = R \sin \frac{1}{2} \phi$ . It follows that

$$I = 2m_{\text{H}}R^2 \sin^2 \frac{1}{2} \phi$$

Substitution of the data gives

$$\begin{aligned} I &= 2 \times (1.0078 \times 1.6605 \times 10^{-27} \text{ kg}) \times (9.57 \times 10^{-11} \text{ m})^2 \\ &\quad \times \sin^2 \left( \frac{1}{2} \times 104.5^\circ \right) \\ &= 1.92 \times 10^{-47} \text{ kg m}^2 \end{aligned}$$

Note that the mass of the O atom makes no contribution to the moment of inertia for this mode of rotation as the atom is immobile while the H atoms circulate around it.

**Self-test 12B.1** Calculate the moment of inertia of a  $\text{CH}^{35}\text{Cl}_3$  molecule around a rotational axis that contains the C–H bond. The C–Cl bond length is 177 pm and the HCCl angle is  $107^\circ$ ;  $m(^{35}\text{Cl}) = 34.97m_{\text{u}}$ .

Answer:  $4.99 \times 10^{-45} \text{ kg m}^2$

We shall suppose initially that molecules are **rigid rotors**, bodies that do not distort under the stress of rotation. Rigid rotors can be classified into four types (Fig. 12B.3):

**Spherical rotors** have three equal moments of inertia (examples:  $\text{CH}_4$ ,  $\text{SiH}_4$ , and  $\text{SF}_6$ ).

**Symmetric rotors** have two equal moments of inertia and a third that is non-zero (examples:  $\text{NH}_3$ ,  $\text{CH}_3\text{Cl}$ , and  $\text{CH}_3\text{CN}$ ).

**Figure 12B.3** A schematic illustration of the classification of rigid rotors.

**Linear rotors** have two equal moments of inertia and a third that is zero (examples:  $\text{CO}_2$ ,  $\text{HCl}$ ,  $\text{OCS}$ , and  $\text{HC}\equiv\text{CH}$ ).

**Asymmetric rotors** have three different and non-zero moments of inertia (examples:  $\text{H}_2\text{O}$ ,  $\text{H}_2\text{CO}$ , and  $\text{CH}_3\text{OH}$ ).

Spherical, symmetric, and asymmetric rotors are also called *spherical tops*.

## 12B.2 The rotational energy levels

The rotational energy levels of a rigid rotor may be obtained by solving the appropriate Schrödinger equation. Fortunately, however, there is a much less onerous short cut to the exact expressions: we note the classical expression for the energy of a rotating body, express it in terms of the angular momentum, and then import the quantum mechanical properties of angular momentum into the equations.

The classical expression for the energy of a body rotating about an axis  $a$  is

$$E_a = \frac{1}{2} I_a \omega_a^2 \quad (12B.2)$$

where  $\omega_a$  is the angular velocity about that axis and  $I_a$  is the corresponding moment of inertia. A body free to rotate about three axes has an energy

$$E = \frac{1}{2} I_a \omega_a^2 + \frac{1}{2} I_b \omega_b^2 + \frac{1}{2} I_c \omega_c^2 \quad (12B.3)$$

Because the classical angular momentum about the axis  $a$  is  $J_a = I_a \omega_a$  (eqn B.3 of *Foundations B*) with similar expressions for the other axes, it follows that

$$E = \frac{J_a^2}{2I_a} + \frac{J_b^2}{2I_b} + \frac{J_c^2}{2I_c} \quad \text{Classical expression} \quad \text{Rotational energy} \quad (12B.4)$$

This is the key equation, which can be used in conjunction with the quantum mechanical properties of angular momentum developed in Topic 8C.

### (a) Spherical rotors

When all three moments of inertia are equal to some value  $I$ , as in  $\text{CH}_4$  and  $\text{SF}_6$ , the classical expression for the energy is

$$E = \frac{J_a^2 + J_b^2 + J_c^2}{2I} = \frac{J^2}{2I} \quad (12B.5)$$

where  $J^2 = J_a^2 + J_b^2 + J_c^2$  is the square of the magnitude of the angular momentum. We can immediately generate the quantum expression by making the replacement

$$J^2 \rightarrow J(J+1)\hbar^2 \quad J=0, 1, 2, \dots$$

where  $J$  is the angular momentum quantum number. Therefore, the energy of a spherical rotor is confined to the values

$$E_J = J(J+1) \frac{\hbar^2}{2I} \quad J=0, 1, 2, \dots \quad \text{Spherical rotor} \quad \text{Rotational energy levels} \quad (12B.6)$$

The resulting ladder of energy levels is illustrated in Fig. 12B.4. The energy is normally expressed in terms of the **rotational constant**,  $\tilde{B}$ , of the molecule, where

$$hc\tilde{B} = \frac{\hbar^2}{2I} \quad \text{so} \quad \tilde{B} = \frac{\hbar}{4\pi cI} \quad \text{Spherical rotor} \quad \text{Rotational constant} \quad (12B.7)$$

It follows that  $\tilde{B}$  is a wavenumber. The expression for the energy is then

$$E_J = hc\tilde{B}J(J+1) \quad J=0, 1, 2, \dots \quad \text{Spherical rotor} \quad \text{Energy levels} \quad (12B.8)$$

It is also common to express the rotational constant as a frequency and to denote it simply  $B$ . Then  $B = \hbar/4\pi I$  and the energy is  $E = hBJ(J+1)$ . The two quantities are related by  $B = c\tilde{B}$ .

The energy of a rotational state is normally reported as the **rotational term**,  $\tilde{F}(J)$ , a wavenumber, by division of both sides of eqn 12B.8 by  $hc$ :

$$\tilde{F}(J) = \tilde{B}J(J+1) \quad \text{Spherical rotor} \quad \text{Rotational terms} \quad (12B.9)$$

To express the rotational term as a frequency, use  $F = c\tilde{F}$ . The separation of adjacent levels is

$$\tilde{F}(J+1) - \tilde{F}(J) = \tilde{B}(J+1)(J+2) - \tilde{B}J(J+1) = 2\tilde{B}(J+1) \quad (12B.10)$$

Because the rotational constant is inversely proportional to  $I$ , large molecules have closely spaced rotational energy levels.

**Figure 12B.4** The rotational energy levels of a linear or spherical rotor. Note that the energy separation between neighbouring levels increases as  $J$  increases.

### Brief illustration 12B.1 Spherical rotors

Consider  $^{12}\text{C}^{35}\text{Cl}_4$ : from Table 12B.1, the C–Cl bond length ( $R_{\text{C-Cl}} = 177 \text{ pm}$ ) and the mass of the  $^{35}\text{Cl}$  nuclide ( $m(^{35}\text{Cl}) = 34.97m_u$ ), we find

$$\begin{aligned} I &= \frac{8}{3} m(^{35}\text{Cl}) R_{\text{C-Cl}}^2 \\ &= \frac{8}{3} \times \overbrace{(34.97 \times (1.66054 \times 10^{-27} \text{ kg}))}^{34.97 \times (1.66054 \times 10^{-27} \text{ kg})} \times (1.77 \times 10^{-10} \text{ m})^2 \\ &= 4.85 \times 10^{-45} \text{ kg m}^2 \end{aligned}$$

and, from eqn 12B.7,

$$\begin{aligned} \tilde{B} &= \frac{1.05457 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-2}}{4\pi \times (2.998 \times 10^8 \text{ m s}^{-1}) \times (4.85 \times 10^{-45} \text{ kg m}^2)} \\ &= 5.77 \text{ m}^{-1} = 0.0577 \text{ cm}^{-1} \end{aligned}$$

It follows from eqn 12B.10 that the energy separation between the  $J=0$  and  $J=1$  levels is  $\tilde{F}(1) - \tilde{F}(0) = 2\tilde{B} = 0.1154 \text{ cm}^{-1}$ .

**Self-test 12B.2** Calculate  $\tilde{F}(2) - \tilde{F}(0)$  for  $^{12}\text{C}^{35}\text{Cl}_4$ .

Answer:  $6\tilde{B} = 0.3462 \text{ cm}^{-1}$

### (b) Symmetric rotors

In symmetric rotors, all three moments of inertia are non-zero but two are the same and different from the third (as in  $\text{CH}_3\text{Cl}$ ,  $\text{NH}_3$ , and  $\text{C}_6\text{H}_6$ ); the unique axis of the molecule is its **principal axis** (or *figure axis*). We shall write the unique moment of inertia (that about the principal axis) as  $I_{\parallel}$  and the other two as  $I_{\perp}$ . If  $I_{\parallel} > I_{\perp}$ , the rotor is classified as **oblate** (like a pancake, and  $\text{C}_6\text{H}_6$ ); if  $I_{\parallel} < I_{\perp}$  it is classified as **prolate** (like a cigar, and  $\text{CH}_3\text{Cl}$ ). The classical expression for the energy, eqn 12B.5, becomes

$$E = \frac{J_b^2 + J_c^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}} \quad (12B.11)$$

Again, this expression can be written in terms of  $J^2 = J_a^2 + J_b^2 + J_c^2$ :

$$E = \frac{J^2 - J_a^2}{2I_{\perp}} + \frac{J_a^2}{2I_{\parallel}} = \frac{J^2}{2I_{\perp}} + \left( \frac{1}{2I_{\parallel}} - \frac{1}{2I_{\perp}} \right) J_a^2 \quad (12B.12)$$

Now we generate the quantum expression by first replacing  $J^2$  by  $J(J+1)\hbar^2$ . Then, using the quantum theory of angular momentum (Topic 8C), we note that the component of angular momentum about any axis is restricted to the values  $K\hbar$ , with  $K=0, \pm 1, \dots, \pm J$ . ( $K$  is the quantum number used to signify a component on the principal axis;  $M_J$  is reserved for a component on an externally defined axis.) Therefore, we also replace  $J_a^2$  by  $K^2\hbar^2$ . It follows that the rotational terms are

$$\tilde{F}(J, K) = \tilde{B}J(J+1) + (\tilde{A} - \tilde{B})K^2 \quad \text{Symmetric rotor} \quad \text{Rotational terms} \quad (12B.13)$$

$$J = 0, 1, 2, \dots \quad K = 0, \pm 1, \dots, \pm J$$

with

$$\tilde{A} = \frac{\hbar}{4\pi c I_{\parallel}} \quad \tilde{B} = \frac{\hbar}{4\pi c I_{\perp}} \quad (12B.14)$$

As eqn 12B.13 matches what we should expect for the dependence of the energy levels on the two distinct moments of inertia of the molecule:

- When  $K=0$ , there is no component of angular momentum about the principal axis, and the energy levels depend only on  $I_{\perp}$  (Fig. 12B.5).
- When  $K=\pm J$ , almost all the angular momentum arises from rotation around the principal axis, and the energy levels are determined largely by  $I_{\parallel}$ .
- The sign of  $K$  does not affect the energy because opposite values of  $K$  correspond to opposite senses of rotation, and the energy does not depend on the sense of rotation.

Physical interpretation

**Figure 12B.5** The significance of the quantum number  $K$ . (a) When  $|K|$  is close to its maximum value,  $J$ , most of the molecular rotation is around the figure axis. (b) When  $K=0$  the molecule has no angular momentum about its principal axis: it is undergoing end-over-end rotation.

### Example 12B.2 Calculating the rotational energy levels of a symmetric rotor

A  $^{14}\text{NH}_3$  molecule is a symmetric rotor with bond length 101.2 pm and HNH bond angle  $106.7^\circ$ . Calculate its rotational terms.

*A note on good practice* To calculate moments of inertia precisely, it is necessary to specify the nuclide.

**Method** Begin by calculating the rotational constants  $\tilde{A}$  and  $\tilde{B}$  by using the expressions for moments of inertia given in Table 12B.1 and eqn 12B.14. Then use eqn 12B.13 to find the rotational terms.

**Answer** Substitution of  $m_A = 1.0078m_u$ ,  $m_B = 14.0031m_u$ ,  $R = 101.2$  pm, and  $\theta = 106.7^\circ$  into the second of the symmetric rotor expressions in Table 12B.1 gives  $I_{\parallel} = 4.4128 \times 10^{-47}$  kg m<sup>2</sup> and  $I_{\perp} = 2.8059 \times 10^{-47}$  kg m<sup>2</sup>. Hence, by the same kind of calculations as in *Brief illustration* 12B.1,  $\tilde{A} = 6.344$  cm<sup>-1</sup> and  $\tilde{B} = 9.977$  cm<sup>-1</sup>. It follows from eqn 12B.13 that

$$\tilde{F}(J, K)/\text{cm}^{-1} = 9.977 \times J(J+1) - 3.933K^2$$

Multiplication by  $c$  converts  $\tilde{F}(J, K)$  to a frequency, denoted  $F(J, K)$ :

$$F(J, K)/\text{GHz} = 299.1 \times J(J+1) - 108.9K^2$$

For  $J=1$ , the energy needed for the molecule to rotate mainly about its figure axis ( $K=\pm J$ ) is equivalent to  $16.32$  cm<sup>-1</sup> (489.3 GHz), but end-over-end rotation ( $K=0$ ) corresponds to  $19.95$  cm<sup>-1</sup> (598.1 GHz).

**Self-test 12B.3** A  $\text{CH}_3^{35}\text{Cl}$  molecule has a C–Cl bond length of 178 pm, a C–H bond length of 111 pm, and an HCH angle of  $110.5^\circ$ . Calculate its rotational energy terms.

Answer:  $\tilde{F}(J, K)/\text{cm}^{-1} = 0.444J(J+1) + 4.58K^2$ ;  
also  $F(J, K)/\text{GHz} = 13.3J(J+1) + 137K^2$

The energy of a symmetric rotor depends on  $J$  and  $K$ , and each level except those with  $K=0$  is doubly degenerate: the states with  $K$  and  $-K$  have the same energy. However, we must not forget that the angular momentum of the molecule has a component on an external, laboratory-fixed axis. This component is quantized, and its permitted values are  $M_J\hbar$ , with  $M_J = 0, \pm 1, \dots, \pm J$ , giving  $2J+1$  values in all (Fig. 12B.6). The quantum number  $M_J$  does not appear in the expression for the energy, but it is necessary for a complete specification of the state of

**Figure 12B.6** The significance of the quantum number  $M_J$ . (a) When  $M_J$  is close to its maximum value,  $J$ , most of the molecular rotation is around the laboratory  $z$ -axis. (b) An intermediate value of  $M_J$ . (c) When  $M_J=0$  the molecule has no angular momentum about the  $z$ -axis. All three diagrams correspond to a state with  $K=0$ ; there are corresponding diagrams for different values of  $K$ , in which the angular momentum makes a different angle to the molecule's principal axis.

the rotor. Consequently, all  $2J+1$  orientations of the rotating molecule have the same energy. It follows that a symmetric rotor level is  $2(2J+1)$ -fold degenerate for  $K \neq 0$  and  $(2J+1)$ -fold degenerate for  $K=0$ .

A spherical rotor can be regarded as a version of a symmetric rotor in which  $\tilde{A} = \tilde{B}$ . The quantum number  $K$  may still take any one of  $2J+1$  values, but the energy is independent of which value it takes. Therefore, as well as having a  $(2J+1)$ -fold degeneracy arising from its orientation in space, the rotor also has a  $(2J+1)$ -fold degeneracy arising from its orientation with respect to an arbitrary axis in the molecule. The overall degeneracy of a symmetric rotor with quantum number  $J$  is therefore  $(2J+1)^2$ . This degeneracy increases very rapidly: when  $J=10$ , for instance, there are 441 states of the same energy.

### (c) Linear rotors

For a linear rotor (such as  $\text{CO}_2$ ,  $\text{HCl}$ , and  $\text{C}_2\text{H}_2$ ), in which the nuclei are regarded as mass points, the rotation occurs only about an axis perpendicular to the line of atoms and there is zero angular momentum around the line. Therefore, the component of angular momentum around the figure axis of a linear rotor is identically zero, and  $K \equiv 0$  in eqn 12B.13. The rotational terms of a linear molecule are therefore

$$\tilde{F}(J) = \tilde{B}J(J+1) \quad J=0, 1, 2, \dots \quad \begin{array}{l} \text{Linear} \\ \text{rotor} \end{array} \quad \begin{array}{l} \text{Rotational} \\ \text{terms} \end{array} \quad (12B.15)$$

This expression is the same as eqn 12B.9 but we have arrived at it in a significantly different way: here  $K \equiv 0$  but for a spherical rotor  $\tilde{A} = \tilde{B}$ . A linear rotor has  $2J+1$  components on the laboratory axis, so its degeneracy is  $2J+1$ .

#### Brief illustration 12B.2 Linear rotors

Equation 12B.10 for the energy separation of adjacent levels of a spherical rotor also applies to linear rotors. For  $^1\text{H}^{35}\text{Cl}$ ,  $\tilde{F}(3) - \tilde{F}(2) = 63.56 \text{ cm}^{-1}$ , and it follows that  $6\tilde{B} = 63.56 \text{ cm}^{-1}$  and  $\tilde{B} = 10.59 \text{ cm}^{-1}$ .

**Self-test 12B.4** For  $^1\text{H}^{81}\text{Br}$ ,  $\tilde{F}(1) - \tilde{F}(0) = 16.93 \text{ cm}^{-1}$ . Determine the value of  $\tilde{B}$ .

Answer:  $8.465 \text{ cm}^{-1}$

### (d) Centrifugal distortion

We have treated molecules as rigid rotors. However, the atoms of rotating molecules are subject to centrifugal forces that tend to distort the molecular geometry and change the moments of inertia (Fig. 12B.7). The effect of centrifugal distortion on a diatomic molecule is to stretch the bond and hence to increase the

**Figure 12B.7** The effect of rotation on a molecule. The centrifugal force arising from rotation distorts the molecule, opening out bond angles and stretching bonds slightly. The effect is to increase the moment of inertia of the molecule and hence to decrease its rotational constant.

moment of inertia. As a result, centrifugal distortion reduces the rotational constant and consequently the energy levels are slightly closer than the rigid-rotor expressions predict. The effect is usually taken into account largely empirically by subtracting a term from the energy and writing

$$\tilde{F}(J) = \tilde{B}J(J+1) - \tilde{D}_J J^2(J+1)^2 \quad \begin{array}{l} \text{Rotational terms affected} \\ \text{by centrifugal distortion} \end{array} \quad (12B.16)$$

The parameter  $\tilde{D}_J$  is the **centrifugal distortion constant**. It is large when the bond is easily stretched. The centrifugal distortion constant of a diatomic molecule is related to the vibrational wavenumber of the bond,  $\tilde{\nu}$  (which, as we see in Topic 12D, is a measure of its stiffness), through the approximate relation (see Problem 12.2)

$$\tilde{D}_J = \frac{4\tilde{B}^3}{\tilde{\nu}^2} \quad \begin{array}{l} \text{Centrifugal distortion constant} \end{array} \quad (12B.17)$$

Hence the observation of the convergence of the rotational levels as  $J$  increases can be interpreted in terms of the rigidity of the bond.

#### Brief illustration 12B.3 The effect of centrifugal distortion

For  $^{12}\text{C}^{16}\text{O}$ ,  $\tilde{B} = 1.931 \text{ cm}^{-1}$  and  $\tilde{\nu} = 2170 \text{ cm}^{-1}$ . It follows that

$$\tilde{D}_J = \frac{4 \times (1.931 \text{ cm}^{-1})^3}{(2170 \text{ cm}^{-1})^2} = 6.116 \times 10^{-6} \text{ cm}^{-1}$$

and that, because  $\tilde{D}_J \ll \tilde{B}$ , centrifugal distortion has a very small effect on the energy levels.

**Self-test 12B.5** Does centrifugal distortion increase or decrease the separation between adjacent energy levels?

Answer: decrease

## Checklist of concepts

- 1. A **rigid rotor** is a body that does not distort under the stress of rotation.
- 2. Rigid rotors are classified **spherical, symmetric, linear,** or **asymmetric** by noting the number of equal principal moments of inertia.
- 3. **Symmetric rotors** are classified as prolate or oblate.
- 4. A linear rotor rotates only about an axis perpendicular to the line of atoms.
- 5. The **degeneracies** of spherical, symmetric ( $K \neq 0$ ), and linear rotors are  $(2J + 1)^2$ ,  $2(2J + 1)$ , and  $2J + 1$ , respectively.
- 6. **Centrifugal distortion** arises from forces that change the geometry of a molecule.

### ► Why do you need to know this material?

Rotational spectroscopy provides very precise details of bond lengths and bond angles of molecules in the gas phase. Transitions between rotational levels also contribute to vibrational and electronic spectra and are used in the investigation of gas-phase reactions such as those taking place in the atmosphere.

### ► What is the key idea?

Analysis of rotational spectra yields the bond lengths and dipole moments of molecules in the gas phase.

### ► What do you need to know already?

You should be familiar with the quantum mechanical treatment of molecular rotation (Topic 12B), the general principles of molecular spectroscopy (Topic 12A), and the Pauli principle (Topic 9B).

Pure rotational spectra, in which only the rotational state of a molecule changes, can be observed only in the gas phase. In spite of this limitation, rotational spectroscopy can provide a wealth of information about molecules, including precise bond lengths and dipole moments.

Our approach to the description of rotational spectra consists of developing the gross and specific selection rules for rotational transitions, examining the appearance of rotational spectra, and exploring the information that can be obtained from the spectra. This material is also used in the discussion of the fine details observed in vibrational spectra (Topic 12D) and electronic spectra (Topic 13A). Our discussion of the appearance of rotational spectra is based principally on the expression for the rotational terms of a linear rotor developed in Topic 12B:

$$\text{Eqn. 12B.9: } \tilde{F}(J) = \tilde{B}J(J+1) \quad \tilde{B} = \hbar / 4\pi cI$$

where  $I$  is the moment of inertia of the molecule (the energies themselves are  $E_J = hc\tilde{F}(J)$ ). The same expression applies to spherical rotors; the expression for symmetric rotors is slightly more elaborate:

$$\text{Eqn. 12B.13: } \tilde{F}(J, K) = \tilde{B}J(J+1) + (\tilde{A} - \tilde{B})K^2 \\ \tilde{A} = \hbar / 4\pi cI_{\parallel} \quad \tilde{B} = \hbar / 4\pi cI_{\perp}$$

The values allowed to  $J$ ,  $K$ , and  $M_J$  (which does not affect the energy but is needed to define the state fully) are set out in Topic 12B.

## 12C.1 Microwave spectroscopy

Typical values of the rotational constant  $\tilde{B}$  for small molecules are in the region of 0.1–10 cm<sup>-1</sup> (Topic 12B); two examples are 0.356 cm<sup>-1</sup> for NF<sub>3</sub> and 10.59 cm<sup>-1</sup> for HCl. It follows that rotational transitions can be studied with **microwave spectroscopy**, a technique that monitors the absorption or emission of radiation in the microwave region of the spectrum.

### (a) Selection rules

We show in the following *Justification* that the gross selection rule for the observation of a pure rotational transition in a microwave spectrum is that a molecule must have a permanent electric dipole moment. That is, *to absorb or emit microwave radiation and undergo a pure rotational transition, a molecule must be polar*. The classical basis of this rule is that a polar molecule appears to possess a fluctuating dipole when rotating but a nonpolar molecule does not (Fig. 12C.1). The permanent

**Figure 12C.1** To a stationary observer, a rotating polar molecule looks like an oscillating dipole which can stir the electromagnetic field into oscillation (and vice versa for absorption). This picture is the classical origin of the gross selection rule for rotational transitions.

dipole can be regarded as a handle with which the molecule stirs the electromagnetic field into oscillation (and vice versa for absorption).

#### Brief illustration 12C.1 Gross selection rules for microwave spectroscopy

Homomuclear diatomic molecules and nonpolar polyatomic molecules, such as  $\text{CO}_2$ ,  $\text{CH}_2=\text{CH}_2$ , and  $\text{C}_6\text{H}_6$ , are rotationally inactive. On the other hand,  $\text{OCS}$  and  $\text{H}_2\text{O}$  are polar, and have microwave spectra. Spherical rotors cannot have electric dipole moments unless they become distorted by rotation, so they are rotationally inactive except in special cases. An example of a spherical rotor that does become sufficiently distorted for it to acquire a dipole moment is  $\text{SiH}_4$ , which has a dipole moment of about  $8.3 \mu\text{D}$  by virtue of its rotation when  $J \approx 10$  (for comparison,  $\text{HCl}$  has a permanent dipole moment of  $1.1 \text{ D}$ ; molecular dipole moments and their units are discussed in Topic 16A).

**Self-test 12C.1** Which of the molecules  $\text{H}_2$ ,  $\text{NO}$ ,  $\text{N}_2\text{O}$ ,  $\text{CH}_4$  can have a pure rotational spectrum?

Answer:  $\text{NO}, \text{N}_2\text{O}$

The specific rotational selection rules are found by evaluating the transition dipole moment (Topic 12A) between rotational states. We show in the following *Justification* that, for a linear molecule, the transition moment vanishes unless the following conditions are fulfilled:

$$\Delta J = \pm 1 \quad \Delta M_J = 0, \pm 1 \quad \text{Linear rotors} \quad \text{Rotational selection rules} \quad (12C.1)$$

The transition  $\Delta J = +1$  corresponds to absorption and the transition  $\Delta J = -1$  corresponds to emission.

- The allowed change in  $J$  arises from the conservation of angular momentum when a photon, a spin-1 particle, is emitted or absorbed (Fig. 12C.2).
- The allowed change in  $M_J$  also arises from the conservation of angular momentum when a photon is emitted into or absorbed from a specific direction.

Physical interpretation

**Figure 12C.2** When a photon is absorbed by a molecule, the angular momentum of the combined system is conserved. If the molecule is rotating in the same sense as the spin of the incoming photon, then  $J$  increases by 1.

#### Justification 12C.1 Selection rules for microwave spectra

The starting point for any discussion about selection rules is the transition dipole moment (Topic 12A) and the total wavefunction for a molecule, which can be written as  $\psi_{\text{total}} = \psi_{\text{c.m.}} \psi$ , where  $\psi_{\text{c.m.}}$  describes the motion of the centre of mass and  $\psi$  describes the internal motion of the molecule. The Born–Oppenheimer approximation (Topic 10A) allows us to write  $\psi$  as the product of an electronic part,  $\psi_{\text{e}}$ , a vibrational part,  $\psi_{\text{v}}$ , and a rotational part, which for a diatomic molecule can be represented by the spherical harmonics  $Y_{J,M_J}(\theta, \phi)$  (Topic 8C). The transition dipole moment for the spectroscopic transition  $i \rightarrow f$  can now be written as

$$\mu_{fi} = \int \psi_{\text{e},f}^* \psi_{\text{v},f}^* Y_{J_f, M_{J_f}}^* \hat{\mu} \psi_{\text{e},i} \psi_{\text{v},i} Y_{J_i, M_{J_i}} d\tau \quad (12C.2)$$

and our task is to explore conditions for which this integral does not vanish.

For a pure rotational transition the initial and final electronic and vibrational states are the same, and we identify  $\mu_i = \int \psi_{\text{e},i}^* \psi_{\text{v},i}^* \hat{\mu} \psi_{\text{e},i} \psi_{\text{v},i} d\tau$  with the permanent electric dipole moment of the molecule in the state  $i$ . Equation 12C.2 then becomes

$$\mu_{fi} = \int Y_{J_f, M_{J_f}}^* \mu_i Y_{J_i, M_{J_i}} d\tau \quad (12C.3)$$

The remaining integration is over the angles representing the orientation of the molecule. We see immediately that the molecule must have a permanent dipole moment in order to have a microwave spectrum. This is the gross selection rule for microwave spectroscopy.

From this point on, the deduction of the specific selection rules proceeds as in the case of atomic transitions (Topic 9C), and makes use of the fact that the three components of the dipole moment (Fig. 12C.3) are

$$\mu_{i,x} = \mu_0 \sin \theta \cos \phi \quad \mu_{i,y} = \mu_0 \sin \theta \sin \phi \quad \mu_{i,z} = \mu_0 \cos \theta \quad (12C.4)$$

and can be expressed in terms of the spherical harmonics  $Y_{j,m}$ , with  $j=1$  and  $m=0, \pm 1$  (see *Justification 9C.1*). The condition

for the non-vanishing of the integral over the product of three spherical harmonics, which is described in Topic 9C, then implies that

$$\int Y_{J_i, M_{J_i}}^* Y_{j, m} Y_{J_f, M_{J_f}} d\tau_{\text{angles}} = 0 \quad (12C.5)$$

unless  $M_{J_f} = M_{J_i} + m$  and lines of length  $J_f$ ,  $J_i$ , and  $j$  can form a triangle (such as 1, 2, and 3, or 1, 1, and 1, but not 1, 2, and 4). By exactly the same argument as in *Justification 9C.1*, we conclude that  $J_f - J_i = \pm 1$  and  $M_{J_f} - M_{J_i} = 0$  or  $\pm 1$ .

Figure 12C.3 The axis system used in the calculation of the transition dipole moment.

When the transition moment is evaluated for all possible relative orientations of the molecule to the line of flight of the photon, it is found that the total  $J+1 \leftrightarrow J$  transition intensity is proportional to

$$|\mu_{J+1, J}|^2 = \left( \frac{J+1}{2J+1} \right) \mu_0^2 \quad (12C.6)$$

where  $\mu_0$  is the permanent electric dipole moment of the molecule. The intensity is proportional to the square of  $\mu_0$ , so strongly polar molecules give rise to much more intense rotational lines than less polar molecules.

For symmetric rotors, an additional selection rule states that  $\Delta K = 0$ . To understand this rule, consider the symmetric rotor  $\text{NH}_3$ , where the electric dipole moment lies parallel to the figure axis. Such a molecule cannot be accelerated into different states of rotation around this axis by the absorption of radiation, so  $\Delta K = 0$ . Therefore, for symmetric rotors the selection rules are:

$$\Delta J = \pm 1 \quad \Delta M_J = 0, \pm 1 \quad \Delta K = 0 \quad \begin{array}{l} \text{Symmetric} \\ \text{rotors} \end{array} \quad \begin{array}{l} \text{Rotational} \\ \text{selection} \\ \text{rules} \end{array} \quad (12C.7)$$

The degeneracy associated with the quantum number  $M_J$  (the orientation of the rotation in space) is partly removed when an electric field is applied to a polar molecule (for example,  $\text{HCl}$  or  $\text{NH}_3$ ), as illustrated in Fig. 12C.4. The splitting of states by an electric field is called the **Stark effect**. The energy shift depends on the permanent electric dipole moment,  $\mu_0$ , so the observation of the Stark effect can be used to measure the magnitudes of electric dipole moments with a rotational spectrum.

Figure 12C.4 The effect of an electric field on the energy levels of a polar linear rotor. All levels are doubly degenerate except that with  $M_J = 0$ .

### (b) The appearance of microwave spectra

When the selection rules are applied to the expressions for the energy levels of a rigid spherical or linear rotor, it follows that the wavenumbers of the allowed  $J+1 \leftarrow J$  absorptions are

$$\begin{aligned} \tilde{\nu}(J+1 \leftarrow J) &= \tilde{F}(J+1) - \tilde{F}(J) \\ &= 2\tilde{B}(J+1) \end{aligned} \quad \begin{array}{l} \text{Linear and} \\ \text{spherical} \\ \text{rotors} \end{array} \quad \begin{array}{l} \text{Wavenumbers} \\ \text{of rotational} \\ \text{transitions} \end{array} \quad (12C.8a)$$

$$J = 0, 1, 2, \dots$$

When centrifugal distortion (Topic 12B) is taken into account, the corresponding expression obtained from eqn 12B.16 is

$$\tilde{\nu}(J+1 \leftarrow J) = 2\tilde{B}(J+1) - 4\tilde{D}_J(J+1)^3 \quad (12C.8b)$$

However, because the second term is typically very small compared with the first (see *Brief illustration 12B.3*), the appearance of the spectrum closely resembles that predicted from eqn 12C.8a.

#### Example 12C.1 Predicting the appearance of a rotational spectrum

Predict the form of the rotational spectrum of  $^{14}\text{NH}_3$ , for which  $\tilde{B} = 9.977 \text{ cm}^{-1}$ .

**Method** The  $^{14}\text{NH}_3$  molecule is a polar symmetric rotor, so the rotational terms are given by  $\tilde{F}(J, K) = \tilde{B}J(J+1) + (\tilde{A} - \tilde{B})K^2$ . Because  $\Delta J = \pm 1$  and  $\Delta K = 0$ , the expression for the wavenumbers of the rotational transitions is identical to eqn 12C.8a and depends only on  $\tilde{B}$ . For absorption,  $\Delta J = +1$ .

**Answer** We can draw up the following table for the  $J+1 \leftarrow J$  transitions.

$J$	0	1	2	3	...
$\tilde{\nu}/\text{cm}^{-1}$	19.95	39.91	59.86	79.82	...
$\nu/\text{GHz}$	598.1	1197	1795	2393	...

The line spacing is  $19.95 \text{ cm}^{-1}$  (598.1 GHz).

**Self-test 12C.2** Repeat the problem for  $\text{CH}_3^{35}\text{Cl}$ , for which  $\tilde{B} = 0.444 \text{ cm}^{-1}$ .

Answer: Lines of separation  $0.888 \text{ cm}^{-1}$  (26.6 GHz)

The form of the spectrum predicted by eqn 12C.8 is shown in Fig. 12C.5. The most significant feature is that it consists of a series of lines with wavenumbers  $2\tilde{B}, 4\tilde{B}, 6\tilde{B}, \dots$  and of separation  $2\tilde{B}$ . The measurement of the line spacing therefore gives  $\tilde{B}$ , and hence the moment of inertia perpendicular to the figure axis of the molecule. Because the masses of the atoms are known, it is a simple matter to deduce the bond length of a diatomic molecule. However, in the case of a polyatomic molecule such as OCS or  $\text{NH}_3$ , the analysis gives only a single quantity,  $I_{\perp}$ , and it is not possible to infer both bond lengths (in OCS) or the bond length and bond angle (in  $\text{NH}_3$ ). This difficulty can be overcome by using isotopologues, isotopically substituted molecules, such as ABC and A'BC; then, by assuming that  $R(\text{A}-\text{B}) = R(\text{A}'-\text{B})$ , both A-B and B-C bond lengths can be extracted from the two moments of inertia. A famous example of this procedure is the study of OCS; the actual calculation is worked through in Problem 12C.5. The assumption that bond lengths are unchanged in isotopologues is only an approximation, but it is a good approximation in most cases. Nuclear spin (Topic 14A), which differs from one isotope to another, also affects the appearance of high-resolution rotational spectra because spin is a source of angular momentum and can couple with the rotation of the molecule itself and hence affect the rotational energy levels.

The intensities of spectral lines increase with increasing  $J$  and pass through a maximum before tailing off as  $J$  becomes large. The most important reason for the maximum in intensity

**Figure 12C.5** The rotational energy levels of a linear rotor, the transitions allowed by the selection rule  $\Delta J = +1$ , and a typical pure rotational absorption spectrum (displayed here in terms of the radiation transmitted through the sample). The intensities reflect the populations of the initial level in each case and the strengths of the transition dipole moments.

is the existence of a maximum in the population of rotational levels. The Boltzmann distribution (Foundations B and Topic 15A) implies that the population of each state decreases exponentially with increasing  $J$ , but the degeneracy of the levels increases. These two opposite trends result in the population of the energy levels (as distinct from the individual states) passing through a maximum. Specifically, the population of a rotational energy level  $J$  is given by the Boltzmann expression

$$N_J \propto N g_J e^{-E_J/kT}$$

where  $N$  is the total number of molecules in the sample and  $g_J$  is the degeneracy of the level  $J$ . The value of  $J$  corresponding to a maximum of this expression is found by treating  $J$  as a continuous variable, differentiating with respect to  $J$ , and then setting the result equal to zero. The result is (see Problem 12C.9)

$$J_{\max} \approx \left( \frac{kT}{2hc\tilde{B}} \right)^{1/2} - \frac{1}{2} \quad \text{Linear rotors} \quad \text{Rotational state with largest population} \quad (12C.9)$$

For a typical molecule (for example, OCS, with  $\tilde{B} = 0.2 \text{ cm}^{-1}$ ) at room temperature,  $kT \approx 1000hc\tilde{B}$ , so  $J_{\max} \approx 30$ . However, it must be recalled that the intensity of each transition also depends on the value of  $J$  (eqn 12C.6) and on the population difference between the two states involved in the transition. Hence the value of  $J$  corresponding to the most intense line is not quite the same as the value of  $J$  for the most highly populated level.

## 12C.2 Rotational Raman spectroscopy

Raman scattering (Topic 12A) can also lead to rotational transitions. The gross selection rule for rotational Raman transitions is *that the molecule must be anisotropically polarizable*. To understand this criterion we need to know that the distortion of a molecule in an electric field is determined by its polarizability,  $\alpha$  (Topic 16A). More precisely, if the strength of the field is  $\mathcal{E}$ , then the molecule acquires an induced dipole moment of magnitude

$$\mu = \alpha \mathcal{E} \quad (12C.10)$$

in addition to any permanent dipole moment it might have. An atom is isotropically polarizable. That is, the same distortion is induced whatever the direction of the applied field. The polarizability of a spherical rotor is also isotropic. However, non-spherical rotors have polarizabilities that do depend on the direction of the field relative to the molecule, so these molecules are anisotropically polarizable (Fig. 12C.6). The electron distribution in  $\text{H}_2$ , for example, is more distorted when the field is applied parallel to the bond than when it is applied perpendicular to it, and we write  $\alpha_{\parallel} > \alpha_{\perp}$ .

**Figure 12C.6** An electric field applied to a molecule results in its distortion, and the distorted molecule acquires a contribution to its dipole moment (even if it is nonpolar initially). The polarizability may be different when the field is applied (a) parallel or (b) perpendicular to the molecular axis (or, in general, in different directions relative to the molecule); if that is so, then the molecule has an anisotropic polarizability.

All linear and diatomic molecules (whether homonuclear or heteronuclear) have anisotropic polarizabilities, and so are rotationally Raman active. This activity is one reason for the importance of rotational Raman spectroscopy, for the technique can be used to study many of the molecules that are inaccessible to microwave spectroscopy. Spherical rotors such as  $\text{CH}_4$  and  $\text{SF}_6$ , however, are rotationally Raman inactive as well as microwave inactive. This inactivity does not mean that such molecules are never found in rotationally excited states. Molecular collisions do not have to obey such restrictive selection rules, and hence collisions between molecules can result in the population of any rotational state.

The specific rotational Raman selection rules are:

Linear rotors:	$\Delta J = 0, \pm 2$	Rotational Raman selection rules	(12C.11)
Symmetric rotors:	$\Delta J = 0, \pm 1, \pm 2$		
	$\Delta K = 0$		

The  $\Delta J = 0$  transitions do not lead to a shift in frequency of the scattered photon in pure rotational Raman spectroscopy, and contribute to the unshifted radiation (the Rayleigh radiation, Topic 12A). The specific selection rule for linear rotors is explored in the following *Justification*.

### Justification 12C.2 Selection rules for rotational Raman spectra

The origin of the gross and specific selection rules for rotational Raman spectroscopy can be illustrated by using a diatomic molecule as an example. The incident electric field,  $\mathcal{E}$ , of a wave of electromagnetic radiation of frequency  $\omega_i$  induces a molecular dipole moment that is given by

$$\mu_{\text{ind}} = \alpha \mathcal{E}(t) = \alpha \mathcal{E} \cos \omega_i t \quad (12C.12)$$

If the molecule is rotating at an angular frequency  $\omega_R$ , to an external observer its polarizability is also time dependent (if it is anisotropic), and we can write

$$\alpha = \alpha_0 + \Delta\alpha \cos 2\omega_R t \quad (12C.13)$$

where  $\Delta\alpha = \alpha_{\parallel} - \alpha_{\perp}$  and  $\alpha$  ranges from  $\alpha_0 + \Delta\alpha$  to  $\alpha_0 - \Delta\alpha$  as the molecule rotates. The  $2\omega_R$  appears because the polarizability returns to its initial value twice each revolution (Fig. 12C.7). Substituting this expression into the expression for the induced dipole moment gives

$$\begin{aligned} \mu_{\text{ind}} &= (\alpha_0 + \Delta\alpha \cos 2\omega_R t) \times (\mathcal{E} \cos \omega_i t) \\ &= \alpha_0 \mathcal{E} \cos \omega_i t + \mathcal{E} \Delta\alpha \cos 2\omega_R t \cos \omega_i t \\ &\stackrel{\cos x \cos y}{=} \frac{1}{2} \{\cos(x+y) + \cos(x-y)\} \\ &\equiv \alpha_0 \mathcal{E} \cos \omega_i t + \frac{1}{2} \mathcal{E} \Delta\alpha \{\cos(\omega_i + 2\omega_R)t \\ &\quad + \cos(\omega_i - 2\omega_R)t\} \end{aligned} \quad (12C.14)$$

This calculation shows that the induced dipole has a component oscillating at the incident frequency (which generates Rayleigh radiation), and that it also has two components at  $\omega_i \pm 2\omega_R$ , which give rise to the shifted Raman lines. These lines appear only if  $\Delta\alpha \neq 0$ ; hence the polarizability must be anisotropic for there to be Raman lines. This is the gross selection rule for rotational Raman spectroscopy.

**Figure 12C.7** The distortion induced in a molecule by an applied electric field returns the polarizability to its initial value after a rotation of only  $180^\circ$  (that is, twice a revolution). This is the origin of the  $\Delta J = \pm 2$  selection rule in rotational Raman spectroscopy.

We also see that the distortion induced in the molecule by the incident electric field returns to its initial value after a rotation of  $180^\circ$  (that is, twice a revolution). This is the classical origin of the specific selection rule  $\Delta J = \pm 2$ .<sup>1</sup>

<sup>1</sup> See our *Molecular Quantum Mechanics* (2011) for the quantum mechanical calculation of the selection rules for rotational Raman spectroscopy.

**Figure 12C.8** The rotational energy levels of a linear rotor and the transitions allowed by the  $\Delta J = \pm 2$  Raman selection rules. The form of a typical rotational Raman spectrum is also shown. The Rayleigh line is much stronger than depicted in the figure; it is shown as a weaker line to improve visualization of the Raman lines.

To predict the form of the Raman spectrum of a linear rotor we apply the selection rule  $\Delta J = \pm 2$  to the rotational energy levels (Fig. 12C.8). When the molecule makes a transition with  $\Delta J = +2$ , the scattered radiation leaves the molecule in a higher rotational state, so the wavenumber of the incident radiation, initially  $\tilde{\nu}_i$ , is decreased. These transitions account for the Stokes lines (the lines at lower than the incident frequency, Topic 12A) in the spectrum:

$$\begin{aligned} \tilde{\nu}(J+2 \leftarrow J) &= \tilde{\nu}_i - \{\tilde{F}(J+2) - \tilde{F}(J)\} \\ &= \tilde{\nu}_i - 2\tilde{B}(2J+3) \end{aligned} \quad \begin{array}{l} \text{Linear} \\ \text{rotors} \end{array} \quad \begin{array}{l} \text{Wave-} \\ \text{numbers of} \\ \text{Stokes lines} \end{array} \quad (12C.15a)$$

The Stokes lines appear to low frequency of the incident radiation and at displacements  $6\tilde{B}, 10\tilde{B}, 14\tilde{B}, \dots$  from  $\tilde{\nu}_i$ , for  $J=0, 1, 2, \dots$ . When the molecule makes a transition with  $\Delta J = -2$ , the scattered photon emerges with increased energy. These transitions account for the anti-Stokes lines (the lines at higher than the incident frequency, Topic 12A) of the spectrum:

$$\begin{aligned} \tilde{\nu}(J-2 \leftarrow J) &= \tilde{\nu}_i + \{\tilde{F}(J) - \tilde{F}(J-2)\} = \tilde{\nu}_i + 2\tilde{B}(2J-1) \end{aligned} \quad \begin{array}{l} \text{Linear rotors} \end{array} \quad \begin{array}{l} \text{Wavenumbers of anti-Stokes lines} \end{array} \quad (12C.15b)$$

The anti-Stokes lines occur at displacements of  $6\tilde{B}, 10\tilde{B}, 14\tilde{B}, \dots$  (for  $J=2, 3, 4, \dots$ ;  $J=2$  is the lowest state that can contribute under the selection rule  $\Delta J = -2$ ) to high frequency of the incident radiation. The separation of adjacent lines in both the Stokes and the anti-Stokes regions is  $4\tilde{B}$ , so from its measurement  $I_{\perp}$  can be determined and then used to find the bond lengths exactly as in the case of microwave spectroscopy.

### Example 12C.2 Predicting the form of a Raman spectrum

Predict the form of the rotational Raman spectrum of  $^{14}\text{N}_2$ , for which  $\tilde{B} = 1.99 \text{ cm}^{-1}$ , when it is exposed to 336.732 nm laser radiation.

**Method** The molecule is rotationally Raman active because end-over-end rotation modulates its polarizability as viewed by a stationary observer. The Stokes and anti-Stokes lines are given by eqn 12C.15.

**Answer** Because  $\lambda_i = 336.732 \text{ nm}$  corresponds to  $\tilde{\nu}_i = 29697.2 \text{ cm}^{-1}$ , eqns 12C.15a and 12C.15b give the following line positions:

$J$	0	1	2	3
Stokes lines				
$\tilde{\nu}/\text{cm}^{-1}$	29 685.3	29 677.3	29 669.3	29 661.4
$\lambda/\text{nm}$	336.867	336.958	337.048	337.139
Anti-Stokes lines				
$\tilde{\nu}/\text{cm}^{-1}$			29 709.1	29 717.1
$\lambda/\text{nm}$			336.597	336.507

There will be a strong central line at 336.732 nm accompanied on either side by lines of increasing and then decreasing intensity (as a result of transition moment and population effects). The spread of the entire spectrum is very small, so the incident light must be highly monochromatic.

**Self-test 12C.3** Repeat the calculation for the rotational Raman spectrum of  $\text{NH}_3$  ( $\tilde{B} = 9.977 \text{ cm}^{-1}$ ).

Answer: Stokes lines at 29 637.3, 29 597.4, 29 557.5, 29 517.6  $\text{cm}^{-1}$ ; anti-Stokes lines at 29 757.1, 29 797.0  $\text{cm}^{-1}$

## 12C.3 Nuclear statistics and rotational states

If eqn 12C.15 is used in conjunction with the rotational Raman spectrum of  $\text{CO}_2$ , the rotational constant is inconsistent with other measurements of C–O bond lengths. The results are consistent only if it is supposed that the molecule can exist in states with even values of  $J$ , so the Stokes lines are  $2 \leftarrow 0, 4 \leftarrow 2, \dots$  and not  $2 \leftarrow 0, 3 \leftarrow 1, 4 \leftarrow 2, 5 \leftarrow 3, \dots$

The explanation of the missing lines is the Pauli principle (Topic 9B) and the fact that  $^{16}\text{O}$  nuclei are spin-0 bosons: just as the Pauli principle excludes certain electronic states, so too does it exclude certain molecular rotational states. The form of the Pauli principle given in Topic 9B states that, when two identical bosons are exchanged, the overall wavefunction must remain unchanged in every respect, including sign. When a  $\text{CO}_2$  molecule rotates through  $180^\circ$ , two identical O nuclei are interchanged, so the overall wavefunction of the molecule must remain unchanged. However, inspection of the form of the rotational wavefunctions (which have the same form as the s, p, etc. orbitals of atoms) shows that they change sign by  $(-1)^J$  under such a rotation (Fig. 12C.9). Therefore, only even values of  $J$  are permissible for  $\text{CO}_2$ , and hence the Raman spectrum shows only alternate lines.

**Figure 12C.9** The symmetries of rotational wavefunctions (shown here, for simplicity as a two-dimensional rotor) under a rotation through  $180^\circ$ . Wavefunctions with  $J$  even do not change sign; those with  $J$  odd do change sign.

The selective occupation of rotational states that stems from the Pauli principle is termed **nuclear statistics**. Nuclear statistics must be taken into account whenever a rotation interchanges equivalent nuclei. However, the consequences are not always as simple as for  $\text{CO}_2$  because there are complicating features when the nuclei have nonzero spin: there may be several different relative nuclear spin orientations consistent with even values of  $J$  and a different number of spin orientations consistent with odd values of  $J$ . For molecular hydrogen and fluorine, for instance, with their two identical spin- $\frac{1}{2}$  nuclei, we show in the following *Justification* that there are three times as many ways of achieving a state with odd  $J$  than with even  $J$ , and there is a corresponding 3:1 alternation in intensity in their rotational Raman spectra (Fig. 12C.10). In general, for a homonuclear diatomic molecule with nuclei of spin  $I$ , the numbers of ways of achieving states of odd and even  $J$  are in the ratio

$$\frac{\text{Number of ways of achieving odd } J}{\text{Number of ways of achieving even } J} = \begin{cases} (I+1)/I & \text{for half-integral spin nuclei} \\ I/(I+1) & \text{for integral spin nuclei} \end{cases}$$

*Homonuclear diatomic molecules*   Nuclear statistics   (12C.16)

**Figure 12C.10** The rotational Raman spectrum of a diatomic molecule with two identical spin- $\frac{1}{2}$  nuclei shows an alternation in intensity as a result of nuclear statistics. The Rayleigh line is much stronger than depicted in the figure; it is shown as a weaker line to improve visualization of the Raman lines.

For hydrogen,  $I = \frac{1}{2}$ , and the ratio is 3:1. For  $\text{N}_2$ , with  $I = 1$ , the ratio is 1:2.

### Justification 12C.3 The effect of nuclear statistics on rotational spectra

Hydrogen nuclei are fermions, so the Pauli principle requires the overall wavefunction to change sign under particle interchange. However, the rotation of an  $\text{H}_2$  molecule through  $180^\circ$  has a more complicated effect than merely relabelling the nuclei, because it interchanges their spin states too if the nuclear spins are paired ( $\uparrow\downarrow$ ;  $I_{\text{total}} = 0$ ) but not if they are parallel ( $\uparrow\uparrow$ ,  $I_{\text{total}} = 1$ ).

First, consider the case when the spins are parallel and their state is  $\alpha(A)\alpha(B)$ ,  $\alpha(A)\beta(B) + \alpha(B)\beta(A)$ , or  $\beta(A)\beta(B)$ . The  $\alpha(A)\alpha(B)$  and  $\beta(A)\beta(B)$  combinations are unchanged when the molecule rotates through  $180^\circ$  so the rotational wavefunction must change sign to achieve an overall change of sign. Hence, only odd values of  $J$  are allowed. Although at first sight the spins must be interchanged in the combination  $\alpha(A)\beta(B) + \alpha(B)\beta(A)$  so as to achieve a simple  $A \leftrightarrow B$  interchange of labels (Fig. 12C.11),  $\beta(A)\alpha(B) + \beta(B)\alpha(A)$  is the same as  $\alpha(A)\beta(B) + \alpha(B)\beta(A)$  apart from the order of terms, so only odd values of  $J$  are allowed for it too. In contrast, if the nuclear spins are paired, their wavefunction is  $\alpha(A)\beta(B) - \alpha(B)\beta(A)$ . This combination changes sign when  $\alpha$  and  $\beta$  are exchanged (in order to achieve a simple  $A \leftrightarrow B$  interchange overall). Therefore, for the overall wavefunction to change sign in this case requires the rotational wavefunction *not* to change sign. Hence, only even values of  $J$  are allowed if the nuclear spins are paired. In accord with the prediction of eqn 12C.16, there are three ways of achieving odd  $J$  but only one of achieving even  $J$ .

**Figure 12C.11** The interchange of two identical fermion nuclei results in the change in sign of the overall wavefunction. The relabelling can be thought of as occurring in two steps: the first is a rotation of the molecule; the second is the interchange of unlike spins (represented by the different colours of the nuclei). The wavefunction changes sign in the second step if the nuclei have antiparallel spins.

**Brief illustration 12C.2** *Ortho- and para-hydrogen*

Different relative nuclear spin orientations change into one another only very slowly, so an  $\text{H}_2$  molecule with parallel

**Figure 12C.12** When hydrogen is cooled, the molecules with parallel nuclear spins accumulate in their lowest available rotational state, the one with  $J=1$ . They can enter the lowest rotational state ( $J=0$ ) only if the spins change their relative orientation and become antiparallel. This is a slow process under normal circumstances, so energy is slowly released.

nuclear spins remains distinct from one with paired nuclear spins for long periods. The form with parallel nuclear spins is called *ortho-hydrogen* and the form with paired nuclear spins is called *para-hydrogen*. Because *ortho-hydrogen* cannot exist in a state with  $J=0$ , it continues to rotate at very low temperatures and has an effective rotational zero-point energy (Fig. 12C.12).

**Self-test 12C.4** Does  $\text{BeF}_2$  exist in *ortho* and *para* forms? *Hints:* (a) Determine the geometry of  $\text{BeF}_2$ , then (b) decide whether fluorine nuclei are fermions or bosons.

Answer: Yes

## Checklist of concepts

- 1. Pure rotational transitions can be studied with **microwave spectroscopy** and **rotational Raman spectroscopy**.
- 2. For a molecule to give a pure rotational spectrum, it must be polar.
- 3. The **specific selection rules** for microwave spectroscopy are  $\Delta J = \pm 1$ ,  $\Delta M_J = 0, \pm 1$ ,  $\Delta K = 0$ .
- 4. Bond lengths and dipole moments may be obtained from analysis of rotational spectra.
- 5. A molecule must be **anisotropically polarizable** for it to be rotationally Raman active.
- 6. The **specific selection rules** for rotational Raman spectroscopy are: (i) linear rotors,  $\Delta J = 0, \pm 2$ ; (ii) symmetric rotors,  $\Delta J = 0, \pm 1, \pm 2$ ;  $\Delta K = 0$ .
- 7. The appearance of rotational spectra is affected by **nuclear statistics**, the selective occupation of rotational states that stems from the Pauli principle.

## Checklist of equations

Property	Equation	Comment	Equation number
Wavenumbers of rotational transitions	$\tilde{\nu}(J+1 \leftarrow J) = 2\tilde{B}(J+1)$	$J=0, 1, 2, \dots$ spherical and linear rotors	12C.8a

### ► Why do you need to know this material?

The observation of the frequencies of transitions between the vibrational states of a molecule gives information about the identity of the molecule and provides quantitative information about the flexibility of its bonds. Infrared spectroscopy is a valuable analytical tool and is widely used in chemical laboratories.

### ► What is the key idea?

The vibrational spectrum of a diatomic molecule can be interpreted by using the harmonic oscillator model, with modifications that account for bond dissociation and the coupling of rotational and vibrational motion.

### ► What do you need to know already?

You need to be familiar with the harmonic oscillator (Topic 8B) and rigid rotor (Topic 12B) models of molecular motion, the general principles of spectroscopy (Topic 12A), and the interpretation of rotational spectra (Topic 12C).

Here we explore the vibrational energy levels of diatomic molecules and establish the selection rules for spectroscopic transitions between these levels. We also see how the simultaneous excitation of rotation modifies the appearance of a vibrational spectrum. This material sets the stage for the discussion of vibrations of polyatomic molecules in Topic 12E.

## 12D.1 Vibrational motion

We base our discussion on Fig. 12D.1, which shows a typical potential energy curve of a diatomic molecule (it is essentially a reproduction of Fig. 8B.1 of Topic 8B). In regions close to  $R_e$  (at the minimum of the curve) the potential energy can be approximated by a parabola, so we can write

$$V = \frac{1}{2}k_f x^2 \quad x = R - R_e \quad \text{Parabolic potential energy} \quad (12D.1)$$

where  $k_f$  is the **force constant** of the bond. The steeper the walls of the potential (the stiffer the bond), the greater the force constant.

To see the connection between the shape of the molecular potential energy curve and the value of  $k_f$ , note that we can expand the potential energy around its minimum by using a Taylor series (*Mathematical background* 1 following Chapter 1), which is a common way of expressing how a function varies near a selected point (in this case, the minimum of the curve at  $x=0$ ):

$$V(x) = V(0) + \left(\frac{dV}{dx}\right)_0 x + \frac{1}{2} \left(\frac{d^2V}{dx^2}\right)_0 x^2 + \dots \quad (12D.2)$$

**Figure 12D.1** A molecular potential energy curve can be approximated by a parabola near the bottom of the well. The parabolic potential energy results in harmonic oscillations. At high excitation energies the parabolic approximation is poor (the true potential energy is less confining), and is totally wrong near the dissociation limit.

The notation  $(\dots)_0$  means that the derivatives are first evaluated and then  $x$  is set equal to 0. The term  $V(0)$  can be set arbitrarily to zero. The first derivative of  $V$  is zero at the minimum. Therefore, the first surviving term is proportional to the square of the displacement. For small displacements we can ignore all the higher terms, and so write

$$V(x) \approx \frac{1}{2} \left( \frac{d^2V}{dx^2} \right)_0 x^2 \quad (12D.3)$$

Therefore, the first approximation to a molecular potential energy curve is a parabolic potential, and we can identify the force constant as

$$k_f = \left( \frac{d^2V}{dx^2} \right)_0 \quad \text{Formal definition} \quad \text{Force constant} \quad (12D.4)$$

We see that if the potential energy curve is sharply curved close to its minimum, then  $k_f$  will be large and the bond stiff. Conversely, if the potential energy curve is wide and shallow, then  $k_f$  will be small and the bond easily stretched or compressed (Fig. 12D.2).

The Schrödinger equation for the relative motion of two atoms of masses  $m_1$  and  $m_2$  with a parabolic potential energy is

$$-\frac{\hbar^2}{2m_{\text{eff}}} \frac{d^2\psi}{dx^2} + \frac{1}{2} k_f x^2 \psi = E\psi \quad (12D.5)$$

where  $m_{\text{eff}}$  is the **effective mass**:

$$m_{\text{eff}} = \frac{m_1 m_2}{m_1 + m_2} \quad \text{Definition} \quad \text{Effective mass} \quad (12D.6)$$

These equations are derived in the same way as in Topic 8B, but here the separation of variables procedure is used to separate

**Figure 12D.2** The force constant is a measure of the curvature of the potential energy close to the equilibrium extension of the bond. A strongly confining well (one with steep sides, a stiff bond) corresponds to high values of  $k_f$ .

the relative motion of the atoms from the motion of the molecule as a whole.

*A note on good practice* Distinguish *effective mass* from *reduced mass*. The former is a measure of the mass that is moved during a vibration. The latter is the quantity that emerges from the separation of relative internal and overall translational motion. For a diatomic molecule the two are the same, but that is not true in general for vibrations of polyatomic molecules. Many, however, do not make this distinction and refer to both quantities as the ‘reduced mass’.

The Schrödinger equation in eqn 12D.5 is the same as eqn 8B.3 for a particle of mass  $m$  undergoing harmonic motion. Therefore, we can use the results of Topic 8B to write down the permitted vibrational energy levels:

$$E_v = \left( v + \frac{1}{2} \right) \hbar \omega \quad \omega = \left( \frac{k_f}{m_{\text{eff}}} \right)^{1/2} \quad v = 0, 1, 2, \dots$$

*Diatomic molecule*   **Vibrational energy levels**   (12D.7)

The **vibrational terms** of a molecule, the energies of its vibrational states expressed as wavenumbers, are denoted  $\tilde{G}(v)$ , with  $E_v = hc\tilde{G}(v)$ , so

$$\tilde{G}(v) = \left( v + \frac{1}{2} \right) \tilde{\nu} \quad \tilde{\nu} = \frac{1}{2\pi c} \left( \frac{k_f}{m_{\text{eff}}} \right)^{1/2}$$

*Diatomic molecule*   **Vibrational terms**   (12D.8)

The vibrational wavefunctions are the same as those discussed in Topic 8B for a harmonic oscillator.

It is important to note that the vibrational terms depend on the *effective* mass of the molecule, not directly on its total mass. This dependence is physically reasonable, for if atom 1 were as heavy as a brick wall, then we would find  $m_{\text{eff}} \approx m_2$ , the mass of the lighter atom. The vibration would then be that of a light atom relative to that of a stationary wall (this is approximately

the case in HI, for example, where the I atom barely moves and  $m_{\text{eff}} \approx m_{\text{H}}$ ). For a homonuclear diatomic molecule  $m_1 = m_2$ , and the effective mass is half the total mass:  $m_{\text{eff}} = \frac{1}{2}m$ .

### Brief illustration 12D.1 The vibrational frequency of a diatomic molecule

The force constant of the bond in HCl is  $516 \text{ N m}^{-1}$ , a reasonably typical value for a single bond. The effective mass of  $^1\text{H}^{35}\text{Cl}$  is  $1.63 \times 10^{-27} \text{ kg}$  (note that this mass is very close to the mass of the hydrogen atom,  $1.67 \times 10^{-27} \text{ kg}$ , so the Cl atom is acting like a brick wall). These values imply that

$$\omega = \left( \frac{516 \frac{\text{kg m s}^{-2}}{\text{N m}^{-1}}}{1.63 \times 10^{-27} \text{ kg}} \right)^{1/2} = 5.63 \times 10^{14} \text{ s}^{-1}$$

or  $\nu = \omega/2\pi = 89.5 \text{ THz}$  (1 THz =  $10^{12}$  Hz).

**Self-test 12D.1** The vibrational frequency  $\nu$  of  $^{35}\text{Cl}_2$  is 16.94 THz. Calculate the force constant of the bond.

Answer: 327.8 N m<sup>-1</sup>

## 12D.2 Infrared spectroscopy

The gross selection rule for a change in vibrational state brought about by absorption or emission of radiation is that *the electric dipole moment of the molecule must change when the atoms are displaced relative to one another*. Such vibrations are said to be **infrared active**. The classical basis of this rule is that the molecule can shake the electromagnetic field into oscillation if its dipole changes as it vibrates, and vice versa (Fig. 12D.3); its formal basis is given in the following *Justification*. Note that the molecule need not have a permanent dipole: the rule requires only a *change* in dipole moment, possibly from zero. Some vibrations do not affect the molecule's dipole moment (for instance, the stretching motion of a homonuclear diatomic molecule), so they neither absorb nor generate radiation: such vibrations are said to be **infrared inactive**.

**Figure 12D.3** The oscillation of a molecule, even if it is nonpolar, may result in an oscillating electric dipole moment that can interact with the electromagnetic field.

### Brief illustration 12D.2 The gross selection rule for infrared spectroscopy

Homonuclear diatomic molecules are infrared inactive because their dipole moments remain zero however long the bond; heteronuclear diatomic molecules are infrared active. Weak infrared transitions can be observed from homonuclear diatomic molecules trapped within various nanomaterials. For instance, when incorporated into solid  $\text{C}_{60}$ ,  $\text{H}_2$  molecules interact through van der Waals forces with the surrounding  $\text{C}_{60}$  molecules and acquire dipole moments, with the result that they have observable infrared spectra.

**Self-test 12D.2** Identify the infrared active molecules in the group:  $\text{N}_2$ , NO, and CO.

Answer: NO and CO

The specific selection rule, which is obtained from an analysis of the expression for the transition moment and the properties of integrals over harmonic oscillator wavefunctions (as shown in the following *Justification*), is

$$\Delta\nu = \pm 1 \quad \text{Infrared spectroscopy} \quad \text{Specific selection rule} \quad (12D.9)$$

### Justification 12D.1 Gross and specific selection rules for infrared spectra

The gross selection rule for infrared spectroscopy is based on an analysis of the transition dipole moment  $\mu_{fi} = \int \psi_{v_f}^* \hat{\mu} \psi_{v_i} d\tau$ , (Topic 12B) which arises from eqn 12B.2 of that Topic ( $\mu_{fi} = \int \psi_{\epsilon_f}^* \psi_{\epsilon_i}^* Y_{J_f, M_{J_f}}^* \hat{\mu} \psi_{\epsilon_i} \psi_{v_i} Y_{J_i, M_{J_i}} d\tau$ ) when the molecule does not change electronic or rotational states. For simplicity, we consider a one-dimensional oscillator (like a diatomic molecule, which can stretch and compress only along the direction parallel to its bond). The electric dipole moment operator depends on the location of all the electrons and all the nuclei in the molecule, so it varies as the internuclear separation changes (Fig. 12D.4). We can write its variation with displacement from the equilibrium separation,  $x$ , as

$$\hat{\mu} = \hat{\mu}_0 + \left( \frac{d\hat{\mu}}{dx} \right)_0 x + \dots$$

where  $\hat{\mu}_0$  is the electric dipole moment operator when the nuclei have their equilibrium separation. It then follows that, with  $f \neq i$  and keeping only the term linear in the small displacement  $x$ ,

$$\mu_{fi} = \int \psi_{v_f}^* \hat{\mu} \psi_{v_i} dx = \mu_0 \int \psi_{v_f}^* \psi_{v_i} dx + \left( \frac{d\mu}{dx} \right)_0 \int \psi_{v_f}^* x \psi_{v_i} dx$$

**Figure 12D.4** The electric dipole moment of a heteronuclear diatomic molecule varies as shown by the purple curve. For small displacements the change in dipole moment is proportional to the displacement.

The term multiplying  $\mu_0$  is zero because the states with different values of  $\nu$  are orthogonal (Topic 8B). It follows that the transition dipole moment is

$$\mu_{fi} = \left( \frac{d\mu}{dx} \right)_0 \int \psi_{\nu_f}^* x \psi_{\nu_i} dx$$

We see that the right-hand side is zero unless the dipole moment varies with displacement. This is the gross selection rule for infrared spectroscopy.

The specific selection rule is determined by considering the value of  $\int \psi_{\nu_f}^* x \psi_{\nu_i} dx$ . We need to write out the wavefunctions in terms of the Hermite polynomials given in Topic 8B and then to use their properties. We note that  $x = \alpha y$  with  $\alpha = (\hbar^2/m_{\text{eff}}k_f)^{1/4}$  (this is eqn 8B.8 of Topic 8B). Then we write

$$\begin{aligned} \int \psi_{\nu_f}^* x \psi_{\nu_i} dx &= N_{\nu_f} N_{\nu_i} \int_{-\infty}^{\infty} H_{\nu_f} x H_{\nu_i} e^{-y^2} dx \\ &= \alpha^2 N_{\nu_f} N_{\nu_i} \int_{-\infty}^{\infty} H_{\nu_f} y H_{\nu_i} e^{-y^2} dy \end{aligned}$$

To evaluate the integral we use the ‘recursion’ relation

$$yH_\nu = \nu H_{\nu-1} + \frac{1}{2}H_{\nu+1}$$

which leads to

$$\begin{aligned} \int \psi_{\nu_f}^* x \psi_{\nu_i} dx &= \alpha^2 N_{\nu_f} N_{\nu_i} \left\{ \nu_i \int_{-\infty}^{\infty} H_{\nu_f} H_{\nu_i-1} e^{-y^2} dy + \frac{1}{2} \int_{-\infty}^{\infty} H_{\nu_f} H_{\nu_i+1} e^{-y^2} dy \right\} \end{aligned}$$

The first integral is zero unless  $\nu_f = \nu_i - 1$  and the second is zero unless  $\nu_f = \nu_i + 1$  (Table 8B.1). It follows that the transition dipole moment is zero unless  $\Delta\nu = \pm 1$ .

Transitions for which  $\Delta\nu = +1$  correspond to absorption and those with  $\Delta\nu = -1$  correspond to emission. It follows that the wavenumbers of allowed vibrational transitions, which are denoted  $\Delta\tilde{G}_{\nu+\frac{1}{2}}$  for the transition  $\nu+1 \leftarrow \nu$ , are

$$\Delta\tilde{G}_{\nu+\frac{1}{2}} = \tilde{G}(\nu+1) - \tilde{G}(\nu) = \tilde{\nu} \quad (12D.10)$$

The wavenumbers of vibrational transitions correspond to those of radiation in the infrared region of the electromagnetic spectrum, so vibrational transitions absorb and generate infrared radiation.

At room temperature  $kT/hc \approx 200 \text{ cm}^{-1}$ , and most vibrational wavenumbers are significantly greater than  $200 \text{ cm}^{-1}$ . It follows from the Boltzmann distribution (Foundations B and Topic 15A) that at room temperature almost all the molecules are in their vibrational ground states. Hence, the dominant spectral transition will be the **fundamental transition**,  $1 \leftarrow 0$ . As a result, the spectrum is expected to consist of a single absorption line. If the molecules are formed in a vibrationally excited state, such as when vibrationally excited HF molecules are formed in the reaction  $\text{H}_2 + \text{F}_2 \rightarrow 2 \text{HF}^*$ , where the star indicates a vibrationally ‘hot’ molecule, the transitions  $5 \rightarrow 4, 4 \rightarrow 3, \dots$  may also appear (in emission). In the harmonic approximation, all these lines lie at the same frequency, and the spectrum is also a single line. However, as we shall now show, the breakdown of the harmonic approximation causes the transitions to lie at slightly different frequencies, so several lines are observed.

### 12D.3 Anharmonicity

The vibrational terms in eqn 12D.8 are only approximate because they are based on a parabolic approximation to the actual potential energy curve. A parabola cannot be correct at all extensions because it does not allow a bond to dissociate. At high vibrational excitations the swing of the atoms (more precisely, the spread of the vibrational wavefunction) allows the molecule to explore regions of the potential energy curve where the parabolic approximation is poor and additional terms in the Taylor expansion of  $V$  (eqn 12D.2) must be retained. The motion then becomes **anharmonic**, in the sense that the restoring force is no longer proportional to the displacement. Because the actual curve is less confining than a parabola, we can anticipate that the energy levels become more closely spaced at high excitations.

#### (a) The convergence of energy levels

One approach to the calculation of the energy levels in the presence of anharmonicity is to use a function that resembles the

true potential energy more closely. The **Morse potential energy** is

$$V = hc\tilde{D}_e \{1 - e^{-a(R-R_e)}\}^2 \quad a = \left( \frac{m_{\text{eff}}\omega^2}{2hc\tilde{D}_e} \right)^{1/2} \quad \text{Morse potential energy} \quad (12D.11)$$

where  $\tilde{D}_e$  is the depth of the potential minimum (Fig. 12D.5). Near the well minimum the variation of  $V$  with displacement resembles a parabola (as can be checked by expanding the exponential as far as the first term) but, unlike a parabola, eqn 12D.11 allows for dissociation at large displacements. The Schrödinger equation can be solved for the Morse potential and the permitted energy levels are

$$\tilde{G}(v) = \left(v + \frac{1}{2}\right)\tilde{\nu} - \left(v + \frac{1}{2}\right)^2 x_e \tilde{\nu} \quad \text{Morse potential energy} \quad \text{Vibrational terms} \quad (12D.12)$$

$$x_e = \frac{a^2 \hbar}{2m_{\text{eff}}\omega} = \frac{\tilde{\nu}}{4\tilde{D}_e}$$

The dimensionless parameter  $x_e$  is called the **anharmonicity constant**. The number of vibrational levels of a Morse oscillator is finite, and  $v=0, 1, 2, \dots, v_{\text{max}}$  as shown in Fig. 12D.6 (see also Problem 12D.7). The second term in the expression for  $\tilde{G}$  subtracts from the first with increasing effect as  $v$  increases, and hence gives rise to the convergence of the levels at high quantum numbers.

### Example 12D.1 Estimating an anharmonicity constant

Estimate the anharmonicity constant  $x_e$  for  $^1\text{H}^{19}\text{F}$  from the data in Table 12D.1 of the *Resource section*.

**Method** The anharmonicity constant is evaluated from  $\tilde{\nu}$ ,  $\tilde{D}_e$ , and eqn 12D.12. However, note that Table 12D.1 lists values of  $\tilde{D}_0 = \tilde{D}_e - \frac{1}{2}\tilde{\nu}$  (Fig. 12D.5), so calculate  $\tilde{D}_e$  first before using eqn 12D.12. A useful conversion factor is  $1 \text{ kJ mol}^{-1} = 83.593 \text{ cm}^{-1}$ .

**Answer** The depth of the potential minimum is

$$\tilde{D}_e = \tilde{D}_0 + \frac{1}{2}\tilde{\nu} = \overbrace{(4.718 \times 10^4 \text{ cm}^{-1})}^{564.4 \text{ kJ mol}^{-1} \times \frac{83.593 \text{ cm}^{-1}}{1 \text{ kJ mol}^{-1}}} + \frac{1}{2} \times (4138.32 \text{ cm}^{-1})$$

$$= (4.718 \times 10^4 + \frac{1}{2} \times 4138.32) \text{ cm}^{-1}$$

It follows from eqn 12D.12 that the anharmonicity constant is

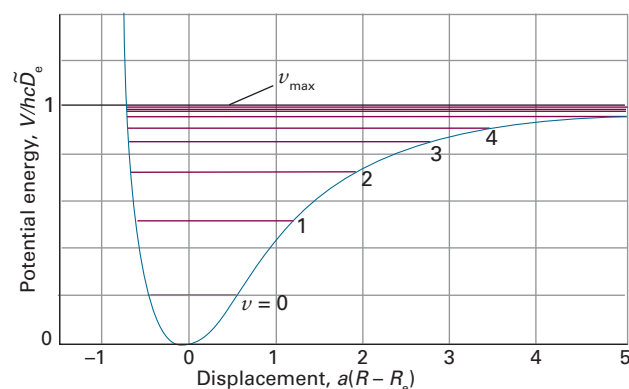

$$x_e = \frac{4138.32 \text{ cm}^{-1}}{(4.718 \times 10^4 + \frac{1}{2} \times 4138.32) \text{ cm}^{-1}} = 2.101 \times 10^{-2}$$

**Self-test 12D.3** Estimate the anharmonicity constant for  $^1\text{H}^{81}\text{Br}$ .

Answer:  $2.093 \times 10^{-2}$

**Figure 12D.5** The dissociation energy of a molecule,  $hc\tilde{D}_0$ , differs from the depth of the potential well,  $hc\tilde{D}_e$ , on account of the zero-point energy of the vibrations of the bond.

**Figure 12D.6** The Morse potential energy curve reproduces the general shape of a molecular potential energy curve. The corresponding Schrödinger equation can be solved, and the values of the energies obtained. The number of bound levels is finite.

Although the Morse oscillator is quite useful theoretically, in practice the more general expression

$$\tilde{G}(v) = \left(v + \frac{1}{2}\right)\tilde{\nu} - \left(v + \frac{1}{2}\right)^2 x_e \tilde{\nu} + \left(v + \frac{1}{2}\right)^3 y_e \tilde{\nu} + \dots \quad (12D.13)$$

where  $x_e, y_e, \dots$  are empirical dimensionless constants characteristic of the molecule, is used to fit the experimental data and to find the dissociation energy of the molecule. When anharmonicities are present, the wavenumbers of transitions with  $\Delta v = +1$  are

$$\Delta\tilde{G}_{v+\frac{1}{2}} = \tilde{G}(v+1) - \tilde{G}(v) = \tilde{\nu} - 2(v+1)x_e\tilde{\nu} + \dots \quad (12D.14)$$

Equation 12D.14 shows that, when  $x_e > 0$ , the transitions move to lower wavenumbers as  $v$  increases.

Anharmonicity also accounts for the appearance of additional weak absorption lines corresponding to the transitions  $2 \leftarrow 0$ ,  $3 \leftarrow 0$ , ..., even though these first, second, ... overtones are forbidden by the selection rule  $\Delta\nu = \pm 1$ . The first overtone, for example, gives rise to an absorption at

$$\tilde{G}(v+2) - \tilde{G}(v) = 2\tilde{\nu} - 2(2v+3)x_c\tilde{\nu} + \dots \quad (12D.15)$$

The reason for the appearance of overtones is that the selection rule is derived from the properties of harmonic oscillator wavefunctions, which are only approximately valid when anharmonicity is present. Therefore, the selection rule is also only an approximation. For an anharmonic oscillator, all values of  $\Delta\nu$  are allowed, but transitions with  $\Delta\nu > 1$  are allowed only weakly if the anharmonicity is slight.

### (b) The Birge–Sponer plot

When several vibrational transitions are detectable, a graphical technique called a **Birge–Sponer plot** may be used to determine the dissociation energy,  $hc\tilde{D}_0$ , of the bond. The basis of the Birge–Sponer plot is that the sum of successive intervals  $\Delta\tilde{G}_{v+\frac{1}{2}}$  from the zero-point level to the dissociation limit is the dissociation energy:

$$\tilde{D}_0 = \Delta\tilde{G}_{1/2} + \Delta\tilde{G}_{3/2} + \dots = \sum_v \Delta\tilde{G}_{v+1/2} \quad (12D.16)$$

just as the height of the ladder is the sum of the separations of its rungs (Fig. 12D.7). The construction in Fig. 12D.8 shows that the area under the plot of  $\Delta\tilde{G}_{v+\frac{1}{2}}$  against  $v+\frac{1}{2}$  is equal to the sum, and therefore to  $\tilde{D}_0$ . The successive terms decrease linearly when only the  $x_c$  anharmonicity constant is taken into account and the inaccessible part of the spectrum can be estimated by linear extrapolation. Most actual plots differ from the linear plot as shown in Fig. 12D.8, so the value of  $\tilde{D}_0$  obtained in this way is usually an overestimate of the true value.

**Figure 12D.7** The dissociation energy is the sum of the separations  $h_i$  of the vibrational energy levels up to the dissociation limit just as the length of a ladder is the sum of the separations of its rungs.

**Figure 12D.8** The area under a plot of transition wavenumber against vibrational quantum number is equal to the dissociation energy of the molecule. The assumption that the differences approach zero linearly is the basis of the Birge–Sponer extrapolation.

### Example 12D.2 Using a Birge–Sponer plot

The observed vibrational intervals of  $\text{H}_2^+$  lie at the following values for  $1 \leftarrow 0$ ,  $2 \leftarrow 1$ , ..., respectively (in  $\text{cm}^{-1}$ ): 2191, 2064, 1941, 1821, 1705, 1591, 1479, 1368, 1257, 1145, 1033, 918, 800, 677, 548, 411. Determine the dissociation energy of the molecule.

**Method** Plot the separations against  $v+\frac{1}{2}$ , extrapolate linearly to the point cutting the horizontal axis, and then measure the area under the curve.

**Answer** The points are plotted in Fig. 12D.9, and a linear extrapolation is shown as a dotted line. The area under the curve (use the formula for the area of a triangle or count the squares) is 214. Each square corresponds to  $100 \text{ cm}^{-1}$  (refer to the scale of the vertical axis); hence the dissociation energy is  $21\,400 \text{ cm}^{-1}$  (corresponding to  $256 \text{ kJ mol}^{-1}$ ).

**Figure 12D.9** The Birge–Sponer plot used in Example 12D.2. The area is obtained simply by counting the squares beneath the line or using the formula for the area of a right triangle (area =  $\frac{1}{2} \times \text{base} \times \text{height}$ ).

**Self-test 12D.4** The vibrational levels of HgH converge rapidly, and successive intervals are 1203.7 (which corresponds to the  $1 \leftarrow 0$  transition), 965.6, 632.4, and  $172 \text{ cm}^{-1}$ . Estimate the dissociation energy.

Answer:  $35.6 \text{ kJ mol}^{-1}$

## 12D.4 Vibration–rotation spectra

Each line of the high resolution vibrational spectrum of a gas-phase heteronuclear diatomic molecule is found to consist of a large number of closely spaced components (Fig. 12D.10). Hence, molecular spectra are often called **band spectra**. The separation between the components is less than  $10 \text{ cm}^{-1}$ , which suggests that the structure is due to rotational transitions accompanying the vibrational transition. A rotational change should be expected because classically we can think of the vibrational transition as leading to a sudden increase or decrease in the instantaneous bond length. Just as ice-skaters rotate more rapidly when they bring their arms in, and more slowly when they throw them out, so the molecular rotation is either accelerated or retarded by a vibrational transition.

### (a) Spectral branches

A detailed analysis of the quantum mechanics of simultaneous vibrational and rotational changes shows that the rotational quantum number  $J$  changes by  $\pm 1$  during the vibrational transition of a diatomic molecule. If the molecule also possesses angular momentum about its axis, as in the case of the electronic orbital angular momentum of the paramagnetic molecule NO with its configuration  $\dots \pi^1$ , then the selection rules also allow  $\Delta J=0$ .

**Figure 12D.10** A high-resolution vibration–rotation spectrum of HCl. The lines appear in pairs because  $\text{H}^{35}\text{Cl}$  and  $\text{H}^{37}\text{Cl}$  both contribute (their abundance ratio is 3:1). There is no Q branch, because  $\Delta J=0$  is forbidden for this molecule.

The appearance of the vibration–rotation spectrum of a diatomic molecule can be discussed in terms of the combined vibration–rotation terms,  $\tilde{S}$ :

$$\tilde{S}(\nu, J) = \tilde{G}(\nu) + \tilde{F}(J) \quad (12D.17)$$

If we ignore anharmonicity and centrifugal distortion we can use eqn 12D.8 for the first term on the right and eqn 12B.9 ( $\tilde{F}(J) = \tilde{B}J(J+1)$ ) for the second, and obtain

$$\tilde{S}(\nu, J) = \left(\nu + \frac{1}{2}\right)\tilde{\nu} + \tilde{B}J(J+1) \quad (12D.18)$$

In a more detailed treatment,  $\tilde{B}$  is allowed to depend on the vibrational state because, as  $\nu$  increases, the molecule swells slightly and the moment of inertia changes. We shall continue with the simple expression initially.

When the vibrational transition  $\nu+1 \leftarrow \nu$  occurs,  $J$  changes by  $\pm 1$  and in some cases by 0 (when  $\Delta J=0$  is allowed). The absorptions then fall into three groups called **branches** of the spectrum. The **P branch** consists of all transitions with  $\Delta J = -1$ :

$$\tilde{\nu}_P(J) = \tilde{S}(\nu+1, J-1) - \tilde{S}(\nu, J) = \tilde{\nu} - 2\tilde{B}J \quad \text{P branch transitions} \quad (12D.19a)$$

This branch consists of lines at  $\tilde{\nu} - 2\tilde{B}, \tilde{\nu} - 4\tilde{B}, \dots$  with an intensity distribution reflecting both the populations of the rotational levels and the magnitude of the  $J-1 \leftarrow J$  transition moment (Fig. 12D.11). The **Q branch** consists of all lines with  $\Delta J=0$ , and its wavenumbers are all

$$\tilde{\nu}_Q(J) = \tilde{S}(\nu+1, J) - \tilde{S}(\nu, J) = \tilde{\nu} \quad \text{Q branch transitions} \quad (12D.19b)$$

for all values of  $J$ . This branch, when it is allowed (as in NO), appears at the vibrational transition wavenumber. In Fig. 12D.11 there is a gap at the expected location of the Q branch

**Figure 12D.11** The formation of P, Q, and R branches in a vibration–rotation spectrum. The intensities reflect the populations of the initial rotational levels and magnitudes of the transition moments.

Table 12D.1\* Properties of diatomic molecules

	$\tilde{\nu}/\text{cm}^{-1}$	$R_e/\text{pm}$	$\tilde{B}/\text{cm}^{-1}$	$k_f/(\text{N m}^{-1})$	$hc\tilde{D}_0/(\text{kJ mol}^{-1})$
$^1\text{H}_2$	4400	74	60.86	575	432
$^1\text{H}^{35}\text{Cl}$	2991	127	10.59	516	428
$^1\text{H}^{127}\text{I}$	2308	161	6.51	314	295
$^{35}\text{Cl}_2$	560	199	0.244	323	239

\* More values are given in the *Resource section*.

because it is forbidden in HCl. The **R branch** consists of lines with  $\Delta J = +1$ :

$$\tilde{\nu}_R(J) = \tilde{S}(\nu+1, J+1) - \tilde{S}(\nu, J) = \tilde{\nu} + 2\tilde{B}(J+1) \quad (12\text{D.19c})$$

R branch  
transitions

This branch consists of lines displaced from  $\tilde{\nu}$  to high wavenumber by  $2\tilde{B}, 4\tilde{B}, \dots$

The separation between the lines in the P and R branches of a vibrational transition gives the value of  $\tilde{B}$ . Therefore, the bond length can be deduced without needing to take a pure rotational microwave spectrum. However, the latter is more precise because microwave frequencies can be measured with greater precision than infrared frequencies.

### Brief illustration 12D.3 The wavenumber of an R branch transition

Infrared absorption by  $^1\text{H}^{81}\text{Br}$  gives rise to an R branch from  $\nu=0$ . It follows from eqn 12D.19c and the data in Table 12D.1 (in the *Resource section*) that the wavenumber of the line originating from the rotational state with  $J=2$  is

$$\begin{aligned} \tilde{\nu}_R(2) &= \tilde{\nu} + 6\tilde{B} = (2648.98 \text{ cm}^{-1}) + 6 \times (8.465 \text{ cm}^{-1}) \\ &= 2699.77 \text{ cm}^{-1} \end{aligned}$$

**Self-test 12D.5** Infrared absorption by  $^1\text{H}^{127}\text{I}$  gives rise to an R branch from  $\nu=0$ . What is the wavenumber of the line originating from the rotational state with  $J=2$ ?

Answer: 2347.16  $\text{cm}^{-1}$

## (b) Combination differences

The rotational constant of the vibrationally excited state,  $\tilde{B}_1$  (in general,  $\tilde{B}_\nu$ ), is different from that of the ground vibrational state,  $\tilde{B}_0$ . One contribution to the difference is the anharmonicity of the vibration, which results in a slightly extended bond in the upper state. However, even in the absence of anharmonicity, the average value of  $1/R^2$  ( $\langle 1/R^2 \rangle$ ) varies with the vibrational state (see Problems 12D.12 and 12D.13). As a result, the Q branch (if it exists) consists of a series of closely spaced lines. The lines of the R branch converge slightly as  $J$  increases; and those of the P branch diverge:

$$\begin{aligned} \tilde{\nu}_P(J) &= \tilde{\nu} - (\tilde{B}_1 + \tilde{B}_0)J + (\tilde{B}_1 - \tilde{B}_0)J^2 \\ \tilde{\nu}_Q(J) &= \tilde{\nu} + (\tilde{B}_1 - \tilde{B}_0)J(J+1) \\ \tilde{\nu}_R(J) &= \tilde{\nu} + (\tilde{B}_1 + \tilde{B}_0)(J+1) + (\tilde{B}_1 - \tilde{B}_0)(J+1)^2 \end{aligned} \quad (12\text{D.20})$$

To determine the two rotational constants individually, we use the method of **combination differences**. This procedure is used widely in spectroscopy to extract information about a particular state. It involves setting up expressions for the difference in the wavenumbers of transitions to a common state; the resulting expression then depends solely on properties of the other state.

As can be seen from Fig. 12D.12, the transitions  $\tilde{\nu}_R(J-1)$  and  $\tilde{\nu}_P(J+1)$  have a common upper state, and hence can be anticipated to depend on  $\tilde{B}_0$ . Indeed, it is easy to show from eqn 12D.20 that

$$\tilde{\nu}_R(J-1) - \tilde{\nu}_P(J+1) = 4\tilde{B}_0(J + \frac{1}{2}) \quad (12\text{D.21a})$$

Therefore, a plot of the combination difference against  $J + \frac{1}{2}$  should be a straight line of slope  $4\tilde{B}_0$ , so the rotational constant of the molecule in the state  $\nu=0$  can be determined. (Any deviation from a straight line is a consequence of centrifugal distortion, so that effect can be investigated too.) Similarly,  $\tilde{\nu}_R(J)$  and  $\tilde{\nu}_P(J)$  have a common lower state, and hence their combination difference gives information about the upper state:

$$\tilde{\nu}_R(J) - \tilde{\nu}_P(J) = 4\tilde{B}_1(J + \frac{1}{2}) \quad (12\text{D.21b})$$

Figure 12D.12 The method of combination differences makes use of the fact that some transitions share a common level.

### Brief illustration 12D.4 Combination differences

To develop a sense of the relative values of the rotational constants for different vibrational states, we can estimate the rotational constants of  $\tilde{B}_0$  and  $\tilde{B}_1$  from a quick calculation involving only a few transitions. For  $^1\text{H}^{35}\text{Cl}$ ,  $\tilde{\nu}_R(0) - \tilde{\nu}_P(2) = 62.6 \text{ cm}^{-1}$ , and it follows from eqn 12D.21a, with  $J=1$ , that  $\tilde{B}_0 = 62.6 / \{4 \times (1 + \frac{1}{2})\} \text{ cm}^{-1} = 10.4 \text{ cm}^{-1}$ . Similarly,  $\tilde{\nu}_R(1) - \tilde{\nu}_P(1) = 60.8 \text{ cm}^{-1}$ , and it follows from eqn 12D.21b,

again with  $J=1$  that  $\tilde{B}_1 = 60.8 / \{4 \times (1 + \frac{1}{2})\} \text{ cm}^{-1} = 10.1 \text{ cm}^{-1}$ . The linear least-squares procedure applied to a richer data set gives  $\tilde{B}_0 = 10.440 \text{ cm}^{-1}$  and  $\tilde{B}_1 = 10.136 \text{ cm}^{-1}$ . We see that the two rotational constants do not differ by much.

**Self-test 12D.6** For  $^{12}\text{C}^{16}\text{O}$ ,  $\tilde{\nu}_R(0) = 2147.084 \text{ cm}^{-1}$ ,  $\tilde{\nu}_R(1) = 2150.858 \text{ cm}^{-1}$ ,  $\tilde{\nu}_P(1) = 2139.427 \text{ cm}^{-1}$ , and  $\tilde{\nu}_P(2) = 2135.548 \text{ cm}^{-1}$ . Estimate the values of  $\tilde{B}_0$  and  $\tilde{B}_1$ .

Answer:  $\tilde{B}_0 = 1.923 \text{ cm}^{-1}$ ,  $\tilde{B}_1 = 1.905 \text{ cm}^{-1}$

## 12D.5 Vibrational Raman spectra

The gross selection rule for vibrational Raman transitions (see the following *Justification*) is that *the polarizability should change as the molecule vibrates*. The polarizability plays a role in vibrational Raman spectroscopy because the molecule must be squeezed and stretched by the incident radiation in order that a vibrational excitation may occur during the photon–molecule collision.

### Brief illustration 12D.5 The gross selection rule for vibrational Raman spectra

Both homonuclear and heteronuclear diatomic molecules swell and contract during a vibration, the control of the nuclei over the electrons varies, and hence the molecular polarizability changes. Both types of diatomic molecule are therefore vibrationally Raman active.

**Self-test 12D.7** Can a linear, nonpolar molecule like  $\text{CO}_2$  have a Raman spectrum?

Answer: Yes

The specific selection rule for vibrational Raman transitions in the harmonic approximation is  $\Delta\nu = \pm 1$ . The formal basis for the gross and specific selection rules is given in the following *Justification*.

### Justification 12D.2 Gross and specific selection rules for vibrational Raman spectra

For simplicity, we consider a one-dimensional harmonic oscillator (like a diatomic molecule). First, we note that the oscillating electric field,  $\mathcal{E}(t)$ , of the incident electromagnetic radiation can induce a dipole moment that is proportional to the strength of the field. We write  $\hat{\mu} = \alpha(x)\mathcal{E}(t)$ , where  $\alpha(x)$  is the polarizability of the molecule (Topic 12B). The transition dipole moment is then

$$\mu_{fi} = \int \psi_{v_f}^* \hat{\mu} \psi_{v_i} d\tau = \int \psi_{v_f}^* \alpha(x) \mathcal{E}(t) \psi_{v_i} dx = \mathcal{E}(t) \int \psi_{v_f}^* \alpha(x) \psi_{v_i} dx$$

The polarizability varies with the length of the bond because the control of the nuclei over the electrons varies as their position changes, so  $\alpha(x) = \alpha_0 + (d\alpha/dx)_0 x + \dots$ . Now the calculation proceeds as in *Justification 12D.1*, but  $(d\mu/dx)_0$  is replaced by  $\mathcal{E}(t)(d\alpha/dx)_0$  in the expression for  $\mu_{fi}$ . For  $f \neq i$ ,

$$\mu_{fi} = \mathcal{E}(t) \left( \frac{d\alpha}{dx} \right)_0 \int \psi_{v_f}^* x \psi_{v_i} dx$$

Therefore, the vibration is Raman active only if  $(d\alpha/dx)_0 \neq 0$ ; that is, only if the polarizability varies with displacement, and, as we saw in *Justification 12D.1*, if  $v_f - v_i = \pm 1$ .

The lines to high frequency of the incident radiation, in the language introduced in Topic 12A, the ‘anti-Stokes lines’, are those for which  $\Delta\nu = -1$ . The lines to low frequency, the ‘Stokes lines’, correspond to  $\Delta\nu = +1$ . The intensities of the anti-Stokes and Stokes lines are governed largely by the Boltzmann populations of the vibrational states involved in the transition. It follows that anti-Stokes lines are usually weak because very few molecules are in an excited vibrational state initially.

In gas-phase spectra, the Stokes and anti-Stokes lines have a branch structure arising from the simultaneous rotational transitions that accompany the vibrational excitation (Fig. 12D.13). The selection rules are  $\Delta J = 0, \pm 2$  (as in pure rotational Raman spectroscopy), and give rise to the **O branch** ( $\Delta J = -2$ ), the **Q branch** ( $\Delta J = 0$ ), and the **S branch** ( $\Delta J = +2$ ):

$$\begin{aligned} \tilde{\nu}_O(J) &= \tilde{\nu}_i - \tilde{\nu} - 2\tilde{B} + 4\tilde{B}J && \text{O branch transitions} \\ \tilde{\nu}_Q(J) &= \tilde{\nu}_i - \tilde{\nu} && \text{Q branch transitions} \\ \tilde{\nu}_S(J) &= \tilde{\nu}_i - \tilde{\nu} - 6\tilde{B} + 4\tilde{B}J && \text{S branch transitions} \end{aligned} \quad (12D.22)$$

**Figure 12D.13** The formation of O, Q, and S branches in a vibration–rotation Raman spectrum of a linear rotor. Note that the frequency scale runs in the opposite direction to that in Fig. 12D.11, because the higher energy transitions (on the right) extract more energy from the incident beam and leave it at lower frequency.

where  $\tilde{\nu}_i$  is the wavenumber of the incident radiation. Note that, unlike in infrared spectroscopy, a Q branch is obtained for all linear molecules. The spectrum of CO, for instance, is shown in Fig. 12D.14: the structure of the Q branch arises from the differences in rotational constants of the upper and lower vibrational states.

The information available from vibrational Raman spectra adds to that from infrared spectroscopy because homonuclear diatomics can also be studied. The spectra can be interpreted in terms of the force constants, dissociation energies, and bond lengths, and some of the information obtained is included in Table 12D.1.

**Figure 12D.14** The structure of a vibrational line in the vibrational Raman spectrum of carbon monoxide, showing the O, Q, and S branches. The horizontal axis represents the wavenumber difference between the incident and scattered radiation.

## Checklist of concepts

- 1. The vibrational energy levels of a diatomic molecule modelled as a harmonic oscillator depend on a **force constant**  $k_f$  (a measure of the bond's stiffness) and the **effective mass** of the vibration.
- 2. The **gross selection rule** for infrared spectra is that the electric dipole moment of the molecule must change when the atoms are displaced relative to one another.
- 3. The **specific selection rule** for infrared spectra (within the harmonic approximation) is  $\Delta\nu = \pm 1$ .
- 4. The **Morse potential energy function** can be used to model anharmonic motion.
- 5. The strongest infrared transitions are the **fundamental transitions** ( $\nu = 1 \leftarrow \nu = 0$ ).
- 6. Anharmonicity gives rise to weaker **overtone transitions** ( $\nu = 2 \leftarrow \nu = 0$ ,  $\nu = 3 \leftarrow \nu = 0$ , etc.).
- 7. A **Birge–Sponer plot** may be used to determine the dissociation energy of the bond in a diatomic molecule.
- 8. In the gas phase vibrational transitions have a **P, Q, R branch structure** due to simultaneous rotational transitions.
- 9. For a vibration to be **Raman active**, the polarizability must change as the molecule vibrates.
- 10. The **specific selection rule** for vibrational Raman spectra (within the harmonic approximation) is  $\Delta\nu = \pm 1$ .
- 11. In gas-phase spectra, the Stokes and anti-Stokes lines in a Raman spectrum have an **O, Q, S branch structure**.

## Checklist of equations

Property	Equation	Comment	Equation number
Vibrational terms	$\tilde{G}(\nu) = (\nu + \frac{1}{2})\tilde{\nu}, \tilde{\nu} = (1/2\pi c)(k_f/m_{\text{eff}})^{1/2}$	Diatomic molecules; simple harmonic oscillator	12D.8
Infrared spectra (vibrational)	$\Delta\tilde{G}_{\nu+\frac{1}{2}} = \tilde{\nu}$	Diatomic molecules; simple harmonic oscillator	12D.10
Morse potential energy	$V = hc\tilde{D}_e\{1 - e^{-a(R-R_e)}\}^2,$ $a = (m_{\text{eff}}\omega^2/2hc\tilde{D}_e)^{1/2},$ $m_{\text{eff}} = m_1m_2/(m_1 + m_2)$		12D.11
Vibrational terms (diatomic molecules)	$\tilde{G}(\nu) = (\nu + \frac{1}{2})\tilde{\nu} - (\nu + \frac{1}{2})^2 x_e \tilde{\nu},$ $x_e = \tilde{\nu}/4\tilde{D}_e$	Morse potential energy	12D.12

Property	Equation	Comment	Equation number

## ► What do you need to know already?

You need to be familiar with the harmonic oscillator (Topic 8B), the general principles of spectroscopy (Topic 12A), and the selection rules for infrared and Raman spectroscopy (Topic 12D). The treatment of the symmetry aspects of infrared and Raman active vibrations requires concepts from Chapter 11.

There is only one mode of vibration for a diatomic molecule: bond stretch. In polyatomic molecules there are several, sometimes hundreds, of modes of vibration because all the bond lengths and angles may change. Consequently, the vibrational spectra are very complex. Nonetheless, infrared and Raman spectroscopy can be used to obtain information about the structure of systems as large as animal and plant tissues. Raman spectroscopy is particularly useful for characterizing nanomaterials, especially carbon nanotubes.

## 12E.1 Normal modes

We begin by calculating the total number of vibrational modes of a polyatomic molecule. We then see that we can choose combinations of these atomic displacements that give the simplest description of the vibrations.

As we show in the following *Justification*, the number of independent modes of motion of an  $N$ -atom molecule depends on whether it is linear or nonlinear:

$$\begin{array}{ll} \text{Linear molecule:} & 3N - 5 \\ \text{Nonlinear molecule:} & 3N - 6 \end{array}$$

## ► Why do you need to know this material?

The analysis of vibrational spectra provides information about the identity and conformation of polyatomic molecules in the gas and condensed phases. Even complex systems, such as synthetic materials and biological cells, can be studied.

## ► What is the key idea?

The vibrational spectrum of a polyatomic molecule can be interpreted in terms of the coordinated, collective harmonic motion of groups of atoms.

### Brief illustration 12E.1 The number of normal modes

Water,  $\text{H}_2\text{O}$ , is a nonlinear triatomic molecule,  $N=3$ , and has  $3N-6=3$  modes of vibration (and three modes of rotation);  $\text{CO}_2$  is a linear triatomic molecule, and has  $3N-5=4$  modes

of vibration (and only two modes of rotation). A biological macromolecule with  $N \approx 500$  atoms can vibrate in nearly 1500 different independent ways.

**Self-test 12E.1** How many normal modes does naphthalene ( $C_{10}H_8$ ) have?

Answer: 48

### Justification 12E.1 The number of vibrational modes

The total number of coordinates needed to specify the locations of  $N$  atoms is  $3N$ . Each atom may change its location by varying one of its three coordinates ( $x$ ,  $y$ , and  $z$ ), so the total number of displacements available is  $3N$ . These displacements can be grouped together in a physically sensible way. For example, three coordinates are needed to specify the location of the centre of mass of the molecule, so three of the  $3N$  displacements correspond to the translational motion of the molecule as a whole. The remaining  $3N - 3$  displacements are non-translational ‘internal’ modes of the molecule.

Two angles are needed to specify the orientation of a linear molecule in space: in effect, we need to give only the latitude and longitude of the direction in which the molecular axis is pointing (Fig. 12E.1a). However, three angles are needed for a nonlinear molecule because we also need to specify the orientation of the molecule around the direction defined by the latitude and longitude (Fig. 12E.1b). Therefore, two (linear) or three (nonlinear) of the  $3N - 3$  internal displacements are rotational. This leaves  $3N - 5$  (linear) or  $3N - 6$  (nonlinear) displacements of the atoms relative to one another: these are the vibrational modes. It follows that the number of modes of vibration  $N_{\text{vib}}$  is  $3N - 5$  for linear molecules and  $3N - 6$  for nonlinear molecules.

**Figure 12E.1** (a) The orientation of a linear molecule requires the specification of two angles. (b) The orientation of a nonlinear molecule requires the specification of three angles.

The next step is to find the best description of the modes. One choice for the four modes of  $CO_2$ , for example, might be the ones in Fig. 12E.2a. This illustration shows the stretching of one bond (the mode  $\nu_L$ ), the stretching of the other ( $\nu_R$ ), and the two perpendicular bending modes ( $\nu_2$ ). The description, while permissible, has a disadvantage: when one CO bond vibration is excited, the motion of the C atom sets the other CO bond in motion, so energy flows backwards and forwards between  $\nu_L$  and  $\nu_R$ . Moreover, the position of the centre of mass of the molecule varies in the course of either vibration.

The description of the vibrational motion is much simpler if linear combinations of  $\nu_L$  and  $\nu_R$  are taken. For example, one combination is  $\nu_1$  in Fig. 12E.2b: this mode is the **symmetric stretch**. In this mode, the C atom is buffeted simultaneously from each side and the motion continues indefinitely. Another mode is  $\nu_2$ , the **antisymmetric stretch**, in which the two O atoms always move in the same direction as each other and opposite to that of the C atom. Both modes are independent in the sense that, if one is excited, then it does not excite the other. They are two of the ‘normal modes’ of the molecule, its independent, collective vibrational displacements. The two other normal modes are the two bending modes  $\nu_3$ . In general, a **normal mode** is an independent, synchronous motion of atoms or groups of atoms that may be excited without leading to the excitation of any other normal mode and without involving translation or rotation of the molecule as a whole.

The four normal modes of  $CO_2$ , and the  $N_{\text{vib}}$  normal modes of polyatomics in general, are the key to the description of molecular vibrations. Each normal mode,  $q$ , behaves like an independent harmonic oscillator (if anharmonicities are neglected), so each has a series of terms

**Figure 12E.2** Alternative descriptions of the vibrations of  $CO_2$ . (a) The stretching modes are not independent, and if one C–O group is excited the other begins to vibrate. They are not normal modes of vibration of the molecule. (b) The symmetric and antisymmetric stretches are independent, and one can be excited without affecting the other: they are normal modes. (c) The two perpendicular bending motions are also normal modes.

**Figure 12E.3** The three normal modes of H<sub>2</sub>O. The mode  $\nu_2$  is predominantly bending, and occurs at lower wavenumber than the other two.

$$\tilde{G}_q(\nu) = (\nu + \frac{1}{2})\tilde{\nu}_q \quad \tilde{\nu}_q = \frac{1}{2\pi c} \left( \frac{k_{f,q}}{m_q} \right)^{1/2} \quad \text{Vibrational terms of normal modes} \quad (12E.1)$$

where  $\tilde{\nu}_q$  is the wavenumber of mode  $q$  and depends on the force constant  $k_{f,q}$  for the mode and on the effective mass  $m_q$  of the mode. The effective mass of the mode is a measure of the mass that is swung about by the vibration and in general is a combination of the masses of the atoms. For example, in the symmetric stretch of CO<sub>2</sub>, the C atom is stationary, and the effective mass depends on the masses of only the O atoms. In the antisymmetric stretch and in the bends, all three atoms move, so all contribute to the effective mass. The three normal modes of H<sub>2</sub>O are shown in Fig. 12E.3: note that the predominantly bending mode ( $\nu_2$ ) has a lower frequency than the others, which are predominantly stretching modes. It is generally the case that the frequencies of bending motions are lower than those of stretching modes. One point that must be appreciated is that only in special cases (such as the CO<sub>2</sub> molecule) are the normal modes purely stretches or purely bends. In general, a normal mode is a composite motion of simultaneous stretching and bending of bonds. Another point in this connection is that heavy atoms generally move less than light atoms in normal modes.

The vibrational state of a polyatomic molecule is specified by the vibrational quantum number  $\nu$  for each of the normal modes. For example, for the water molecule with three normal modes, the vibrational state is designated as  $(\nu_1, \nu_2, \nu_3)$  where  $\nu_i$  is the number of vibrational quanta in normal mode  $i$ . The vibrational ground state of an H<sub>2</sub>O molecule is therefore (0,0,0).

## 12E.2 Infrared absorption spectra

The gross selection rule for infrared activity is that *the motion corresponding to a normal mode should be accompanied by a change of dipole moment*. Simple inspection of atomic motions is sometimes all that is needed in order to assess whether a normal mode is infrared active. For example, the symmetric stretch of CO<sub>2</sub> leaves the dipole moment unchanged (at zero, see Fig. 12E.2), so this mode is infrared inactive. The antisymmetric stretch, however, changes the dipole moment because the molecule becomes unsymmetrical as it vibrates, so this mode is infrared active. Because the dipole moment change is parallel to the principal axis, the transitions arising from this mode

are classified as **parallel bands** in the spectrum. Both bending modes are infrared active: they are accompanied by a changing dipole perpendicular to the principal axis, so transitions involving them lead to a **perpendicular band** in the spectrum.

### Example 12E.1 Using the gross selection rule for infrared spectroscopy

State which of the following molecules are infrared active: N<sub>2</sub>O, OCS, H<sub>2</sub>O, CH<sub>2</sub>=CH<sub>2</sub>.

**Method** Molecules that are infrared active have dipole moments that change during the course of a vibration. Therefore, judge whether a distortion of the molecule can change its dipole moment (including changing it from zero).

**Answer** All the molecules possess at least one normal mode that results in a change of dipole moment, so all are infrared active. Note that not all the modes of complicated molecules are infrared active. For example, a vibration of CH<sub>2</sub>=CH<sub>2</sub> in which the C=C bond stretches and contracts (while the C–H bonds either do not vibrate or stretch and contract synchronously) is inactive because it leaves the dipole moment unchanged (at zero, Fig. 12E.4).

**Figure 12E.4** A normal mode of CH<sub>2</sub>=CH<sub>2</sub> (ethene) that is not infrared active.

**Self-test 12E.2** Identify a normal mode of C<sub>6</sub>H<sub>6</sub> that is not infrared active

**Answer:** A 'breathing' mode in which all the carbon–carbon bonds contract and stretch synchronously, while the C–H bonds either do not vibrate or stretch and contract synchronously (Fig. 12E.5)

**Figure 12E.5** A normal mode of C<sub>6</sub>H<sub>6</sub> (benzene) that is not infrared active.

The active modes are subject to the specific selection rule  $\Delta v_q = \pm 1$  in the harmonic approximation, so the wavenumber of the fundamental transition (the 'first harmonic') of each active mode is  $\tilde{\nu}_q$ . A polyatomic molecule has several fundamental transitions. For example, the spectrum of a molecule with three infrared active normal modes features three fundamental transitions:  $(1,0,0) \leftarrow (0,0,0)$ ,  $(0,1,0) \leftarrow (0,0,0)$ , and  $(0,0,1) \leftarrow (0,0,0)$ . Also possible are **combination bands** corresponding to the excitation of more than one normal mode in the transition, as in  $(1,1,0) \leftarrow (0,0,0)$ . Moreover, overtone transitions, such as  $(2,0,0) \leftarrow (0,0,0)$ , can appear in the spectrum when anharmonicity is important (Topic 12D).

From the analysis of the spectrum, a picture may be constructed of the stiffness of various parts of the molecule, that is, we can establish its **force field**, the set of force constants corresponding to all the displacements of the atoms. The force field may also be estimated by using the computational techniques described in Topic 10E. Superimposed on the simple force-field scheme are the complications arising from anharmonicities and the effects of molecular rotation. In the gas phase, rotational transitions affect the spectrum in a way similar to their effect on diatomic molecules (Topic 12D), but as polyatomic molecules are typically asymmetric rotors, the resulting band structure is very complex.

Molecules are unable to rotate freely in a liquid or a solid. In a liquid, for example, a molecule may be able to rotate through only a few degrees before it is struck by another, so it changes its rotational state frequently. This random changing of orientation is called **tumbling**. As a result of this intermolecular buffeting, the lifetimes of rotational states in liquids are very short, so in most cases the rotational energies are ill-defined. Collisions occur at a rate of about  $10^{13} \text{ s}^{-1}$  and, even allowing for only a 10 per cent success rate in knocking the molecule into another rotational state, a lifetime broadening (eqn 12A.19, in the form  $\delta\tilde{\nu} \approx 1/2\pi c\tau$ ) of more than  $1 \text{ cm}^{-1}$  can easily result. The rotational structure of the vibrational spectrum is blurred by this effect, so the infrared spectra of molecules in condensed phases usually consist of broad lines spanning the entire range of the resolved gas-phase spectrum, and showing no branch structure.

One very important application of infrared spectroscopy to condensed phase samples, and for which the blurring of the rotational structure by random collisions is a welcome simplification, is to chemical analysis. The vibrational spectra of different groups in a molecule give rise to absorptions at characteristic frequencies because a normal mode of even a very large molecule is often dominated by the motion of a small group of atoms. The intensities of the vibrational bands that can be identified with the motions of small groups are also transferable between molecules. Consequently, the molecules in a sample can often be identified by examining its infrared spectrum and referring to a table of characteristic frequencies and intensities (Table 12E.1).

**Table 12E.1\*** Typical vibrational wavenumbers,  $\tilde{\nu}/\text{cm}^{-1}$

Vibration type	$\tilde{\nu}/\text{cm}^{-1}$
C–H stretch	2850–2960
C–H bend	1340–1465
C–C stretch, bend	700–1250
C=C stretch	1620–1680

\* More values are given in the *Resource section*.

### Example 12E.2 Interpreting an infrared spectrum

The infrared spectrum of an organic compound is shown in Fig. 12E.6. Suggest an identification.

**Figure 12E.6** A typical infrared absorption spectrum taken by forming a sample into a disk with potassium bromide. As explained *Example 12E.2*, the substance can be identified as  $\text{O}_2\text{NC}_6\text{H}_4\text{—C}\equiv\text{C—COOH}$ .

**Method** Some of the features at wavenumbers above  $1500 \text{ cm}^{-1}$  can be identified by comparison with the data in Table 12E.1.

**Answer** The features of the spectrum include: (a) C–H stretch of a benzene ring, indicating a substituted benzene; (b) carboxylic acid O–H stretch, indicating a carboxylic acid; (c) the strong absorption of a conjugated C≡C group, indicating a substituted alkyne; (d) this strong absorption is also characteristic of a carboxylic acid that is conjugated to a carbon–carbon multiple bond; (e) a characteristic vibration of a benzene ring, confirming the deduction drawn from (a); (f) a characteristic absorption of a nitro group (–NO<sub>2</sub>) connected to a multiply bonded carbon–carbon system, suggesting a nitro-substituted benzene. The molecule contains as components a benzene ring, an aromatic carbon–carbon bond, a –COOH group, and a –NO<sub>2</sub> group. The molecule is in fact  $\text{O}_2\text{N—C}_6\text{H}_4\text{—C}\equiv\text{C—COOH}$ . A more detailed analysis shows it to be the 1,4-isomer.

**Self-test 12E.3** Suggest an identification of the organic compound responsible for the spectrum shown in Fig. 12E.7. (*Hint*: The molecular formula of the compound is  $\text{C}_3\text{H}_5\text{ClO}$ .)

Figure 12E.7 The spectrum considered in *Self-test* 12E.3.

Answer:  $\text{CH}_2=\text{CClCH}_2\text{OH}$

### 12E.3 Vibrational Raman spectra

As for diatomic molecules (Topic 12D), the normal modes of vibration of molecules are Raman active if they are accompanied by a changing polarizability. A closer analysis of infrared and Raman activity of normal modes based on considerations of symmetry leads to the **exclusion rule**:

If the molecule has a centre of symmetry then no modes can be both infrared and Raman active. Exclusion rule

(A mode may be inactive in both.) Because it is often possible to judge intuitively if a mode changes the molecular dipole moment, we can use this rule to identify modes that are not Raman active.

#### Brief illustration 12E.2 Raman active modes of polyatomic molecules

The symmetric stretch of  $\text{CO}_2$  alternately swells and contracts the molecule: this motion changes the size and hence the polarizability of the molecule, so the mode is Raman active. The other modes of  $\text{CO}_2$  leave the polarizability unchanged, so they are Raman inactive. Furthermore, the exclusion rule applies to  $\text{CO}_2$  because it has a centre of symmetry.

**Self-test 12E.4** Does the exclusion rule apply to  $\text{H}_2\text{O}$  or  $\text{CH}_4$ ?  
Answer: No; neither molecule has centre of symmetry

#### (a) Depolarization

The assignment of Raman lines to particular vibrational modes is aided by noting the state of polarization of the scattered light. The **depolarization ratio**,  $\rho$ , of a line is the ratio of the intensities,  $I$ , of the scattered light with polarizations

Figure 12E.8 The definition of the planes used for the specification of the depolarization ratio,  $\rho$ , in Raman scattering.

perpendicular and parallel to the plane of polarization of the incident radiation:

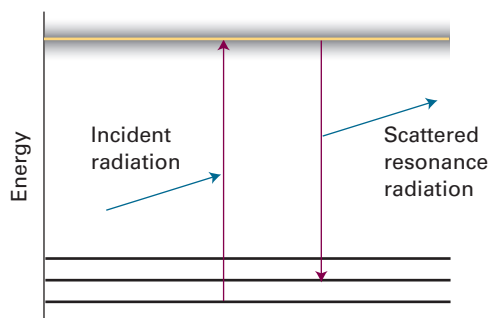

$$\rho = \frac{I_{\perp}}{I_{\parallel}} \quad \text{Definition Depolarization ratio (12E.2)}$$

To measure  $\rho$ , the intensity of a Raman line is measured with a polarizing filter (a 'half-wave plate') first parallel and then perpendicular to the polarization of the incident beam. If the emergent light is not polarized, then both intensities are the same and  $\rho$  is close to 1; if the light retains its initial polarization, then  $I_{\perp} = 0$ , so  $\rho = 0$  (Fig. 12E.8). A line is classified as **depolarized** if it has  $\rho$  close to or greater than 0.75 and as **polarized** if  $\rho < 0.75$ . Only totally symmetrical vibrations give rise to polarized lines in which the incident polarization is largely preserved. Vibrations that are not totally symmetrical give rise to depolarized lines because the incident radiation can give rise to radiation in the perpendicular direction too.

#### (b) Resonance Raman spectra

A modification of the basic Raman effect involves using incident radiation that nearly coincides with the frequency of an electronic transition of the sample (Fig. 12E.9). The technique is then called **resonance Raman spectroscopy**. It is characterized by a much greater intensity in the scattered radiation. Furthermore, because it is often the case that only a few vibrational modes contribute to the more intense scattering, the spectrum is greatly simplified.

Resonance Raman spectroscopy is used to study biological molecules that absorb strongly in the ultraviolet and visible regions of the spectrum. Examples include the pigments  $\beta$ -carotene and chlorophyll, which capture solar energy during plant photosynthesis. The resonance Raman spectra of Fig. 12E.10 show vibrational transitions from only the few pigment molecules that are bound to very large proteins dissolved

**Figure 12E.9** In the resonance Raman effect the incident radiation has a frequency close to an actual electronic excitation of the molecule. A photon is emitted when the excited state returns to a state close to the ground state.

in an aqueous buffer solution. This selectivity arises from the fact that water (the solvent), amino acid residues, and the peptide group do not have electronic transitions at the laser wavelengths used in the experiment, so their conventional Raman spectra are weak compared to the enhanced spectra of the pigments. Comparison of the spectra in Figs. 12E.10a and 12E.10b also shows that, with proper choice of excitation wavelength, it is possible to examine individual classes of pigments bound to the same protein: excitation at 488 nm, where  $\beta$ -carotene absorbs strongly, shows vibrational bands from  $\beta$ -carotene only, whereas excitation at 407 nm, where chlorophyll *a* and  $\beta$ -carotene absorb, reveals features from both types of pigments.

**Figure 12E.10** The resonance Raman spectra of a protein complex that is responsible for some of the initial electron transfer events in plant photosynthesis. (a) Laser excitation of the sample at 407 nm shows Raman bands due to both chlorophyll *a* and  $\beta$ -carotene bound to the protein because both pigments absorb light at this wavelength. (b) Laser excitation at 488 nm shows Raman bands from  $\beta$ -carotene only because chlorophyll *a* does not absorb light very strongly at this wavelength. (Adapted from D.F. Ghanotakis et al., *Biochim. Biophys. Acta* **974**, 44 (1989).)

**Figure 12E.11** The experimental arrangement for the CARS experiment.

### (c) Coherent anti-Stokes Raman spectroscopy

The intensity of Raman transitions may be enhanced by **coherent anti-Stokes Raman spectroscopy** (CARS, Fig. 12E.11). The technique relies on the fact that, if two laser beams of frequencies  $\nu_1$  and  $\nu_2$  pass through a sample, then they may mix together and give rise to coherent radiation of several different frequencies, one of which is

$$\nu' = 2\nu_1 - \nu_2 \quad (12E.3a)$$

Suppose that  $\nu_2$  is varied until it matches any Stokes line from the sample, such as the one with frequency  $\nu_1 - \Delta\nu$ ; then the coherent emission will have frequency

$$\nu' = 2\nu_1 - (\nu_1 - \Delta\nu) = \nu_1 + \Delta\nu \quad (12E.3b)$$

which is the frequency of the corresponding anti-Stokes line. This coherent radiation forms a narrow beam of high intensity.

An advantage of CARS is that it can be used to study Raman transitions in the presence of competing incoherent background radiation, and so can be used to observe the Raman spectra of species in flames. One example is the vibration-rotation CARS spectrum of  $N_2$  gas in a methane-air flame shown in Fig 12E.12.

**Figure 12E.12** CARS spectrum of a methane-air flame at 2104 K. The peaks correspond to the Q branch of the vibration-rotation spectrum of  $N_2$  gas. (Adapted from J.F. Verdick et al., *J. Chem. Ed.* **59**, 495 (1982).)

## 12E.4 Symmetry aspects of molecular vibrations

One of the most powerful ways of dealing with normal modes, especially of complex molecules, is to classify them according to their symmetries. This section makes extensive use of the concepts and procedures introduced in Topic 11C, which is an essential background to this discussion. In particular, each normal mode must belong to one of the symmetry species of the molecular point group, as discussed in that Topic.

### Example 12E.3 Identifying the symmetry species of a normal mode

Establish the symmetry species of the normal mode vibrations of  $\text{CH}_4$ , which belongs to the group  $T_d$ .

**Method** The first step in the procedure is to identify the symmetry species of the irreducible representations spanned by all the  $3N$  displacements of the atoms, using the characters of the molecular point group. Find these characters by counting 1 if the displacement is unchanged under a symmetry operation,  $-1$  if it changes sign, and 0 if it is changed into some other displacement. Next, subtract the symmetry species of the translations. Translational displacements span the same symmetry species as  $x$ ,  $y$ , and  $z$ , so they can be obtained from the right-most column of the character table. Finally, subtract the symmetry species of the rotations, which are also given in the character table (and denoted there by  $R_x$ ,  $R_y$ , and  $R_z$ ).

**Answer** There are  $3 \times 5 = 15$  degrees of freedom, of which  $(3 \times 5) - 6 = 9$  are vibrations. Refer to Fig. 12E.13. Under  $E$ , no displacement coordinates are changed, so the character is 15. Under  $C_3$ , no displacements are left unchanged, so the character is 0. Under the  $C_2$  indicated, the  $z$ -displacement of the central atom is left unchanged, whereas its  $x$ - and  $y$ -components both change sign. Therefore  $\chi(C_2) = 1 - 1 - 1 + 0 + 0 + \dots = -1$ . Under the  $S_4$  indicated, the  $z$ -displacement of the central atom is reversed, so  $\chi(S_4) = -1$ . Under  $\sigma_d$ , the  $x$ - and  $z$ -displacements of C,  $\text{H}_3$ , and  $\text{H}_4$  are left unchanged and the  $y$ -displacements are reversed; hence  $\chi(\sigma_d) = 3 + 3 - 3 = 3$ . The characters are therefore 15, 0,  $-1$ ,  $-1$ , 3. By decomposing the direct product (Topic 11C), we find that this representation spans  $A_1 + E + T_1 + 3T_2$ . The translations span  $T_2$ ; the rotations span  $T_1$ . Hence, the nine vibrations span  $A_1 + E + 2T_2$ . The modes are shown in Fig. 12E.14. We shall see in the next subsection that symmetry analysis gives a quick way of deciding which modes are active.

Figure 12E.13 The atomic displacements of  $\text{CH}_4$  and the symmetry elements used to calculate the characters.

Figure 12E.14 Typical normal modes of vibration of a tetrahedral molecule. There are in fact two modes of symmetry species  $E$  and three modes of each  $T_2$  symmetry species.

**Self-test 12E.5** Establish the symmetry species of the normal modes of  $\text{H}_2\text{O}$ .

Answer:  $2A_1 + B_2$

### (a) Infrared activity of normal modes

It is best to use group theory to judge the activities of more complex modes of vibration. This is easily done by checking the character table of the molecular point group for the symmetry species of the irreducible representations spanned by  $x$ ,  $y$ , and  $z$ , for their species are also the symmetry species of the components of the electric dipole moment. Then apply the following rule, which is developed in the following *Justification*:

If the symmetry species of a normal mode is the same as any of the symmetry species of  $x$ ,  $y$ , or  $z$ , then the mode is infrared active.

Symmetry test for IR activity

#### Brief illustration 12E.3 The infrared activity of normal modes

To decide which normal modes of  $\text{CH}_4$  are IR active, we note that we found in *Example 12E.3* that their symmetry species are  $A_1 + E + 2T_2$ . Therefore, because  $x$ ,  $y$ , and  $z$  span  $T_2$  in the group  $T_d$ , only the  $T_2$  modes are infrared active. The distortions accompanying these modes lead to a changing dipole

moment. The  $A_1$  mode, which is inactive, is the symmetrical 'breathing' mode of the molecule.

**Self-test 12E.6** Which of the normal modes of  $H_2O$  are infrared active?

Answer: All three

### Justification 12E.2 Using symmetry to identify infrared active normal modes

The rule hinges on the form of the transition dipole moment (Topic 12A):  $\mu_{fi,x} \propto \int \psi_{\nu_f}^* x \psi_{\nu_i} dx$  in the  $x$ -direction, with similar expressions for the two other components of the transition moment. Consider a harmonic oscillator in the  $x$ -direction undergoing a transition from the ground vibrational state ( $\nu_i=0$ ) to the first excited state ( $\nu_f=1$ ). Because  $\psi_0 \propto e^{-x^2}$  and  $\psi_1 \propto xe^{-x^2}$  (Topic 8B), the components of the transition dipole moment take the following forms:

- $\int_{-\infty}^{+\infty} \overbrace{xe^{-x^2}}^{\psi_1} \overbrace{x}^{\mu_x} \overbrace{e^{-x^2}}^{\psi_0} dx = \int_{-\infty}^{+\infty} x^2 e^{-2x^2} dx$  in the  $x$ -direction. As can be verified by direct calculation, this integral does not vanish.
- $\int_{-\infty}^{+\infty} xye^{-2x^2} dx$  and  $\int_{-\infty}^{+\infty} xze^{-2x^2} dx$  in the  $y$ - and  $z$ -directions, respectively. A direct calculation shows that both integrals vanish.

Consequently, the excited state wavefunction must have the same symmetry as the displacement  $x$ .

### (b) Raman activity of normal modes

Group theory provides an explicit recipe for judging the Raman activity of a normal mode. First, we need to know that the polarizability transforms in the same way as the quadratic forms ( $x^2$ ,  $xy$ , etc.) listed in character tables. Then we use the following rule:

If the symmetry species of a normal mode is the same as the symmetry species of a quadratic form, then the mode is Raman active.

Symmetry test for Raman activity

### Brief illustration 12E.4 The Raman activity of normal modes

To decide which of the normal modes of  $CH_4$  are Raman active, refer to the  $T_d$  character table. It was established in *Example 12E.3* that the symmetry species of the normal modes are  $A_1 + E + 2T_2$ . Because the quadratic forms span  $A_1 + E + T_2$ , all the normal modes are Raman active. By combining this information with that in *Brief illustration 12E.3*, we see how the infrared and Raman spectra of  $CH_4$  are assigned. The assignment of spectral features to the  $T_2$  modes is straightforward because these are the only modes that are both infrared and Raman active. This leaves the  $A_1$  and  $E$  modes to be assigned in the Raman spectrum. Measurement of the depolarization ratio distinguishes between these modes because the  $A_1$  mode, being totally symmetric, is polarized and the  $E$  mode is depolarized.

**Self-test 12E.7** Which of the vibrational modes of  $H_2O$  are Raman active?

Answer: All three

## Checklist of concepts

1. A **normal mode** is an independent, synchronous motion of atoms or groups of atoms that may be excited without leading to the excitation of any other normal mode.
2. The **number of normal modes** is  $3N-6$  (for nonlinear molecules) or  $3N-5$  (linear molecules).
3. A normal mode is **infrared active** if it is accompanied by a change of dipole moment; the specific selection rule is  $\Delta\nu_q = \pm 1$ .
4. The **exclusion rule** states that, if the molecule has a centre of symmetry, then no modes can be both infrared and Raman active.
5. Totally symmetrical vibrations give rise to **polarized lines**.
6. A normal mode is infrared active if its symmetry species is the same as any of the symmetry species of  $x$ ,  $y$ , or  $z$ .
7. A normal mode is Raman active if its symmetry species is the same as the symmetry species of a quadratic form.

## Checklist of equations

Property	Equation	Comment	Equation number
Vibrational terms of normal modes	$\tilde{G}_q(\nu) = (\nu + \frac{1}{2})\tilde{\nu}_q,$ $\tilde{\nu}_q = (1/2\pi c)(k_{f,q}/m_q)^{1/2}$		12E.1

# CHAPTER 12 Rotational and vibrational spectra

*Note:* The masses of nuclides are listed in Table 0.2 of the *Resource section*.

## TOPIC 12A General features of molecular spectroscopy

### Discussion questions

- 12A.1** What is the physical interpretation of a selection rule?
- 12A.2** Describe the physical origins of linewidths in absorption and emission spectra. Do you expect the same contributions for species in condensed and gas phases?

- 12A.3** Describe the basic experimental arrangements commonly used for absorption, emission, and Raman spectroscopy.

### Exercises

- 12A.1(a)** Calculate the ratio  $A/B$  for transitions with the following characteristics: (i) 70.8 pm X-rays, (ii) 500 nm visible light, (iii) 3000  $\text{cm}^{-1}$  infrared radiation.
- 12A.1(b)** Calculate the ratio  $A/B$  for transitions with the following characteristics: (i) 500 MHz radiofrequency radiation, (ii) 3.0 cm microwave radiation.
- 12A.2(a)** The molar absorption coefficient of a substance dissolved in hexane is known to be  $723 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$  at 260 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 2.50 mm of a solution of concentration  $4.25 \text{ mmol dm}^{-3}$ .
- 12A.2(b)** The molar absorption coefficient of a substance dissolved in hexane is known to be  $227 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$  at 290 nm. Calculate the percentage reduction in intensity when light of that wavelength passes through 2.00 mm of a solution of concentration  $2.52 \text{ mmol dm}^{-3}$ .
- 12A.3(a)** A solution of an unknown component of a biological sample when placed in an absorption cell of path length 1.00 cm transmits 18.1 per cent of light of 320 nm incident upon it. If the concentration of the component is  $0.139 \text{ mmol dm}^{-3}$ , what is the molar absorption coefficient?
- 12A.3(b)** When light of wavelength 400 nm passes through 2.50 mm of a solution of an absorbing substance at a concentration  $0.717 \text{ mmol dm}^{-3}$ , the transmission is 61.5 per cent. Calculate the molar absorption coefficient of the solute at this wavelength and express the answer in  $\text{cm}^2 \text{ mol}^{-1}$ .
- 12A.4(a)** The molar absorption coefficient of a solute at 540 nm is  $386 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . When light of that wavelength passes through a 5.00 mm cell containing a solution of the solute, 38.5 per cent of the light is absorbed. What is the molar concentration of the solute?
- 12A.4(b)** The molar absorption coefficient of a solute at 440 nm is  $423 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . When light of that wavelength passes through a 6.50 mm cell containing a solution of the solute, 48.3 per cent of the light is absorbed. What is the molar concentration of the solute?
- 12A.5(a)** The following data were obtained for the absorption by  $\text{Br}_2$  in carbon tetrachloride using a 2.0 mm cell. Calculate the molar absorption coefficient of bromine at the wavelength employed:

$[\text{Br}_2]/(\text{mol dm}^{-3})$	0.0010	0.0050	0.0100	0.0500
$T/(\text{per cent})$	81.4	35.6	12.7	$3.0 \times 10^{-3}$

- 12A.5(b)** The following data were obtained for the absorption by a dye dissolved in methylbenzene using a 2.50 mm cell. Calculate the molar absorption coefficient of the dye at the wavelength employed:

$[\text{dye}]/(\text{mol dm}^{-3})$	0.0010	0.0050	0.0100	0.0500
$T/(\text{per cent})$	68	18	3.7	$1.03 \times 10^{-5}$

- 12A.6(a)** A 2.0 mm cell was filled with a solution of benzene in a non-absorbing solvent. The concentration of the benzene was  $0.010 \text{ mol dm}^{-3}$  and the wavelength of the radiation was 256 nm (where there is a maximum in the absorption). Calculate the molar absorption coefficient of benzene at this wavelength given that the transmission was 48 per cent. What will the transmittance be in a 4.0 mm cell at the same wavelength?
- 12A.6(b)** A 5.00 mm cell was filled with a solution of a dye. The concentration of the dye was  $18.5 \text{ mmol dm}^{-3}$ . Calculate the molar absorption coefficient of the dye at this wavelength given that the transmission was 29 per cent. What will the transmittance be in a 2.50 mm cell at the same wavelength?

- 12A.7(a)** A swimmer enters a gloomier world (in one sense) on diving to greater depths. Given that the mean molar absorption coefficient of sea water in the visible region is  $6.2 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ , calculate the depth at which a diver will experience (i) half the surface intensity of light, (ii) one tenth the surface intensity.
- 12A.7(b)** Given that the maximum molar absorption coefficient of a molecule containing a carbonyl group is  $30 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$  near 280 nm, calculate the thickness of a sample that will result in (i) half the initial intensity of radiation, (ii) one tenth the initial intensity.

- 12A.8(a)** The absorption associated with a particular transition begins at 220 nm, peaks sharply at 270 nm, and ends at 300 nm. The maximum value of the molar absorption coefficient is  $2.21 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . Estimate the integrated absorption coefficient of the transition assuming a symmetrical triangular lineshape.

- 12A.8(b)** The absorption associated with a certain transition begins at 156 nm, peaks sharply at 210 nm, and ends at 275 nm. The maximum value of the molar absorption coefficient is  $3.35 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . Estimate the integrated absorption coefficient of the transition assuming an inverted parabolic lineshape (Fig. 12.1).

- 12A.9(a)** The electronic absorption bands of many molecules in solution have half-widths at half-height of about  $5000 \text{ cm}^{-1}$ . Estimate the integrated absorption coefficients of bands for which (i)  $\epsilon_{\text{max}} \approx 1 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ , (ii)  $\epsilon_{\text{max}} \approx 5 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ .

- 12A.9(b)** The electronic absorption band of a compound in solution had a Gaussian lineshape and a half-width at half-height of  $4233 \text{ cm}^{-1}$  and  $\epsilon_{\text{max}} = 1.54 \times 10^4 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ . Estimate the integrated absorption coefficient.

Figure 12.1 A model parabolic absorption lineshape.

## Problems

**12A.1** The flux of visible photons reaching Earth from the North Star is about  $4 \times 10^3 \text{ mm}^{-2} \text{ s}^{-1}$ . Of these photons, 30 per cent are absorbed or scattered by the atmosphere and 25 per cent of the surviving photons are scattered by the surface of the cornea of the eye. A further 9 per cent are absorbed inside the cornea. The area of the pupil at night is about  $40 \text{ mm}^2$  and the response time of the eye is about 0.1 s. Of the photons passing through the pupil, about 43 per cent are absorbed in the ocular medium. How many photons from the North Star are focused onto the retina in 0.1 s? For a continuation of this story, see R.W. Rodieck, *The first steps in seeing*, Sinauer, Sunderland (1998).

**12A.2** A Dubosq colorimeter consists of a cell of fixed path length and a cell of variable path length. By adjusting the length of the latter until the transmission through the two cells is the same, the concentration of the second solution can be inferred from that of the former. Suppose that a plant dye of concentration  $25 \mu\text{g dm}^{-3}$  is added to the fixed cell, the length of which is 1.55 cm. Then a solution of the same dye, but of unknown concentration, is added to the second cell. It is found that the same transmittance is obtained when the length of the second cell is adjusted to 1.18 cm. What is the concentration of the second solution?

**12A.3** The Beer–Lambert law is derived on the basis that the concentration of absorbing species is uniform. Suppose, instead, that the concentration falls exponentially as  $[J] = [J]_0 e^{-x/\lambda}$ . Develop an expression for the variation of  $I$  with sample length; suppose that  $L \gg \lambda$ .

**12A.4** It is common to make measurements of absorbance at two wavelengths and use them to find the individual concentrations of two components A and B in a mixture. Show that the molar concentrations of A and B are

$$[A] = \frac{\epsilon_{B2}A_1 - \epsilon_{B1}A_2}{(\epsilon_{A1}\epsilon_{B2} - \epsilon_{A2}\epsilon_{B1})L} \quad [B] = \frac{\epsilon_{A1}A_2 - \epsilon_{A2}A_1}{(\epsilon_{A1}\epsilon_{B2} - \epsilon_{A2}\epsilon_{B1})L}$$

where  $A_1$  and  $A_2$  are absorbances of the mixture at wavelengths  $\lambda_1$  and  $\lambda_2$ , and the molar extinction coefficients of A (and B) at these wavelengths are  $\epsilon_{A1}$  and  $\epsilon_{A2}$  (and  $\epsilon_{B1}$  and  $\epsilon_{B2}$ ).

**12A.5** When pyridine is added to a solution of iodine in carbon tetrachloride the 520 nm band of absorption shifts toward 450 nm. However, the absorbance of the solution at 490 nm remains constant: this feature is called an *isosbestic point*. Show that an isosbestic point should occur when two absorbing species are in equilibrium.

**12A.6†** Ozone absorbs ultraviolet radiation in a part of the electromagnetic spectrum energetic enough to disrupt DNA in biological organisms and that is absorbed by no other abundant atmospheric constituent. This spectral range, denoted UV-B, spans the wavelengths of about 290 nm to 320 nm. The molar extinction coefficient of ozone over this range is given in the table

**12A.10(a)** What is the Doppler-shifted wavelength of a red (680 nm) traffic light approached at  $60 \text{ km h}^{-1}$ ?

**12A.10(b)** At what speed of approach would a red (680 nm) traffic light appear green (530 nm)?

**12A.11(a)** Estimate the lifetime of a state that gives rise to a line of width (i)  $0.20 \text{ cm}^{-1}$ , (ii)  $2.0 \text{ cm}^{-1}$ .

**12A.11(b)** Estimate the lifetime of a state that gives rise to a line of width (i) 200 MHz, (ii)  $2.45 \text{ cm}^{-1}$ .

**12A.12(a)** A molecule in a liquid undergoes about  $1.0 \times 10^{13}$  collisions in each second. Suppose that (i) every collision is effective in deactivating the molecule vibrationally and (ii) that one collision in 100 is effective. Calculate the width (in  $\text{cm}^{-1}$ ) of vibrational transitions in the molecule.

**12A.12(b)** A molecule in a gas undergoes about  $1.0 \times 10^9$  collisions in each second. Suppose that (i) every collision is effective in deactivating the molecule rotationally and (ii) that one collision in 10 is effective. Calculate the width (in hertz) of rotational transitions in the molecule.

below (DeMore et al., *Chemical kinetics and photochemical data for use in stratospheric modeling: Evaluation Number 11*, JPL Publication 94–26 (1994)).

$\lambda/\text{nm}$	292.0	296.3	300.8	305.4	310.1	315.0	320.0
$\epsilon/(\text{dm}^3 \text{ mol}^{-1} \text{ cm}^{-1})$	1512	865	477	257	135.9	69.5	34.5

Compute the integrated absorption coefficient of ozone over the wavelength range 290–320 nm. (*Hint*:  $\epsilon(\tilde{\nu})$  can be fitted to an exponential function quite well.)

**12A.7** In many cases it is possible to assume that an absorption band has a Gaussian lineshape (one proportional to  $e^{-x^2}$ ) centred on the band maximum. Assume such a line shape, and show that  $\mathcal{A} = \int \epsilon(\tilde{\nu}) d\tilde{\nu} \approx 1.0645 \epsilon_{\text{max}} \Delta\tilde{\nu}_{1/2}$ , where  $\Delta\tilde{\nu}_{1/2}$  is the width at half-height. The absorption spectrum of azoethane ( $\text{CH}_3\text{CH}_2\text{N}_2$ ) between  $24\,000 \text{ cm}^{-1}$  and  $34\,000 \text{ cm}^{-1}$  is shown in Fig. 12.2. First, estimate  $\mathcal{A}$  for the band by assuming that it is Gaussian. Then use mathematical software to fit a polynomial to the absorption band (or a Gaussian), and integrate the result analytically.

**12A.8†** Wachewsky et al. (*J. Phys. Chem.* **100**, 11559 (1996)) examined the UV absorption spectrum of  $\text{CH}_3\text{I}$ , a species of interest in connection with stratospheric ozone chemistry. They found the integrated absorption coefficient to be dependent on temperature and pressure to an extent inconsistent with internal structural changes in isolated  $\text{CH}_3\text{I}$  molecules; they explained the changes as due to dimerization of a substantial fraction

Figure 12.2 The absorption spectrum of azoethane.

† These problems were supplied by Charles Trapp and Carmen Giunta.

of the  $\text{CH}_3\text{I}$ , a process which would naturally be pressure and temperature dependent. (a) Compute the integrated absorption coefficient over a triangular lineshape in the range  $31\,250$  to  $34\,483\text{ cm}^{-1}$  and a maximal molar absorption coefficient of  $150\text{ dm}^3\text{ mol}^{-1}\text{ cm}^{-1}$  at  $31\,250\text{ cm}^{-1}$ . (b) Suppose 1.0 per cent of the  $\text{CH}_3\text{I}$  units in a sample at 2.4 Torr and 373 K exists as dimers. Compute the absorbance expected at  $31\,250\text{ cm}^{-1}$  in a sample cell of length 12.0 cm. (c) Suppose 18 per cent of the  $\text{CH}_3\text{I}$  units in a sample at 100 Torr and 373 K exists as dimers. Compute the absorbance expected at  $31\,250\text{ cm}^{-1}$  in a sample cell of length 12.0 cm; compute the molar absorption coefficient which would be inferred from this absorbance if dimerization was not considered.

**12A.9** The spectrum of a star is used to measure its *radial velocity* with respect to the Sun, the component of the star's velocity vector that is parallel to a vector connecting the star's centre to the centre of the Sun. The measurement relies on the Doppler effect. When a star emitting electromagnetic radiation of frequency  $\nu$  moves with a speed  $s$  relative to an observer, the observer detects radiation of frequency  $\nu_{\text{receding}} = \nu f$  or  $\nu_{\text{approaching}} = \nu/f$ , where  $f = \{(1 - s/c)/(1 + s/c)\}^{1/2}$  and  $c$  is the speed of light. (a) Three Fe I lines of the star HDE 271 182, which belongs to the Large Magellanic Cloud, occur at 438.882 nm, 441.000 nm, and 442.020 nm. The same lines occur at 438.392 nm, 440.510 nm, and 441.510 nm in the spectrum of an Earth-bound iron arc. Determine whether HDE 271 182 is receding from or approaching the Earth and estimate the star's radial speed with respect to the Earth. (b) What additional information would you need to calculate the radial velocity of HDE 271 182 with respect to the Sun?

**12A.10** In Problem 12A.9, we saw that Doppler shifts of atomic spectral lines are used to estimate the speed of recession or approach of a star. A spectral line of  $^{48}\text{Ti}^{8+}$  (of mass  $47.95m_{\text{u}}$ ) in a distant star was found to be shifted from

654.2 nm to 706.5 nm and to be broadened to 61.8 pm. What is the speed of recession and the surface temperature of the star?

**12A.11** The Gaussian shape of a Doppler-broadened spectral line reflects the Maxwell distribution of speeds in the sample at the temperature of the experiment. In a spectrometer that makes use of *phase-sensitive detection* the output signal is proportional to the first derivative of the signal intensity,  $dI/d\nu$ . Plot the resulting line shape for various temperatures. How is the separation of the peaks related to the temperature?

**12A.12** The collision frequency  $z$  of a molecule of mass  $m$  in a gas at a pressure  $p$  is  $z = 4\sigma(kT/\pi m)^{1/2}p/kT$ , where  $\sigma$  is the collision cross-section. Find an expression for the collision-limited lifetime of an excited state assuming that every collision is effective. Estimate the width of rotational transition in HCl ( $\sigma = 0.30\text{ nm}^2$ ) at 25 °C and 1.0 atm. To what value must the pressure of the gas be reduced in order to ensure that collision broadening is less important than Doppler broadening?

**12A.13** Refer to Fig. 12A.9, which depicts a Michelson interferometer. The mirror  $M_1$  moves in finite distance increments, so the path difference  $p$  is also incremented in finite steps. Explore the effect of increasing the step size on the shape of the interferogram for a monochromatic beam of wavenumber  $\tilde{\nu}$  and intensity  $I_0$ . That is, draw plots of  $I(p)/I_0$  against  $\tilde{\nu}p$ , each with a different number of data points spanning the same total distance path taken by the movable mirror  $M_1$ .

**12A.14** Using mathematical software, elaborate on the results of *Example 12A.2* by: (a) exploring the effect of varying the wavenumbers and intensities of the three components of the radiation on the shape of the interferogram; and (b) calculating the Fourier transforms of the functions you generated in part (a).

## TOPIC 12B Molecular rotation

### Discussion questions

**12B.1** Account for the rotational degeneracy of the various types of rigid rotor. Would their lack of rigidity affect your conclusions?

**12B.2** Describe the differences between an oblate and a prolate symmetric rotor and give several examples of each.

### Exercises

**12B.1(a)** Calculate the moment of inertia around the  $C_2$  axis (the bisector of the OOO angle) and the corresponding rotational constant of an  $^{16}\text{O}_3$  molecule (bond angle 117°; OO bond length 128 pm).

**12B.1(b)** Calculate the moment of inertia around the  $C_3$  axis (the threefold symmetry axis) and the corresponding rotational constant of a  $^{31}\text{P}^{1}\text{H}_3$  molecule (bond angle 93.5°; PH bond length 142 pm).

**12B.2(a)** Plot the expressions for the two moments of inertia of a  $C_{3v}$  symmetric top version of an  $\text{AB}_3$  molecule (Table 12B.1) with equal bond lengths but with the angle  $\theta$  increasing from 90° to the tetrahedral angle.

**12B.2(b)** Plot the expressions for the two moments of inertia of a  $C_{3v}$  symmetric top version of an  $\text{AB}_3$  molecule (Table 12B.1) with  $\theta$  equal to the tetrahedral angle but with one A–B bond varying. *Hint:* Write  $\rho = R'_{\text{AB}}/R_{\text{AB}}$ , and allow  $\rho$  to vary from 2 to 1.

**12B.3(a)** Classify the following rotors: (i)  $\text{O}_3$ , (ii)  $\text{CH}_3\text{CH}_3$ , (iii)  $\text{XeO}_4$ , (iv)  $\text{FeCp}_2$  (Cp denotes the cyclopentadienyl group,  $\text{C}_5\text{H}_5$ ).

**12B.3(b)** Classify the following rotors: (i)  $\text{CH}_2=\text{CH}_2$ , (ii)  $\text{SO}_3$ , (iii)  $\text{ClF}_3$ , (iv)  $\text{N}_2\text{O}$ .

**12B.4(a)** Determine the HC and CN bond lengths in HCN from the rotational constants  $B(^1\text{H}^{12}\text{C}^{14}\text{N}) = 44.316\text{ GHz}$  and  $B(^2\text{H}^{12}\text{C}^{14}\text{N}) = 36.208\text{ GHz}$ .

**12B.4(b)** Determine the CO and CS bond lengths in OCS from the rotational constants  $B(^{16}\text{O}^{12}\text{C}^{32}\text{S}) = 6081.5\text{ MHz}$ ,  $B(^{16}\text{O}^{12}\text{C}^{34}\text{S}) = 5932.8\text{ MHz}$ .

**12B.5(a)** Estimate the centrifugal distortion constant for  $^1\text{H}^{127}\text{I}$ , for which  $\tilde{B} = 6.511\text{ cm}^{-1}$  and  $\tilde{\nu} = 2308\text{ cm}^{-1}$ . By what factor would the constant change when  $^2\text{H}$  is substituted for  $^1\text{H}$ ?

**12B.5(b)** Estimate the centrifugal distortion constant for  $^{79}\text{Br}^{81}\text{Br}$ , for which  $\tilde{B} = 0.0809\text{ cm}^{-1}$  and  $\tilde{\nu} = 323.2\text{ cm}^{-1}$ . By what factor would the constant change when the  $^{79}\text{Br}$  is replaced by  $^{81}\text{Br}$ ?

### Problems

**12B.1** Show that the moment of inertia of a diatomic molecule composed of atoms of masses  $m_A$  and  $m_B$  and bond length  $R$  is equal to  $m_{\text{eff}}R^2$ , where  $m_{\text{eff}} = m_A m_B / (m_A + m_B)$ .

**12B.2** Confirm the expression given in Table 12B.1 for the moment of inertia of a linear ABC molecule. *Hint:* Begin by locating the centre of mass.

## TOPIC 12C Rotational spectroscopy

### Discussion questions

**12C.1** Describe the physical origins of the gross selection rules for microwave spectroscopy.

**12C.2** Describe the physical origins of the gross selection rules for rotational Raman spectroscopy.

### Exercises

**12C.1(a)** Which of the following molecules may show a pure rotational microwave absorption spectrum: (i) H<sub>2</sub>, (ii) HCl, (iii) CH<sub>4</sub>, (iv) CH<sub>3</sub>Cl, (v) CH<sub>2</sub>Cl<sub>2</sub>?

**12C.1(b)** Which of the following molecules may show a pure rotational microwave absorption spectrum: (i) H<sub>2</sub>O, (ii) H<sub>2</sub>O<sub>2</sub>, (iii) NH<sub>3</sub>, (iv) N<sub>2</sub>O?

**12C.2(a)** Calculate the frequency and wavenumber of the  $J=3 \leftarrow 2$  transition in the pure rotational spectrum of <sup>14</sup>N<sup>16</sup>O. The equilibrium bond length is 115 pm. Does the frequency increase or decrease if centrifugal distortion is considered?

**12C.2(b)** Calculate the frequency and wavenumber of the  $J=2 \leftarrow 1$  transition in the pure rotational spectrum of <sup>12</sup>C<sup>16</sup>O. The equilibrium bond length is 112.81 pm. Does the frequency increase or decrease if centrifugal distortion is considered?

**12C.3(a)** The wavenumber of the  $J=3 \leftarrow 2$  rotational transition of <sup>1</sup>H<sup>35</sup>Cl considered as a rigid rotor is 63.56 cm<sup>-1</sup>; what is the H–Cl bond length?

**12C.3(b)** The wavenumber of the  $J=1 \leftarrow 0$  rotational transition of <sup>1</sup>H<sup>81</sup>Br considered as a rigid rotor is 16.93 cm<sup>-1</sup>; what is the H–Br bond length?

**12C.4(a)** The spacing of lines in the microwave spectrum of <sup>27</sup>Al<sup>1</sup>H is 12.604 cm<sup>-1</sup>; calculate the moment of inertia and bond length of the molecule.

**12C.4(b)** The spacing of lines in the microwave spectrum of <sup>35</sup>Cl<sup>19</sup>F is 1.033 cm<sup>-1</sup>; calculate the moment of inertia and bond length of the molecule.

**12C.5(a)** What is the most highly populated rotational level of Cl<sub>2</sub> at (i) 25 °C, (ii) 100 °C? Take  $\tilde{B}=0.244$  cm<sup>-1</sup>.

### Problems

**12C.1** The rotational constant of NH<sub>3</sub> is 298 GHz. Compute the separation of the pure rotational spectrum lines as a frequency (in GHz), a wavenumber (in cm<sup>-1</sup>), and a wavelength (in mm), and show that the value of  $B$  is consistent with an N–H bond length of 101.4 pm and a bond angle of 106.78°.

**12C.2** Rotational absorption lines from <sup>1</sup>H<sup>35</sup>Cl gas were found at the following wavenumbers (R.L. Hausler and R.A. Oetjen, *J. Chem. Phys.* 21, 1340 (1953)): 83.32, 104.13, 124.73, 145.37, 165.89, 186.23, 206.60, 226.86 cm<sup>-1</sup>. Calculate the moment of inertia and the bond length of the molecule. Predict the positions of the corresponding lines in <sup>2</sup>H<sup>35</sup>Cl.

**12C.3** Is the bond length in HCl the same as that in DCl? The wavenumbers of the  $J=1 \leftarrow 0$  rotational transitions for H<sup>35</sup>Cl and <sup>2</sup>H<sup>35</sup>Cl are 20.8784 and 10.7840 cm<sup>-1</sup>, respectively. Accurate atomic masses are 1.007 825  $m_u$  and 2.0140  $m_u$  for <sup>1</sup>H and <sup>2</sup>H, respectively. The mass of <sup>35</sup>Cl is 34.96885  $m_u$ . Based on this information alone, can you conclude that the bond lengths are the same or different in the two molecules?

**12C.4** Thermodynamic considerations suggest that the copper monohalides CuX should exist mainly as polymers in the gas phase, and indeed it proved difficult to obtain the monomers in sufficient abundance to detect spectroscopically. This problem was overcome by flowing the halogen gas over copper heated to 1100 K (Manson et al. (*J. Chem. Phys.* 63, 2724 (1975))).

**12C.3** Describe the role of nuclear statistics in the occupation of energy levels in <sup>1</sup>H<sup>12</sup>C≡<sup>12</sup>C<sup>1</sup>H, <sup>1</sup>H<sup>13</sup>C≡<sup>13</sup>C<sup>1</sup>H, and <sup>2</sup>H<sup>12</sup>C≡<sup>12</sup>C<sup>2</sup>H. For nuclear spin data, see Table 14A.2.

**12C.4** Account for the existence of a rotational zero-point energy in molecular hydrogen.

**12C.5(b)** What is the most highly populated rotational level of Br<sub>2</sub> at (i) 25 °C, (ii) 100 °C? Take  $\tilde{B}=0.0809$  cm<sup>-1</sup>.

**12C.6(a)** Which of the following molecules may show a pure rotational Raman spectrum: (i) H<sub>2</sub>, (ii) HCl, (iii) CH<sub>4</sub>, (iv) CH<sub>3</sub>Cl?

**12C.6(b)** Which of the following molecules may show a pure rotational Raman spectrum: (i) CH<sub>2</sub>Cl<sub>2</sub>, (ii) CH<sub>3</sub>CH<sub>3</sub>, (iii) SF<sub>6</sub>, (iv) N<sub>2</sub>O?

**12C.7(a)** The wavenumber of the incident radiation in a Raman spectrometer is 20 487 cm<sup>-1</sup>. What is the wavenumber of the scattered Stokes radiation for the  $J=2 \leftarrow 0$  transition of <sup>14</sup>N<sub>2</sub>?

**12C.7(b)** The wavenumber of the incident radiation in a Raman spectrometer is 20 623 cm<sup>-1</sup>. What is the wavenumber of the scattered Stokes radiation for the  $J=4 \leftarrow 2$  transition of <sup>16</sup>O<sub>2</sub>?

**12C.8(a)** The rotational Raman spectrum of <sup>35</sup>Cl<sub>2</sub> shows a series of Stokes lines separated by 0.9752 cm<sup>-1</sup> and a similar series of anti-Stokes lines. Calculate the bond length of the molecule.

**12C.8(b)** The rotational Raman spectrum of <sup>19</sup>F<sub>2</sub> shows a series of Stokes lines separated by 3.5312 cm<sup>-1</sup> and a similar series of anti-Stokes lines. Calculate the bond length of the molecule.

**12C.9(a)** What is the ratio of weights of populations due to the effects of nuclear statistics for <sup>35</sup>Cl<sub>2</sub>?

**12C.9(b)** What is the ratio of weights of populations due to the effects of nuclear statistics for <sup>12</sup>C<sup>32</sup>S<sub>2</sub>? What effect would be observed when <sup>12</sup>C is replaced by <sup>13</sup>C? For nuclear spin data, see Table 14A.2.

For CuBr the  $J=13-14$ ,  $14-15$ , and  $15-16$  transitions occurred at 84 421.34, 90 449.25, and 96 476.72 MHz, respectively. Calculate the rotational constant and bond length of CuBr.

**12C.5** The microwave spectrum of <sup>16</sup>O<sup>12</sup>CS gave absorption lines (in GHz) as follows:

$J$	1	2	3	4
<sup>32</sup> S	24.325 92	36.48882	48.651 64	60.814 08
<sup>34</sup> S	23.732 33		47.462 40	

Using the expressions for moments of inertia in Table 12B.1 and assuming that the bond lengths are unchanged by substitution, calculate the CO and CS bond lengths in OCS.

**12C.6** Equation 12C.8b may be rearranged into

$$\tilde{\nu}(J+1 \leftarrow J) / \{2(J+1)\} = \tilde{B} - 2\tilde{D}_J(J+1)^2$$

which is the equation of a straight line when the left-hand side is plotted against  $(J+1)^2$ . The following wavenumbers of transitions (in cm<sup>-1</sup>) were observed for <sup>12</sup>C<sup>16</sup>O:

$J$ :	0	1	2	3	4
	3.845 033	7.689 919	11.534 510	15.378 662	19.222 223

Determine  $\tilde{B}$ ,  $\tilde{D}_J$ , and the equilibrium bond length of CO.

**12C.7\*** In a study of the rotational spectrum of the linear FeCO radical, Tanaka et al. (*J. Chem. Phys.* **106**, 6820 (1997)) report the following  $J+1 \leftarrow J$  transitions:

$J$	24	25	26	27	28	29
MHz	214 777.7	223 379.0	231 981.2	240 584.4	249 188.5	257 793.5

Evaluate the rotational constant of the molecule. Also, estimate the value of  $J$  for the most highly populated rotational energy level at 298 K and at 100 K.

**12C.8** The rotational terms of a symmetric top, allowing for centrifugal distortion, are commonly written

$$\tilde{F}(J, K) = \tilde{B}J(J+1) + (\tilde{A} - \tilde{B})K^2 - \tilde{D}_J J^2(J+1)^2 - \tilde{D}_{JK} J(J+1)K^2 - \tilde{D}_K K^4$$

(a) Develop an expression for the wavenumbers of the allowed rotational transitions. (b) The following transition frequencies (in gigahertz, GHz) were observed for  $\text{CH}_3\text{F}$ :

51.0718	102.1426	153.2103	153.2076
---------	----------	----------	----------

Determine the values of as many constants in the expression for the rotational terms as these values permit.

**12C.9** Develop an expression for the value of  $J$  corresponding to the most highly populated rotational energy level of a diatomic rotor at a temperature

$T$  remembering that the degeneracy of each level is  $2J+1$ . Evaluate the expression for ICl (for which  $\tilde{B}=0.1142 \text{ cm}^{-1}$ ) at  $25^\circ\text{C}$ . Repeat the problem for the most highly populated level of a spherical rotor, taking note of the fact that each level is  $(2J+1)^2$ -fold degenerate. Evaluate the expression for  $\text{CH}_4$  (for which  $\tilde{B}=5.24 \text{ cm}^{-1}$ ) at  $25^\circ\text{C}$ .

**12C.10** A. Dalgarno, in *Chemistry in the interstellar medium*, *Frontiers of Astrophysics*, ed. E.H. Avrett, Harvard University Press, Cambridge (1976), notes that although both CH and CN spectra show up strongly in the interstellar medium in the constellation Ophiuchus, the CN spectrum has become the standard for the determination of the temperature of the cosmic microwave background radiation. Demonstrate through a calculation why CH would not be as useful for this purpose as CN. The rotational constant  $\tilde{B}_0$  for CH is  $14.190 \text{ cm}^{-1}$ .

**12C.11** The space immediately surrounding stars, the *circumstellar space*, is significantly warmer because stars are very intense black-body emitters with temperatures of several thousand kelvin. Discuss how such factors as cloud temperature, particle density, and particle velocity may affect the rotational spectrum of CO in an interstellar cloud. What new features in the spectrum of CO can be observed in gas ejected from and still near a star with temperatures of about 1000 K, relative to gas in a cloud with temperature of about 10 K? Explain how these features may be used to distinguish between circumstellar and interstellar material on the basis of the rotational spectrum of CO.

**12C.12** Pure rotational Raman spectra of gaseous  $\text{C}_6\text{H}_6$  and  $\text{C}_6\text{D}_6$  yield the following rotational constants:  $B(\text{C}_6\text{H}_6)=0.18960 \text{ cm}^{-1}$ ,  $B(\text{C}_6\text{D}_6)=0.15681 \text{ cm}^{-1}$ . The moments of inertia of the molecules about any axis perpendicular to the  $\text{C}_6$  axis were calculated from these data as  $I(\text{C}_6\text{H}_6)=1.4759 \times 10^{-45} \text{ kg m}^2$ ,  $I(\text{C}_6\text{D}_6)=1.7845 \times 10^{-45} \text{ kg m}^2$ . Calculate the CC, CH, and CD bond lengths.

## TOPIC 12D Vibrational spectroscopy of diatomic molecules

### Discussion questions

**12D.1** Discuss the strengths and limitations of the parabolic and Morse functions as descriptors of the potential energy curve of a diatomic molecule.

**12D.2** Describe the effect of vibrational excitation on the rotational constant of a diatomic molecule.

**12D.3** How is the method of combination differences used in rotation-vibration spectroscopy to determine rotational constants?

**12D.4** In what ways may the rotational and vibrational spectra of molecules change as a result of isotopic substitution?

### Exercises

**12D.1(a)** An object of mass 100 g suspended from the end of a rubber band has a vibrational frequency of 2.0 Hz. Calculate the force constant of the rubber band.

**12D.1(b)** An object of mass 1.0 g suspended from the end of a spring has a vibrational frequency of 10.0 Hz. Calculate the force constant of the spring.

**12D.2(a)** Calculate the percentage difference in the fundamental vibrational wavenumbers of  $^{23}\text{Na}^{35}\text{Cl}$  and  $^{23}\text{Na}^{37}\text{Cl}$  on the assumption that their force constants are the same.

**12D.2(b)** Calculate the percentage difference in the fundamental vibrational wavenumbers of  $^1\text{H}^{35}\text{Cl}$  and  $^2\text{H}^{37}\text{Cl}$  on the assumption that their force constants are the same.

**12D.3(a)** The wavenumber of the fundamental vibrational transition of  $^{35}\text{Cl}_2$  is  $564.9 \text{ cm}^{-1}$ . Calculate the force constant of the bond.

**12D.3(b)** The wavenumber of the fundamental vibrational transition of  $^{79}\text{Br}^{81}\text{Br}$  is  $323.2 \text{ cm}^{-1}$ . Calculate the force constant of the bond.

**12D.4(a)** The hydrogen halides have the following fundamental vibrational wavenumbers:  $4141.3 \text{ cm}^{-1}$  (HF);  $2988.9 \text{ cm}^{-1}$  ( $\text{H}^{35}\text{Cl}$ );  $2649.7 \text{ cm}^{-1}$  ( $\text{H}^{81}\text{Br}$ );  $2309.5 \text{ cm}^{-1}$  ( $\text{H}^{127}\text{I}$ ). Calculate the force constants of the hydrogen-halogen bonds.

**12D.4(b)** From the data in Exercise 12D.4(a), predict the fundamental vibrational wavenumbers of the deuterium halides.

**12D.5(a)** Calculate the relative numbers of  $\text{Cl}_2$  molecules ( $\tilde{\nu}=559.7 \text{ cm}^{-1}$ ) in the ground and first excited vibrational states at (i) 298 K, (ii) 500 K.

**12D.5(b)** Calculate the relative numbers of  $\text{Br}_2$  molecules ( $\tilde{\nu}=321 \text{ cm}^{-1}$ ) in the second and first excited vibrational states at (i) 298 K, (ii) 800 K.

**12D.6(a)** For  $^{16}\text{O}_2$ ,  $\Delta\tilde{G}$  values for the transitions  $\nu=1 \leftarrow 0$ ,  $2 \leftarrow 0$ , and  $3 \leftarrow 0$  are, respectively, 1556.22, 3088.28, and  $4596.21 \text{ cm}^{-1}$ . Calculate  $\tilde{\nu}$  and  $x_c$ . Assume  $y_c$  to be zero.

**12D.6(b)** For  $^{14}\text{N}_2$ ,  $\Delta\tilde{G}$  values for the transitions  $\nu=1 \leftarrow 0$ ,  $2 \leftarrow 0$ , and  $3 \leftarrow 0$  are, respectively, 2329.91, 4631.20, and  $6903.69 \text{ cm}^{-1}$ . Calculate  $\tilde{\nu}$  and  $x_c$ . Assume  $y_c$  to be zero.

**12D.7(a)** The first five vibrational energy levels of HCl are at 1481.86, 4367.50, 7149.04, 9826.48, and 12 399.8 cm<sup>-1</sup>. Calculate the dissociation energy of the molecule in reciprocal centimetres and electronvolts.

## Problems

**12D.1** Derive an expression for the force constant of an oscillator that can be modelled by a Morse potential (eqn 12D.14).

**12D.2** Suppose a particle confined to a cavity in a microporous material has a potential energy of the form  $V(x) = V_0(e^{-a^2/x^2} - 1)$ . Sketch  $V(x)$ . What is the value of the force constant corresponding to this potential energy? Would the particle undergo simple harmonic motion? Sketch the likely form of the first two vibrational wavefunctions.

**12D.3** The vibrational levels of NaI lie at the wavenumbers 142.81, 427.31, 710.31, and 991.81 cm<sup>-1</sup>. Show that they fit the expression  $(\nu + \frac{1}{2})\tilde{\nu} - (\nu + \frac{1}{2})^2 x_e \tilde{\nu}$ , and deduce the force constant, zero-point energy, and dissociation energy of the molecule.

**12D.4** The HCl molecule is quite well described by the Morse potential with  $hc\tilde{D}_e = 5.33$  eV,  $\tilde{\nu} = 2989.7$  cm<sup>-1</sup>, and  $x_e \tilde{\nu} = 52.05$  cm<sup>-1</sup>. Assuming that the potential is unchanged on deuteration, predict the dissociation energies ( $hc\tilde{D}_0$ , in electronvolts) of (a) HCl, (b) DCl.

**12D.5** The Morse potential (eqn 12D.14) is very useful as a simple representation of the actual molecular potential energy. When RbH was studied, it was found that  $\tilde{\nu} = 936.8$  cm<sup>-1</sup> and  $x_e \tilde{\nu} = 14.15$  cm<sup>-1</sup>. Plot the potential energy curve from 50 pm to 800 pm around  $R_e = 236.7$  pm. Then go on to explore how the rotation of a molecule may weaken its bond by allowing for the kinetic energy of rotation of a molecule and plotting  $V^* = V + hc\tilde{B}J(J+1)$  with  $\tilde{B} = \hbar/4\pi c\mu R^2$ . Plot these curves on the same diagram for  $J = 40, 80,$  and  $100$ , and observe how the dissociation energy is affected by the rotation. (Taking  $\tilde{B} = 3.020$  cm<sup>-1</sup> at the equilibrium bond length will greatly simplify the calculation.)

**12D.6†** Luo et al. (*J. Chem. Phys.* **98**, 3564 (1993)) reported experimental observation of the He<sub>2</sub> complex, a species which had escaped detection for a long time. The fact that the observation required temperatures in the neighbourhood of 1 mK is consistent with computational studies which suggest that  $hc\tilde{D}_e$  for He<sub>2</sub> is about  $1.51 \times 10^{-23}$  J,  $hc\tilde{D}_0 \approx 2 \times 10^{-26}$  J, and  $R_e$  about 297 pm. (a) Estimate the fundamental vibrational wavenumber, force constant, moment of inertia, and rotational constant based on the harmonic oscillator and rigid-rotor approximations. (b) Such a weakly bound complex is hardly likely to be rigid. Estimate the vibrational wavenumber and anharmonicity constant based on the Morse potential energy.

**12D.7** Confirm that a Morse oscillator has a finite number of bound states. Determine the value of  $\nu_{\max}$  for the highest bound state.

**12D.8** Provided higher order terms are neglected, eqn 12D.17, for the vibrational wavenumbers of an anharmonic oscillator,  $\Delta\tilde{G}_{\nu+1/2} = \tilde{\nu} - 2(\nu+1)x_e \tilde{\nu} + \dots$ , is the equation of a straight line when the left-hand side is plotted against  $\nu+1$ . Use the following data on CO to determine the values of  $\tilde{\nu}$  and  $x_e \tilde{\nu}$  for CO:

$\nu$	0	1	2	3	4
$\Delta\tilde{G}_{\nu+1/2}/\text{cm}^{-1}$	2143.1	2116.1	2088.9	2061.3	2033.5

**12D.7(b)** The first five vibrational energy levels of HI are at 1144.83, 3374.90, 5525.51, 7596.66, and 9588.35 cm<sup>-1</sup>. Calculate the dissociation energy of the molecule in reciprocal centimetres and electronvolts.

**12D.9** The rotational constant for CO is 1.9314 cm<sup>-1</sup> and 1.6116 cm<sup>-1</sup> in the ground and first excited vibrational states, respectively. By how much does the internuclear distance change as a result of this transition?

**12D.10** The average spacing between the rotational lines of the P and R branches of <sup>12</sup>C<sub>2</sub>H<sub>2</sub> and <sup>12</sup>C<sub>2</sub>H<sub>2</sub> is 2.352 cm<sup>-1</sup> and 1.696 cm<sup>-1</sup>, respectively. Estimate the CC and CH bond lengths.

**12D.11** Absorptions in the  $\nu = 1 \leftarrow 0$  vibration-rotation spectrum of <sup>1</sup>H<sup>35</sup>Cl were observed at the following wavenumbers (in cm<sup>-1</sup>):

2998.05	2981.05	2963.35	2944.99	2925.92
2906.25	2865.14	2843.63	2821.59	2799.00

Assign the rotational quantum numbers and use the method of combination differences to determine the rotational constants of the two vibrational levels.

**12D.12** Suppose that the internuclear distance may be written  $R = R_e + x$  where  $R_e$  is the equilibrium bond length. Also suppose that the potential well is symmetrical and confines the oscillator to small displacements. Deduce expressions for  $1/\langle R^2 \rangle$ ,  $1/\langle R^2 \rangle$ , and  $\langle 1/R^2 \rangle$  to the lowest non-zero power of  $\langle x^2 \rangle/R_e^2$  and confirm that values are not the same.

**12D.13** Continue the development of Problem 12D.12 by using the virial expression to relate  $\langle x^2 \rangle$  to the vibrational quantum number. Does your result imply that the rotational constant increases or decreases as the oscillator becomes excited to higher quantum states. What would be the effect of anharmonicity?

**12D.14** The rotational constant for a diatomic molecule in the vibrational state with quantum number  $\nu$  typically fits the expression  $\tilde{B}_\nu = \tilde{B}_e - a(\nu + \frac{1}{2})$ . For the interhalogen molecule IF it is found that  $\tilde{B}_e = 0.27971$  cm<sup>-1</sup> and  $a = 0.187$  m<sup>-1</sup> (note the change of units). Calculate  $\tilde{B}_0$  and  $\tilde{B}_1$  and use these values to calculate the wavenumbers of the  $J' \rightarrow 3$  transitions of the P and R branches. You will need the following additional information:  $\tilde{\nu} = 610.258$  cm<sup>-1</sup> and  $x_e \tilde{\nu} = 3.141$  cm<sup>-1</sup>. Estimate the dissociation energy of the IF molecule.

**12D.15** At low resolution, the strongest absorption band in the infrared absorption spectrum of <sup>12</sup>C<sup>16</sup>O is centred at 2150 cm<sup>-1</sup>. Upon closer examination at higher resolution, this band is observed to be split into two sets of closely spaced peaks, one on each side of the centre of the spectrum at 2143.26 cm<sup>-1</sup>. The separation between the peaks immediately to the right and left of the centre is 7.655 cm<sup>-1</sup>. Make the harmonic oscillator and rigid rotor approximations and calculate from these data: (a) the vibrational wavenumber of a CO molecule, (b) its molar zero-point vibrational energy, (c) the force constant of the CO bond, (d) the rotational constant  $\tilde{B}$ , and (e) the bond length of CO.

**12D.16** The analysis of combination differences summarized in the text considered the R and P branches. Extend the analysis to the O and S branches of a Raman spectrum.

## TOPIC 12E Vibrational spectroscopy of polyatomic molecules

### Discussion questions

**12E.1** Describe the physical origins of the gross selection rules for infrared spectroscopy.

**12E.2** Describe the physical origins of the gross selection rules for vibrational Raman spectroscopy.

**12E.3** Suppose that you wish to characterize the normal modes of benzene in the gas phase. Why is it important to obtain both infrared absorption and Raman spectra of your sample?

## Exercises

**12E.1(a)** Which of the following molecules may show infrared absorption spectra: (i)  $\text{H}_2$ , (ii)  $\text{HCl}$ , (iii)  $\text{CO}_2$ , (iv)  $\text{H}_2\text{O}$ ?

**12E.1(b)** Which of the following molecules may show infrared absorption spectra: (i)  $\text{CH}_3\text{CH}_3$ , (ii)  $\text{CH}_4$ , (iii)  $\text{CH}_3\text{Cl}$ , (iv)  $\text{N}_2$ ?

**12E.2(a)** How many normal modes of vibration are there for the following molecules: (i)  $\text{H}_2\text{O}$ , (ii)  $\text{H}_2\text{O}_2$ , (iii)  $\text{C}_2\text{H}_4$ ?

**12E.2(b)** How many normal modes of vibration are there for the following molecules: (i)  $\text{C}_6\text{H}_6$ , (ii)  $\text{C}_6\text{H}_5\text{H}_3$ , (iii)  $\text{HC}\equiv\text{C}-\text{C}\equiv\text{C}-\text{H}$ ?

**12E.3(a)** How many vibrational modes are there for the molecule  $\text{NC}-(\text{C}\equiv\text{C}-\text{C}\equiv\text{C})_{10}\text{CN}$  detected in an interstellar cloud?

**12E.3(b)** How many vibrational modes are there for the molecule  $\text{NC}-(\text{C}\equiv\text{C}-\text{C}\equiv\text{C})_8\text{CN}$  detected in an interstellar cloud?

**12E.4(a)** Write an expression for the vibrational term for the ground vibrational state of  $\text{H}_2\text{O}$  in terms of the wavenumbers of the normal modes. Neglect anharmonicities, as in eqn 12E.1.

**12E.4(b)** Write an expression for the vibrational term for the ground vibrational state of  $\text{SO}_2$  in terms of the wavenumbers of the normal modes. Neglect anharmonicities, as in eqn 12E.1.

**12E.5(a)** Which of the three vibrations of an  $\text{AB}_2$  molecule are infrared or Raman active when it is (i) angular, (ii) linear?

**12E.5(b)** Which of the vibrations of an  $\text{AB}_3$  molecule are infrared or Raman active when it is (i) trigonal planar, (ii) trigonal pyramidal?

**12E.6(a)** Consider the vibrational mode that corresponds to the uniform expansion of the benzene ring. Is it (i) Raman, (ii) infrared active?

**12E.6(b)** Consider the vibrational mode that corresponds to the boat-like bending of a benzene ring. Is it (i) Raman, (ii) infrared active?

**12E.7(a)** The molecule  $\text{CH}_2\text{Cl}_2$  belongs to the point group  $\text{C}_{2v}$ . The displacements of the atoms span  $5A_1 + 2A_2 + 4B_1 + 4B_2$ . What are the symmetry species of the normal modes of vibration?

**12E.7(b)** A carbon disulfide molecule belongs to the point group  $D_{\infty h}$ . The nine displacements of the three atoms span  $A_{1g} + A_{1u} + A_{2g} + 2E_{1u} + E_{1g}$ . What are the symmetry species of the normal modes of vibration?

**12E.8(a)** Which of the normal modes of  $\text{CH}_2\text{Cl}_2$  (Exercise 12E.7(a)) are infrared active? Which are Raman active?

**12E.8(b)** Which of the normal modes of carbon disulfide (Exercise 12E.7(b)) are infrared active? Which are Raman active?

## Problems

**12E.1** Suppose that the out-of-plane distortion of a planar molecule are described by a potential energy  $V = V_0(1 - e^{-bh^4})$ , where  $h$  is the distance by which the central atom is displaced. Sketch this potential energy as a function of  $h$  (allow  $h$  to be both negative and positive). What could be said about (a) the force constant, (b) the vibrations? Sketch the form of the ground-state wavefunction.

**12E.2** Predict the shape of the nitronium ion,  $\text{NO}_2^+$ , from its Lewis structure and the VSEPR model. It has one Raman active vibrational mode at  $1400\text{ cm}^{-1}$ , two strong IR active modes at  $2360$  and  $540\text{ cm}^{-1}$ , and one weak IR mode at  $3735\text{ cm}^{-1}$ . Are these data consistent with the predicted shape of the molecule? Assign the vibrational wavenumbers to the modes from which they arise.

**12E.3** Consider the molecule  $\text{CH}_3\text{Cl}$ . (a) To what point group does the molecule belong? (b) How many normal modes of vibration does the molecule have? (c) What are the symmetry species of the normal modes of vibration for this molecule? (d) Which of the vibrational modes of this molecule are infrared active? (e) Which of the vibrational modes of this molecule are Raman active?

**12E.4** Suppose that three conformations are proposed for the nonlinear molecule  $\text{H}_2\text{O}_2$  (1, 2, and 3). The infrared absorption spectrum of gaseous  $\text{H}_2\text{O}_2$  has bands at  $870$ ,  $1370$ ,  $2869$ , and  $3417\text{ cm}^{-1}$ . The Raman spectrum of the same sample has bands at  $877$ ,  $1408$ ,  $1435$ , and  $3407\text{ cm}^{-1}$ . All bands correspond to fundamental vibrational wavenumbers and you may assume that: (a) the  $870$  and  $877\text{ cm}^{-1}$  bands arise from the same normal mode, and (b) the  $3417$  and  $3407\text{ cm}^{-1}$  bands arise from the same normal mode. (i) If  $\text{H}_2\text{O}_2$  were linear, how many normal modes of vibration would it have? (ii) Give the symmetry point group of each of the three proposed conformations of nonlinear  $\text{H}_2\text{O}_2$ . (iii) Determine which of the proposed conformations is inconsistent with the spectroscopic data. Explain your reasoning.

## Integrated activities

**12.1** In the group theoretical language developed in Topics 11A–11C, a spherical rotor is a molecule that belongs to a cubic or icosahedral point group, a symmetric rotor is a molecule with at least a threefold axis of symmetry, and an asymmetric rotor is a molecule without a threefold (or higher) axis. Linear molecules are linear rotors. Classify each of the following molecules as a spherical, symmetric, linear, or asymmetric rotor and justify your answers with group theoretical arguments: (a)  $\text{CH}_4$ , (b)  $\text{CH}_3\text{CN}$ , (c)  $\text{CO}_2$ , (d)  $\text{CH}_3\text{OH}$ , (e) benzene, (f) pyridine.

**12.2** Derive eqn 12B.17 ( $\tilde{D}_J = 4\tilde{B}^3/\tilde{\nu}^2$ ) for the centrifugal distortion constant  $D_J$  of a diatomic molecule of effective mass  $m_{\text{eff}}$ . Treat the bond as an elastic spring with force constant  $k_f$  and equilibrium length  $r_e$  that is subjected to a centrifugal distortion to a new length  $r_c$ . Begin the derivation by letting the particles experience a restoring force of magnitude  $k_f(r_c - r_e)$  that is countered perfectly by a centrifugal force  $m_{\text{eff}}\omega^2 r_c$ , where  $\omega$  is the angular velocity of the rotating molecule. Then introduce quantum mechanical effects by writing the angular momentum as  $\{J(J+1)\}^{1/2}\hbar$ . Finally, write an expression for the energy

of the rotating molecule, compare it with eqn 12B.16, and infer an expression for  $\tilde{D}_J$ .

**12.3\*** The  $\text{H}_3^+$  ion has recently been found in the interstellar medium and in the atmospheres of Jupiter, Saturn, and Uranus. The rotational energy levels of  $\text{H}_3^+$ , an oblate symmetric rotor, are given by eqn 12B.13, with  $\tilde{C}$  replacing  $\tilde{A}$ , when centrifugal distortion and other complications are ignored. Experimental values for vibrational-rotational constants are  $\tilde{\nu}(E')=2521.6\text{ cm}^{-1}$ ,  $\tilde{B}=43.55\text{ cm}^{-1}$ , and  $\tilde{C}=20.71\text{ cm}^{-1}$ . (a) Show that for a nonlinear planar molecule (such as  $\text{H}_3^+$ ) that  $I_C=2I_B$ . The rather large discrepancy with the experimental values is due to factors ignored in eqn 12B.13. (b) Calculate an approximate value of the H–H bond length in  $\text{H}_3^+$ . (c) The value of  $R_e$  obtained from the best quantum mechanical calculations by J.B. Anderson (*J. Chem. Phys.* **96**, 3702 (1991)) is 87.32 pm. Use this result to calculate the values of the rotational constants  $\tilde{B}$  and  $\tilde{C}$ . (d) Assuming that the geometry and force constants are the same in  $\text{D}_3^+$  and  $\text{H}_3^+$ , calculate the spectroscopic constants of  $\text{D}_3^+$ . The molecular ion  $\text{D}_3^+$  was first produced by Shy et al. (*Phys. Rev. Lett* **45**, 535 (1980)) who observed the  $\nu_2(E')$  band in the infrared.

**12.4** Use molecular modelling software and the computational method of your choice to construct molecular potential energy curves like the one shown in Fig. 12D.1. Consider the hydrogen halides (HF, HCl, HBr, and HI): (a) plot the calculated energy of each molecule against the bond length, and (b) identify the order of force constants of the H–Hal bonds.

**12.5** The computational methods discussed in Topic 10E can be used to simulate the vibrational spectrum of a molecule, and it is then possible to determine the correspondence between a vibrational frequency and the atomic displacements that give rise to a normal mode. (a) Using molecular modelling software and the computational method of your choice, calculate the fundamental vibrational wavenumbers and depict the vibrational normal modes of  $\text{SO}_2$  in the gas phase graphically. (b) The experimental values of the fundamental vibrational wavenumbers of  $\text{SO}_2$  in the gas phase are  $525\text{ cm}^{-1}$ ,  $1151\text{ cm}^{-1}$ , and  $1336\text{ cm}^{-1}$ . Compare the calculated and experimental values. Even if agreement is poor, is it possible to establish a correlation between an experimental value of the vibrational wavenumber with a specific vibrational normal mode?

**12.6** Use appropriate electronic structure software to perform calculations on  $\text{H}_2\text{O}$  and  $\text{CO}_2$  with basis sets of your or your instructor's choosing. (a) Compute ground-state energies, equilibrium geometries and vibrational frequencies for each molecule. (b) Compute the magnitude of the dipole moment of  $\text{H}_2\text{O}$ ; the experimental value is 1.854 D. (c) Compare computed values to experiment and suggest reasons for any discrepancies.

**12.7** The protein haemerythrin is responsible for binding and carrying  $\text{O}_2$  in some invertebrates. Each protein molecule has two  $\text{Fe}^{2+}$  ions that are in very close proximity and work together to bind one molecule of  $\text{O}_2$ . The  $\text{Fe}_2\text{O}_2$  group of oxygenated haemerythrin is coloured and has an electronic absorption band at 500 nm. The resonance Raman spectrum of oxygenated haemerythrin obtained with laser excitation at 500 nm has a band at  $844\text{ cm}^{-1}$  that has been attributed to the O–O stretching mode of bound  $^{16}\text{O}_2$ . (a) Why is resonance Raman spectroscopy and not infrared spectroscopy the method of choice for the study of the binding of  $\text{O}_2$  to haemerythrin? (b) Proof that the  $844\text{ cm}^{-1}$  band arises from a bound  $\text{O}_2$  species may be obtained by conducting experiments on samples of haemerythrin that have been mixed with  $^{18}\text{O}_2$ , instead of  $^{16}\text{O}_2$ . Predict the fundamental vibrational wavenumber of the  $^{18}\text{O}-^{18}\text{O}$  stretching mode in a sample of haemerythrin that has been treated with  $^{18}\text{O}_2$ . (c) The fundamental vibrational wavenumbers for the

O–O stretching modes of  $\text{O}_2$ ,  $\text{O}_2^-$  (superoxide anion), and  $\text{O}_2^{2-}$  (peroxide anion) are  $1555$ ,  $1107$ , and  $878\text{ cm}^{-1}$ , respectively. Explain this trend in terms of the electronic structures of  $\text{O}_2$ ,  $\text{O}_2^-$ , and  $\text{O}_2^{2-}$ . *Hint*: Review Topic 10C. What are the bond orders of  $\text{O}_2$ ,  $\text{O}_2^-$ , and  $\text{O}_2^{2-}$ ? (d) Based on the data given above, which of the following species best describes the  $\text{Fe}_2\text{O}_2$  group of haemerythrin:  $\text{Fe}_2^{2+}\text{O}_2$ ,  $\text{Fe}^{2+}\text{Fe}^{3+}\text{O}_2^-$ , or  $\text{Fe}_2^{3+}\text{O}_2^{2-}$ ? Explain your reasoning. (e) The resonance Raman spectrum of haemerythrin mixed with  $^{16}\text{O}^{18}\text{O}$  has two bands that can be attributed to the O–O stretching mode of bound oxygen. Discuss how this observation may be used to exclude one or more of the four proposed schemes (4–7) for binding of  $\text{O}_2$  to the  $\text{Fe}_2$  site of haemerythrin.

**12.8** The moments of inertia of the linear mercury(II) halides are very large, so the O and S branches of their vibrational Raman spectra show little rotational structure. Nevertheless, the peaks of both branches can be identified and have been used to measure the rotational constants of the molecules (R.J.H. Clark and D.M. Rippon, *J. Chem. Soc. Faraday Soc. II*, **69**, 1496 (1973)). Show, from a knowledge of the value of  $J$  corresponding to the intensity maximum, that the separation of the peaks of the O and S branches is given by the Placzek–Teller relation  $\delta=(32\tilde{B}kT/hc)^{1/2}$ . The following widths were obtained at the temperatures stated:

	$\text{HgCl}_2$	$\text{HgBr}_2$	$\text{HgI}_2$
$\theta/^\circ\text{C}$	282	292	292
$\delta/\text{cm}^{-1}$	23.8	15.2	11.4

Calculate the bond lengths in the three molecules.

**12.9\*** A mixture of carbon dioxide (2.1 per cent) and helium, at 1.00 bar and 298 K in a gas cell of length 10 cm has an infrared absorption band centred at  $2349\text{ cm}^{-1}$  with absorbances,  $A(\tilde{\nu})$ , described by:

$$A(\tilde{\nu}) = \frac{a_1}{1 + a_2(\tilde{\nu} - a_3)^2} + \frac{a_4}{1 + a_5(\tilde{\nu} - a_6)^2}$$

where the coefficients are  $a_1=0.932$ ,  $a_2=0.005050\text{ cm}^2$ ,  $a_3=2333\text{ cm}^{-1}$ ,  $a_4=1.504$ ,  $a_5=0.01521\text{ cm}^2$ ,  $a_6=2362\text{ cm}^{-1}$ . (a) Draw graphs of  $A(\tilde{\nu})$  and  $\varepsilon(\tilde{\nu})$ . What is the origin of both the band and the band width? What are the allowed and forbidden transitions of this band? (b) Calculate the transition wavenumbers and absorbances of the band with a simple harmonic oscillator–rigid rotor model and compare the result with the experimental spectra. The CO bond length is 116.2 pm. (c) Within what height,  $h$ , is basically all the infrared emission from the Earth in this band absorbed by atmospheric carbon dioxide? The mole fraction of  $\text{CO}_2$  in the atmosphere is  $3.3 \times 10^{-4}$  and  $T/K=288-0.0065(h/m)$  below 10 km. Draw a surface plot of the atmospheric transmittance of the band as a function of both height and wavenumber.

# CHAPTER 13

## Electronic transitions

Unlike for rotational and vibrational modes, simple analytical expressions for the electronic energy levels of molecules cannot be given. Therefore, this chapter concentrates on the qualitative features of electronic transitions.

### 13A Electronic spectra

A common theme throughout the chapter is that electronic transitions occur within a stationary nuclear framework. This Topic begins with a discussion of the electronic spectra of diatomic molecules, and we see that in the gas phase it is possible to observe simultaneous vibrational and rotational transitions that accompany the electronic transition. Then we describe features of the electronic spectra of polyatomic molecules.

### 13B Decay of excited states

We begin this Topic with an account of spontaneous emission by molecules, including the phenomena of 'fluorescence' and 'phosphorescence'. Then we see how non-radiative decay of excited states can result in transfer of energy as heat to the surroundings or can result in molecular dissociation.

### 13C Lasers

A specially important example of stimulated radiative decay is that responsible for the action of lasers, and in this Topic we see how this stimulated emission may be achieved and employed.

### What is the impact of this material?

Absorption and emission spectroscopy is also useful to biochemists. In *Impact* I13.1 we describe how the absorption of visible radiation by special molecules in the eye initiates the process of vision. In *Impact* I13.2 we see how fluorescence techniques can be used to make very small samples visible, ranging from specialized compartments inside biological cells to single molecules.

## ► What do you need to know already?

You need to be familiar with the general features of spectroscopy (Topic 12A), the quantum mechanical origins of selection rules (Topics 9C, 12C, and 12D), and vibration–rotation spectra (Topic 12D); it would be helpful to be aware of atomic term symbols (Topic 9C). One example uses the method of combination differences described in Topic 12D.

Consider a molecule in the lowest vibrational state of its ground electronic state. The nuclei are (in a classical sense) at their equilibrium locations and experience no net force from the electrons and other nuclei in the molecule. The electron distribution is changed when an electronic transition occurs and the nuclei become subjected to different forces. In response, they start to vibrate around their new equilibrium locations. The resulting vibrational transitions that accompany the electronic transition give rise to the **vibrational structure** of the electronic transition. This structure can be resolved for gaseous samples, but in a liquid or solid the lines usually merge together and result in a broad, almost featureless band (Fig. 13A.1).

The energies needed to change the electron distributions of molecules are of the order of several electronvolts (1 eV is equivalent to about 8000 cm<sup>-1</sup> or 100 kJ mol<sup>-1</sup>). Consequently, the photons emitted or absorbed when such changes occur

## ► Why do you need to know this material?

Many of the colours of the objects in the world around us stem from transitions in which an electron is promoted from one orbital of a molecule or ion into another. In some cases the relocation of an electron may be so extensive that it results in the breaking of a bond and the initiation of a chemical reaction. To understand these physical and chemical phenomena, you need to explore the origins of electronic transitions in molecules.

## ► What is the key idea?

Electronic transitions occur within a stationary nuclear framework.

Figure 13A.1 The absorption spectrum of chlorophyll in the visible region. Note that it absorbs in the red and blue regions, and that green light is not absorbed.

**Table 13A.1\*** Colour, wavelength, frequency, and energy of light

Colour	$\lambda/\text{nm}$	$\nu/(10^{14} \text{ Hz})$	$E/(\text{kJ mol}^{-1})$
Infrared	>1000	<3.0	<120
Red	700	4.3	170

lie in the visible and ultraviolet regions of the spectrum (Table 13A.1). What follows is a discussion of absorption processes. Emission processes are discussed in Topic 13B.

## 13A.1 Diatomic molecules

Topic 9C explains how the states of atoms are expressed by using term symbols and how the selection rules for electronic transitions can be expressed in terms of these term symbols. Much the same is true of diatomic molecules, one principal difference being the replacement of full spherical symmetry of atoms by the cylindrical symmetry defined by the axis of the molecule. The second principal difference is the fact that a diatomic molecule can vibrate and rotate.

### (a) Term symbols

The term symbols of linear molecules (the analogues of the symbols  $^2\text{P}$ , etc. for atoms) are constructed in a similar way to those for atoms, with the Roman uppercase letter (the P in this instance for atoms) representing the total orbital angular momentum of the electrons around the nucleus. In a linear molecule, and specifically a diatomic molecule, a Greek uppercase letter represents the total orbital angular momentum of the electrons around the internuclear axis. If this component of orbital angular momentum is  $\Lambda\hbar$  with  $\Lambda=0, \pm 1, \pm 2, \dots$ , we use the following designation:

$ \Lambda $	0	1	2	...
	$\Sigma$	$\Pi$	$\Delta$	...

These labels are the analogues of S, P, D, ... for atoms for states with  $L=0, 1, 2, \dots$ . To decide on the value of  $L$  for atoms we had to use the Clebsch–Gordan series (Topic 9C) to couple the individual angular momenta. The procedure to determine  $\Lambda$  is much simpler in a diatomic molecule because we simply add the values of the individual components of each electron,  $\lambda\hbar$ :

$$\Lambda = \lambda_1 + \lambda_2 + \dots \quad (13A.1)$$

We note the following:

- A single electron in a  $\sigma$  orbital has  $\lambda=0$ .

The orbital is cylindrically symmetrical and has no angular nodes when viewed along the internuclear axis. Therefore, if that is the only type of electron present,  $\Lambda=0$ . The term symbol for the ground state of  $\text{H}_2^+$  with electron configuration  $1\sigma_g^2$  is therefore  $\Sigma$ .

- A  $\pi$  electron in a diatomic molecule has one unit of orbital angular momentum about the internuclear axis ( $\lambda=\pm 1$ ).

If it is the only electron outside a closed shell, it gives rise to a  $\Pi$  term. If there are two  $\pi$  electrons (as in the ground state of  $\text{O}_2$ , with configuration  $\dots 1\pi_g^2$ ), there are two possible outcomes. If the electrons are travelling in opposite directions, then  $\lambda_1=+1$  and  $\lambda_2=-1$  (or vice versa) and  $\Lambda=0$ , corresponding to a  $\Sigma$  term. Alternatively, the electrons might occupy the same  $\pi$  orbital and  $\lambda_1=\lambda_2=+1$  (or  $-1$ ), and  $\Lambda=\pm 2$ , corresponding to a  $\Delta$  term. In  $\text{O}_2$  it is energetically favourable for the electrons to occupy different orbitals, so the ground term is  $\Sigma$ .

As in atoms, we use a left superscript with the value of  $2S+1$  to denote the multiplicity of the term, where  $S$  is the total spin quantum number of the electrons.

#### Brief illustration 13A.1 The multiplicity of a term

It follows from the procedure for assigning multiplicity of terms that for  $S=s=\frac{1}{2}$  because there is only one electron, and the term symbol is  $^2\Sigma$ , a doublet term. In  $\text{O}_2$ , because in the ground state the two  $\pi$  electrons occupy different orbitals (as we saw above), they may have either parallel or antiparallel spins; the lower energy is obtained (as in atoms) if the spins are parallel, so  $S=1$  and the ground state is  $^3\Sigma$ .

**Self-test 13A.1** What is the value of  $S$  and the term symbol for the ground-state of  $\text{H}_2$ ?

Answer:  $S=0, ^1\Sigma$

The overall parity of the state (its symmetry under inversion through the centre of the molecule, if it has one) is added as a right subscript to the term symbol. For  $\text{H}_2^+$  in its ground state, the parity of the only occupied orbital ( $1\sigma_g$ ) is g, so the term itself is also g, and in full dress is  $^2\Sigma_g$ . If there are several electrons, the overall parity is calculated by noting the parity of each occupied orbital and using

$$g \times g = g \quad u \times u = g \quad u \times g = u \quad (13A.2)$$

These rules are generated by interpreting g as +1 and u as -1. As a consequence:

- The term symbol for the ground state of any closed-shell homonuclear diatomic molecule is  $^1\Sigma_g$  because the spin is

zero (a singlet term in which all electrons paired), there is no orbital angular momentum from a closed shell, and the overall parity is *g*.

- If the molecule is heteronuclear, parity is irrelevant and the ground state of a closed-shell species, such as CO, is  $^1\Sigma$ .

#### Brief illustration 13A.2 Term symbol of $O_2$ 1

The parity of the ground state of  $O_2$  is  $g \times g = g$ , so it is denoted  $^3\Sigma_g^-$ . An excited configuration of  $O_2$  is  $\dots 1\pi_g^2$ , with both  $\pi$  electrons in the same orbital. As we have seen,  $|A|=2$ , represented by  $\Delta$ . The two electrons must be paired if they occupy the same orbital, so  $S=0$ . The overall parity is  $g \times g = g$ . Therefore, the term symbol is  $^1\Delta_g$ .

**Self-test 13A.2** The term symbol for one of the lowest excited states of  $H_2$  is  $^3\Pi_u$ . To which excited-state configuration does this term symbol correspond?

Answer:  $1\sigma_g^1 1\pi_u^1$

There is an additional symmetry operation that distinguishes different types of  $\Sigma$  term: reflection in a plane containing the internuclear axis. A + right superscript on  $\Sigma$  is used to denote a wavefunction that does not change sign under this reflection and a – sign is used if the wavefunction changes sign (Fig. 13A.2).

#### Brief illustration 13A.3 Term symbol of $O_2$ 2

If we think of  $O_2$  in its ground state as having one electron in  $1\pi_{g,x}$  which changes sign under reflection in the  $yz$ -plane, and the other electron in  $1\pi_{g,y}$ , which does not change sign under reflection in the same plane, then the overall reflection symmetry is (closed shell)  $\times (+) \times (-) = (-)$ , and the full term symbol of the ground electronic state of  $O_2$  is  $^3\Sigma_g^-$ . Alternatively, if we consider the configuration to be  $1\pi_+^1 1\pi_-^1$ , with  $\pi_{\pm} \propto \pi_{g,x} \pm i\pi_{g,y}$  being two states of definite but opposite orbital angular momentum around the axis, then for the triplet state we must take the linear combination  $\Psi(1,2) \propto \pi_+(1)\pi_-(2) - \pi_+(2)\pi_-(1)$ . Because under reflection in the  $yz$ -plane  $\pi_+ \rightarrow -\pi_-$  and  $\pi_- \rightarrow -\pi_+$ ,  $\Psi(1,2) \rightarrow \pi_-(1)\pi_+(2) - \pi_-(2)\pi_+(1) = -\Psi(1,2)$ , and the state is also  $(-)$ .

**Self-test 13A.3** What is the full term symbol of the ground electronic state of  $Li_2^+$ ?

Answer:  $^2\Sigma_g^+$

As for atoms, sometimes it is necessary to specify the total electronic angular momentum. In atoms we use the quantum number  $J$ , which appears as a right subscript in the term

Figure 13A.2 The + or – on a term symbol refers to the overall symmetry of an electronic wavefunction under reflection in a plane containing the two nuclei.

Figure 13A.3 The coupling of spin and orbital angular momenta in a linear molecule: only the components along the internuclear axis are conserved.

symbol, as in  $^2P_{1/2}$ , with different values of  $J$  corresponding to different levels of a term. In a linear molecule, only the electronic angular momentum about the internuclear axis is well defined, and has the value  $\Omega\hbar$ . For light molecules, where the spin–orbit coupling is weak,  $\Omega$  is obtained by adding together the components of orbital angular momentum around the axis (the value of  $\Lambda$ ) and the component of the electron spin on that axis (Fig. 13A.3). The latter is denoted  $\Sigma$ , where  $\Sigma = S, S-1, S-2, \dots, -S$ . (It is important to distinguish between the upright term symbol  $\Sigma$  and the sloping quantum number  $\Sigma$ .) Then

$$\Omega = \Lambda + \Sigma \quad (13A.3)$$

The value of  $|\Omega|$  may then be attached to the term symbol as a right subscript (just like  $J$  is used in atoms) to denote the different levels. These levels differ in energy, as in atoms, as a result of spin–orbit coupling.

#### Brief illustration 13A.4 The term symbol of NO

The ground-state configuration of NO is  $\dots \pi_g^1$ , so it is a  $^2\Pi$  term with  $\Lambda = \pm 1$  and  $\Sigma = \pm \frac{1}{2}$ . Therefore, there are two levels of the term, one with  $\Omega = \pm \frac{1}{2}$  and the other with  $\pm \frac{3}{2}$ , denoted  $^2\Pi_{1/2}$  and  $^2\Pi_{3/2}$ , respectively. Each level is doubly degenerate (corresponding to the opposite signs of  $\Omega$ ). In NO,  $^2\Pi_{1/2}$  lies slightly lower than  $^2\Pi_{3/2}$ .

**Self-test 13A.4** What are the levels of the term for the ground electronic state of  $O_2^-$ ?

Answer:  $^2\Pi_{1/2}, ^2\Pi_{3/2}$

## (b) Selection rules

A number of selection rules govern which transitions can be observed in the electronic spectrum of a molecule. The selection rules concerned with changes in angular momentum are

$$\begin{array}{l} \Delta L = 0, \pm 1 \quad \Delta S = 0 \\ \Delta \Sigma = 0 \quad \Delta \Omega = 0, \pm 1 \end{array} \quad \begin{array}{l} \text{Linear} \\ \text{molecules} \end{array} \quad \begin{array}{l} \text{Selection rules} \\ \text{for electronic} \\ \text{spectra} \end{array} \quad (13A.4)$$

As in atoms (Topic 9C), the origins of these rules are conservation of angular momentum during a transition and the fact that a photon has a spin of 1.

There are two selection rules concerned with changes in symmetry. First, as we show in the following *Justification*,

For  $\Sigma$  terms, only  $\Sigma^+ \leftrightarrow \Sigma^+$  and  $\Sigma^- \leftrightarrow \Sigma^-$  are allowed.

Second, the **Laporte selection rule** for centrosymmetric molecules (those with a centre of inversion) states that *the only allowed transitions are transitions that are accompanied by a change of parity*. That is,

For centrosymmetric molecules, only  $u \rightarrow g$  and  $g \rightarrow u$  are allowed

Laporte selection rule

**Justification 13A.1** Symmetry-based selection rules

The last two selection rules result from the fact that the electric-dipole transition moment introduced in Topic 9C,  $\mu_{fi} = \int \psi_f^* \hat{\mu} \psi_i d\tau$  vanishes unless the integrand is invariant under all symmetry operations of the molecule.

The  $z$ -component of the electric dipole moment operator is the component of  $\hat{\mu}$  responsible for  $\Sigma \leftrightarrow \Sigma$  transitions (the other components have  $\Pi$  symmetry and cannot make a contribution). The  $z$ -component of  $\hat{\mu}$  has (+) symmetry with respect to reflection in a plane containing the internuclear axis. Therefore, for a (+)  $\leftrightarrow$  (-) transition, the overall symmetry of the transition dipole moment is (+)  $\times$  (+)  $\times$  (-) = (-), so it must be zero and hence  $\Sigma^+ \leftrightarrow \Sigma^-$  transitions are not allowed. The integrals for  $\Sigma^+ \leftrightarrow \Sigma^+$  and  $\Sigma^- \leftrightarrow \Sigma^-$  transform as (+)  $\times$  (+)  $\times$  (+) = (+) and (-)  $\times$  (+)  $\times$  (-) = (+), respectively, and so both transitions are allowed.

The three components of the dipole moment operator transform like  $x$ ,  $y$ , and  $z$ , and in a centrosymmetric molecule are all  $u$ . Therefore, for a  $g \rightarrow g$  transition, the overall parity of the transition dipole moment is  $g \times u \times g = u$ , so it must be zero. Likewise, for a  $u \rightarrow u$  transition, the overall parity is  $u \times u \times u = u$ , so the transition dipole moment must also vanish. Hence, transitions without a change of parity are forbidden. For a  $g \leftrightarrow u$  transition the integral transforms as  $g \times u \times u = g$ , and is allowed.

A forbidden  $g \rightarrow g$  transition can become allowed if the centre of symmetry is eliminated by an asymmetrical vibration,

**Figure 13A.4** A  $d-d$  transition is parity-forbidden because it corresponds to a  $g-g$  transition. However, a vibration of the molecule can destroy the inversion symmetry of the molecule and the  $g,u$  classification no longer applies. The removal of the centre of symmetry gives rise to a vibronically allowed transition.

such as the one shown in Fig. 13A.4. When the centre of symmetry is lost,  $g \rightarrow g$  and  $u \rightarrow u$  transitions are no longer parity-forbidden and become weakly allowed. A transition that derives its intensity from an asymmetrical vibration of a molecule is called a **vibronic transition**.

**Brief illustration 13A.5** Allowed transitions of  $O_2$ 

If we were presented with the following possible transitions in the electronic spectrum of  $O_2$ , namely  ${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^-$ ,  ${}^3\Sigma_g^- \leftrightarrow {}^1\Delta_g$ ,  ${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^+$ , we could decide which are allowed by constructing the following table and referring to the rules. Forbidden values are in red.

	$\Delta S$	$\Delta L$	$\Sigma^\pm \leftrightarrow \Sigma^\pm$	Change of parity	
${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^-$	0	0	$\Sigma^- \leftrightarrow \Sigma^-$	$g \leftarrow u$	Allowed
${}^3\Sigma_g^- \leftrightarrow {}^1\Delta_g$	+1	-2	Not applicable	$g \leftarrow g$	Forbidden
${}^3\Sigma_g^- \leftrightarrow {}^3\Sigma_u^+$	0	0	$\Sigma^- \leftrightarrow \Sigma^+$	$g \leftarrow u$	Forbidden

**Self-test 13A.5** Which of the following electronic transitions are allowed in  $O_2$ :  ${}^3\Sigma_g^- \leftrightarrow {}^1\Sigma_g^+$  and  ${}^3\Sigma_g^- \leftrightarrow {}^3\Delta_u$ ?

Answer: None

The large number of photons in an incident beam generated by a laser gives rise to a qualitatively different branch of spectroscopy, for the photon density is so great that more than one photon may be absorbed by a single molecule and give rise to **multiphoton processes**. One application of multiphoton processes is that states inaccessible by conventional one-photon spectroscopy become observable because the overall transition occurs with no change of parity. For example, in one-photon spectroscopy, only  $g \leftrightarrow u$  transitions are observable; in two-photon spectroscopy, however, the overall outcome of absorbing two photons is a  $g \leftarrow g$  or a  $u \leftarrow u$  transition.

### (c) Vibrational structure

To account for the vibrational structure in electronic spectra of molecules (Fig. 13A.5), we apply the Franck–Condon principle:

Because the nuclei are so much more massive than the electrons, an electronic transition takes place very much faster than the nuclei can respond.

Franck–Condon principle

As a result of the transition, electron density is rapidly built up in new regions of the molecule and removed from others. In classical terms, the initially stationary nuclei suddenly experience a new force field, to which they respond by beginning to vibrate and (in classical terms) swing backwards and forwards from their original separation (which was maintained during the rapid electronic excitation). The stationary equilibrium separation of the nuclei in the initial electronic state therefore becomes a stationary turning point in the final electronic state (Fig. 13A.6). We can imagine the transition as taking place up the vertical line in Fig. 13A.6. This interpretation is the origin of the expression **vertical transition**, which denotes an electronic transition that occurs without change of nuclear geometry and in classical terms, the nuclei remain stationary.

The vibrational structure of the spectrum depends on the relative horizontal position of the two potential energy curves, and a long **vibrational progression**, a lot of vibrational structure, is stimulated if the upper potential energy curve is appreciably displaced horizontally from the lower. The upper curve is usually displaced to greater equilibrium bond lengths because electronically excited states usually have more antibonding character than electronic ground states. The separation of the vibrational lines depends on the vibrational energies of the *upper* electronic state.

**Figure 13A.5** The electronic spectra of some molecules show significant vibrational structure. Shown here is the ultraviolet spectrum of gaseous  $\text{SO}_2$  at 298 K. As explained in the text, the sharp lines in this spectrum are due to transitions from a lower electronic state to different vibrational levels of a higher electronic state. Vibrational structure due to transitions to two different excited electronic states is apparent.

**Figure 13A.6** According to the Franck–Condon principle, the most intense vibronic transition is from the ground vibrational state to the vibrational state lying vertically above it. As a result of the vertical transition, the nuclei suddenly experience a new force field, to which they respond through their vibrational motion. The equilibrium separation of the nuclei in the initial electronic state therefore becomes a stationary turning point in the final electronic state. Transitions to other vibrational levels also occur, but with lower intensity.

The quantum mechanical version of the Franck–Condon principle refines this picture. Instead of saying that the nuclei stay at the same locations and are stationary during the transition, we say that *they retain their initial dynamic state*. In quantum mechanics, the dynamical state is expressed by the wavefunction, so an equivalent statement is that the nuclear wavefunction does not change during the electronic transition. Initially the molecule is in the lowest vibrational state of its ground electronic state with a bell-shaped wavefunction centred on the equilibrium bond length (Fig. 13A.7). To find the nuclear state to which the transition takes place, we look for the vibrational wavefunction that most closely resembles this initial

**Figure 13A.7** In the quantum mechanical version of the Franck–Condon principle, the molecule undergoes a transition to the upper vibrational state that most closely resembles the vibrational wavefunction of the vibrational ground state of the lower electronic state. The two wavefunctions shown here have the greatest overlap integral of all the vibrational states of the upper electronic state and hence are most closely similar.

wavefunction, for that corresponds to the nuclear dynamical state that is least changed in the transition. Intuitively, we can see that the final wavefunction is the one with a large peak close to the position of the initial bell-shaped function. As explained in Topic 8B, provided the vibrational quantum number is not zero, the biggest peaks of vibrational wavefunctions occur close to the edges of the confining potential, so we can expect the transition to occur to those vibrational states, in accord with the classical description. However, several vibrational states have their major peaks in similar positions, so we should expect transitions to occur to a range of vibrational states, as is observed.

The quantitative form of the Franck–Condon principle and the justification of the preceding description is derived from the expression for the transition dipole moment (as in *Justification 13A.1*). The electric dipole moment operator is a sum over all nuclei and electrons in the molecule:

$$\hat{\boldsymbol{\mu}} = -e \sum_i \mathbf{r}_i + e \sum_I Z_I \mathbf{R}_I \quad (13A.5)$$

where the vectors are the distances from the centre of charge of the molecule. The intensity of the transition is proportional to the square modulus,  $|\boldsymbol{\mu}_{fi}|^2$ , of the magnitude of the transition dipole moment, and we show in the following *Justification* that this intensity is proportional to the square modulus of the overlap integral,  $S(\nu_f, \nu_i)$ , between the vibrational states of the initial and final electronic states. This overlap integral is a measure of the match between the vibrational wavefunctions in the upper and lower electronic states:  $S=1$  for a perfect match and  $S=0$  when there is no similarity.

### Justification 13A.2 The Franck–Condon approximation

The overall state of the molecule consists of an electronic part, labelled with  $\epsilon$ , and a vibrational part, labelled with  $\nu$ . Therefore, within the Born–Oppenheimer approximation, the transition dipole moment factorizes as follows:

$$\begin{aligned} \boldsymbol{\mu}_{fi} &= \int \psi_{\epsilon,f}^* \psi_{\nu,f}^* \left\{ -e \sum_i \mathbf{r}_i + e \sum_I Z_I \mathbf{R}_I \right\} \psi_{\epsilon,i} \psi_{\nu,i} d\boldsymbol{\tau} \\ &= -e \sum_i \int \psi_{\epsilon,f}^* \mathbf{r}_i \psi_{\epsilon,i} d\boldsymbol{\tau}_e \int \psi_{\nu,f}^* \psi_{\nu,i} d\boldsymbol{\tau}_n \\ &\quad + e \sum_I Z_I \overbrace{\int \psi_{\epsilon,f}^* \psi_{\epsilon,i} d\boldsymbol{\tau}_e}^0 \int \psi_{\nu,f}^* \mathbf{R}_I \psi_{\nu,i} d\boldsymbol{\tau}_n \end{aligned}$$

The second term on the right of the second row (including the term in blue) is zero, because two different electronic states are orthogonal. Therefore,

$$\boldsymbol{\mu}_{fi} = -e \sum_i \overbrace{\int \psi_{\epsilon,f}^* \mathbf{r}_i \psi_{\epsilon,i} d\boldsymbol{\tau}_e}^{\boldsymbol{\mu}_{\epsilon,fi}} \overbrace{\int \psi_{\nu,f}^* \psi_{\nu,i} d\boldsymbol{\tau}_n}^{S(\nu_f, \nu_i)} = \boldsymbol{\mu}_{\epsilon,fi} S(\nu_f, \nu_i)$$

The quantity  $\boldsymbol{\mu}_{\epsilon,fi}$  is the electric-dipole transition moment arising from the redistribution of electrons (and a measure of the ‘kick’ this redistribution gives to the electromagnetic field, and vice versa for absorption). The factor  $S(\nu_f, \nu_i)$ , is the overlap integral between the vibrational state with quantum number  $\nu_i$  in the initial electronic state of the molecule, and the vibrational state with quantum number  $\nu_f$  in the final electronic state of the molecule.

Because the transition intensity is proportional to the square of the magnitude of the transition dipole moment, the intensity of an absorption is proportional to  $|S(\nu_f, \nu_i)|^2$ , which is known as the **Franck–Condon factor** for the transition:

$$|S(\nu_f, \nu_i)|^2 = \left( \int \psi_{\nu,f}^* \psi_{\nu,i} d\boldsymbol{\tau}_n \right)^2 \quad \text{Franck–Condon factor} \quad (13A.6)$$

It follows that, the greater the overlap of the vibrational state wavefunction in the upper electronic state with the vibrational wavefunction in the lower electronic state, the greater the absorption intensity of that particular simultaneous electronic and vibrational transition.

### Example 13A.1 Calculating a Franck–Condon factor

Consider the transition from one electronic state to another, their bond lengths being  $R_e$  and  $R'_e$  and their force constants equal. Calculate the Franck–Condon factor for the 0–0 transition and show that the transition is most intense when the bond lengths are equal.

**Method** We need to calculate  $S(0,0)$ , the overlap integral of the two ground-state vibrational wavefunctions, and then take its square. The difference between harmonic and anharmonic vibrational wavefunctions is negligible for  $\nu=0$ , so harmonic oscillator wavefunctions can be used (Table 8B.1).

**Answer** We use the (real) wavefunctions

$$\psi_0 = \left( \frac{1}{\alpha\pi^{1/2}} \right)^{1/2} e^{-x^2/2\alpha^2} \quad \psi'_0 = \left( \frac{1}{\alpha\pi^{1/2}} \right)^{1/2} e^{-x'^2/2\alpha^2}$$

where  $x = R - R_e$  and  $x' = R - R'_e$ , with  $\alpha = (\hbar^2/mk_e)^{1/4}$  (Topic 8B). The overlap integral is

$$S(0,0) = \int_{-\infty}^{\infty} \psi'_0 \psi_0 dR = \frac{1}{\alpha\pi^{1/2}} \int_{-\infty}^{\infty} e^{-(x^2+x'^2)/2\alpha^2} dx$$

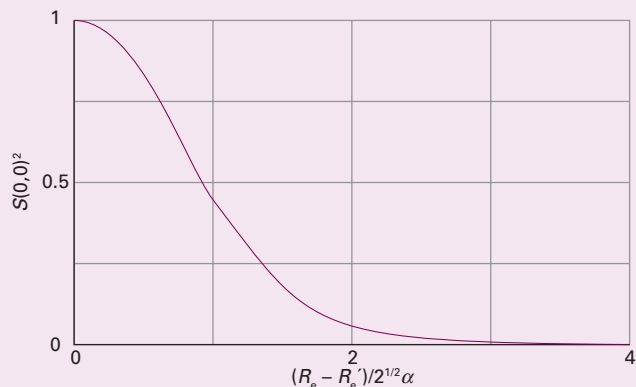

We now write  $\alpha z = R - \frac{1}{2}(R_e + R'_e)$  and manipulate this expression into

$$S(0,0) = \frac{1}{\pi^{1/2}} e^{-(R_e - R'_e)^2/4\alpha^2} \int_{-\infty}^{\infty} e^{-z^2} dz = e^{-(R_e - R'_e)^2/4\alpha^2}$$

and the Franck–Condon factor is

$$S(0,0)^2 = e^{-(R_e - R'_e)^2 / 2\alpha^2}$$

This factor is equal to 1 when  $R'_e = R_e$  and decreases as the equilibrium bond lengths diverge from each other (Fig. 13A.8).

**Figure 13A.8** The Franck–Condon factor for the arrangement discussed in *Example 13A.1*.

For  $\text{Br}_2$ ,  $R_e = 228 \text{ pm}$  and there is an upper state with  $R'_e = 266 \text{ pm}$ . Taking the vibrational wavenumber as  $250 \text{ cm}^{-1}$  gives  $S(0,0)^2 = 5.1 \times 10^{-10}$ , so the intensity of the 0–0 transition is only  $5.1 \times 10^{-10}$  what it would have been if the potential curves had been directly above each other.

**Self-test 13A.6** Suppose the vibrational wavefunctions can be approximated by rectangular functions of width  $W$  and  $W'$ , centred on the equilibrium bond lengths (Fig. 13A.9). Find the corresponding Franck–Condon factors when the centres are coincident and  $W' < W$ .

**Figure 13A.9** The model wavefunctions used in *Self-test 13A.6*.

Answer:  $S^2 = W'/W$

#### (d) Rotational structure

Just as in vibrational spectroscopy, where a vibrational transition is accompanied by rotational excitation, so rotational transitions accompany the excitation of the vibrational excitation that accompanies electronic excitation. We therefore see P, Q, and R branches for each vibrational transition, and the

electronic transition has a very rich structure. However, the principal difference is that electronic excitation can result in much larger changes in bond length than vibrational excitation causes alone, and the rotational branches have a more complex structure than in vibration–rotation spectra.

We suppose that the rotational constants of the electronic ground and excited states are  $\tilde{B}$  and  $\tilde{B}'$ , respectively. The rotational energy levels of the initial and final states are

$$E(J) = hc\tilde{B}J(J+1) \quad E(J') = hc\tilde{B}'J'(J'+1) \quad (13A.7)$$

When a transition occurs with  $\Delta J = -1$  the wavenumber of the vibrational component of the electronic transition is shifted from  $\tilde{\nu}$  to

$$\tilde{\nu} + \tilde{B}'(J-1)J - \tilde{B}J(J+1) = \tilde{\nu} - (\tilde{B}' + \tilde{B})J + (\tilde{B}' - \tilde{B})J^2$$

This transition is a contribution to the P branch (just as in Topic 12D). There are corresponding transitions to the Q and R branches with wavenumbers that may be calculated in a similar way. All three branches are:

$$\text{P branch } (\Delta J = -1): \quad \tilde{\nu}_p(J) = \tilde{\nu} - (\tilde{B}' + \tilde{B})J + (\tilde{B}' - \tilde{B})J^2$$

Branch structure (13A.8a)

$$\text{Q branch } (\Delta J = 0): \quad \tilde{\nu}_q(J) = \tilde{\nu} + (\tilde{B}' - \tilde{B})J(J+1) \quad (13A.8b)$$

$$\text{R branch } (\Delta J = +1): \quad \tilde{\nu}_r(J) = \tilde{\nu} + (\tilde{B}' + \tilde{B})(J+1) + (\tilde{B}' - \tilde{B})(J+1)^2$$

(13A.8c)

These expressions are the analogues of eqn 12D.19.

#### Example 13A.2 Estimating rotational constants from electronic spectra

The following rotational transitions were observed in the 0–0 band of the  ${}^1\Sigma^+ \leftarrow {}^1\Sigma^+$  electronic transition of  ${}^{63}\text{Cu}^{2}\text{H}$ :  $\tilde{\nu}_r(3) = 23\,347.69 \text{ cm}^{-1}$ ,  $\tilde{\nu}_p(3) = 23\,298.85 \text{ cm}^{-1}$ , and  $\tilde{\nu}_p(5) = 23\,275.77 \text{ cm}^{-1}$ . Estimate the values of  $\tilde{B}'$  and  $\tilde{B}$ .

**Method** Use the method of combination differences introduced in Topic 12D: form the differences  $\tilde{\nu}_r(J) - \tilde{\nu}_p(J)$  and  $\tilde{\nu}_r(J-1) - \tilde{\nu}_p(J+1)$  from eqns 13A.8a and 13A.8b, then use the resulting expressions to calculate the rotational constants  $\tilde{B}'$  and  $\tilde{B}$  from the wavenumbers provided.

**Answer** From eqns 13A.8a and 13A.8b it follows that

$$\begin{aligned} \tilde{\nu}_r(J) - \tilde{\nu}_p(J) &= (\tilde{B}' + \tilde{B})(J+1) + (\tilde{B}' - \tilde{B})(J+1)^2 \\ &\quad - \{ -(\tilde{B}' + \tilde{B})J + (\tilde{B}' - \tilde{B})J^2 \} = 4\tilde{B}'\left(J + \frac{1}{2}\right) \\ \tilde{\nu}_r(J-1) - \tilde{\nu}_p(J+1) &= (\tilde{B}' + \tilde{B})J + (\tilde{B}' - \tilde{B})J^2 \\ &\quad - \{ -(\tilde{B}' + \tilde{B})(J+1) + (\tilde{B}' - \tilde{B})(J+1)^2 \} = 4\tilde{B}\left(J + \frac{1}{2}\right) \end{aligned}$$

(These equations are analogous to eqns 12D.21a and 12D.21b.)  
After using the data provided, we obtain:

$$\text{For } J=3: \tilde{\nu}_R(3) - \tilde{\nu}_P(3) = \frac{23\,347.69 - 23\,298.85}{48.84} \text{ cm}^{-1} = 14\tilde{B}'$$

$$\text{For } J=4: \tilde{\nu}_R(3) - \tilde{\nu}_P(5) = \frac{23\,347.69 - 23\,275.77}{71.92} \text{ cm}^{-1} = 18\tilde{B}$$

and calculate  $\tilde{B}' = 3.489 \text{ cm}^{-1}$  and  $\tilde{B} = 3.996 \text{ cm}^{-1}$ .

**Self-test 13A.7** The following rotational transitions were observed in the  ${}^1\Sigma^+ \leftarrow {}^1\Sigma^+$  electronic transition of RhN:  $\tilde{\nu}_R(5) = 22\,387.06 \text{ cm}^{-1}$ ,  $\tilde{\nu}_P(5) = 22\,376.87 \text{ cm}^{-1}$  and  $\tilde{\nu}_P(7) = 22\,373.95 \text{ cm}^{-1}$ . Estimate the values of  $\tilde{B}'$  and  $\tilde{B}$ .

Answer:  $\tilde{B}' = 0.4632 \text{ cm}^{-1}$ ,  $\tilde{B} = 0.5042 \text{ cm}^{-1}$

**Figure 13A.10** When the rotational constants of a diatomic molecule differ significantly in the initial and final states of an electronic transition, the P and R branches show a head. (a) The formation of a head in the R branch when  $\tilde{B}' < \tilde{B}$ ; (b) the formation of a head in the P branch when  $\tilde{B}' > \tilde{B}$ .

Suppose that the bond length in the electronically excited state is greater than that in the ground state; then  $\tilde{B}' < \tilde{B}$  and  $\tilde{B}' - \tilde{B}$  is negative. In this case the lines of the R branch converge with increasing  $J$  and when  $J$  is such that  $|\tilde{B}' - \tilde{B}|(J+1) > \tilde{B}' + \tilde{B}$  the lines start to appear at successively decreasing wavenumbers. That is, the R branch has a **band head** (Fig. 13A.10a). When the bond is shorter in the excited state than in the ground state,  $\tilde{B}' > \tilde{B}$  and  $\tilde{B}' - \tilde{B}$  is positive. In this case, the lines of the P branch begin to converge and go through a head when  $J$  is such that  $|\tilde{B}' - \tilde{B}|J > \tilde{B}' + \tilde{B}$  (Fig. 13A.10b).

## 13A.2 Polyatomic molecules

The absorption of a photon can often be traced to the excitation of specific types of electrons or to electrons that belong to a small group of atoms in a polyatomic molecule. For example, when a carbonyl group ( $\text{C}=\text{O}$ ) is present, an absorption at

**Table 13A.2\*** Absorption characteristics of some groups and molecules

Group	$\tilde{\nu}/\text{cm}^{-1}$	$\lambda_{\text{max}}/\text{nm}$	$\epsilon_{\text{max}}/(\text{dm}^3 \text{ mol}^{-1} \text{ cm}^{-1})$
C=C ( $\pi^* \leftarrow \pi$ )	61 000	163	15 000
C=O ( $\pi^* \leftarrow n$ )	35 000–37 000	270–290	10–20
H <sub>2</sub> O ( $\pi^* \leftarrow n$ )	60 000	167	7 000

\* More values are given in the *Resource section*.

about 290 nm is normally observed, although its precise location depends on the nature of the rest of the molecule. Groups with characteristic optical absorptions are called **chromophores** (from the Greek for ‘colour bringer’), and their presence often accounts for the colours of substances (Table 13A.2).

### (a) d-Metal complexes

In a free atom, all five d orbitals of a given shell are degenerate. In a d-metal complex, where the immediate environment of the atom is no longer spherical, the d orbitals are not all degenerate, and electrons can absorb energy by making transitions between them.

To see the origin of this splitting in an octahedral complex such as  $[\text{Ti}(\text{OH}_2)_6]^{3+}$  (1), we regard the six ligands as point negative charges that repel the d electrons of the central ion (Fig. 13A.11). As a result, the orbitals fall into two groups, with  $d_{x^2-y^2}$  and  $d_{z^2}$  pointing directly towards the ligand positions, and  $d_{xy}$ ,  $d_{yz}$ , and  $d_{zx}$  pointing between them. An electron occupying an orbital of the former group has a less favourable potential energy than when it occupies any of the three orbitals of the other group, and so the d orbitals split into the two sets shown in (2) with an energy difference  $\Delta_O$ : a triply degenerate set comprising the  $d_{xy}$ ,  $d_{yz}$ , and  $d_{zx}$  orbitals and labelled  $t_{2g}$ , and a doubly degenerate set comprising the with  $d_{x^2-y^2}$  and  $d_{z^2}$  orbitals and labelled  $e_g$ . The three  $t_{2g}$  orbitals lie below the two  $e_g$  orbitals in energy; the difference in energy  $\Delta_O$  is called the **ligand-field splitting parameter** (the O denoting octahedral symmetry). The ligand field splitting is typically about 10 per cent of the overall energy of interaction between the ligands and the central metal atom, which is largely responsible for the existence of the complex. The d orbitals also divide into two sets in a tetrahedral complex, but in this case the e orbitals lie below the  $t_2$  orbitals (the g,u classification is no longer relevant as a tetrahedral complex has no centre of inversion) and their separation is written  $\Delta_T$ .

**Figure 13A.11** The classification of d orbitals in an octahedral environment. The open circles represent the positions of the six (point-charge) ligands.

Neither  $\Delta_O$  nor  $\Delta_T$  is large, so transitions between the two sets of orbitals typically occur in the visible region of the spectrum. The transitions are responsible for many of the colours that are so characteristic of d-metal complexes.

#### Brief illustration 13A.6 The electronic spectrum of a d-metal complex

The spectrum of  $[\text{Ti}(\text{OH}_2)_6]^{3+}$  (1) near  $20\,000\text{ cm}^{-1}$  (500 nm) is shown in Fig. 13A.12, and can be ascribed to the promotion of its single d electron from a  $t_{2g}$  orbital to an  $e_g$  orbital. The wavenumber of the absorption maximum suggests that  $\Delta_O \approx 20\,000\text{ cm}^{-1}$  for this complex, which corresponds to about 2.5 eV.

**Figure 13A.12** The electronic absorption spectrum of  $[\text{Ti}(\text{OH}_2)_6]^{3+}$  in aqueous solution.

**Self-test 13A.8** Can a complex of the  $\text{Zn}^{2+}$  ion have a d–d electronic transition? Explain your answer.

Answer: No; all five d orbitals are fully occupied

According to the Laporte rule (Section 13A.1b), d–d transitions are parity-forbidden in octahedral complexes because they are  $g \rightarrow g$  transitions (more specifically  $e_g \leftarrow t_{2g}$  transitions). However, d–d transitions become weakly allowed as **vibronic transitions**, joint vibrational and electronic transitions, as a result of coupling to asymmetrical vibrations such as that shown in Fig. 13A.4.

A d-metal complex may also absorb radiation as a result of the transfer of an electron from the ligands into the d orbitals of the central atom, or vice versa. In such **charge-transfer transitions** the electron moves through a considerable distance, which means that the transition dipole moment may be large and the absorption correspondingly intense. In the permanganate ion,  $\text{MnO}_4^-$ , the charge redistribution that accompanies the migration of an electron from the O atoms to the central Mn atom results in strong transition in the range 420–700 nm that accounts for the intense purple colour of the ion. Such an electronic migration from the ligands to the metal corresponds to a **ligand-to-metal charge-transfer transition** (LMCT). The reverse migration, a **metal-to-ligand charge-transfer transition** (MLCT), can also occur. An example is the migration of a d electron onto the antibonding  $\pi$  orbitals of an aromatic ligand. The resulting excited state may have a very long lifetime if the electron is extensively delocalized over several aromatic rings.

In common with other transitions, the intensities of charge-transfer transitions are proportional to the square of the transition dipole moment. We can think of the transition moment as a measure of the distance moved by the electron as it migrates from metal to ligand or vice versa, with a large distance of migration corresponding to a large transition dipole moment and therefore a high intensity of absorption. However, because the integrand in the transition dipole is proportional to the product of the initial and final wavefunctions, it is zero unless the two wavefunctions have nonzero values in the same region of space. Therefore, although large distances of migration favour high intensities, the diminished overlap of the initial and final wavefunctions for large separations of metal and ligands favours low intensities (see Problem 13A.9).

#### (b) $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions

Absorption by a C=C double bond results in the excitation of a  $\pi$  electron into an antibonding  $\pi^*$  orbital (Fig. 13A.13). The chromophore activity is therefore due to a  **$\pi^* \leftarrow \pi$  transition** (which is normally read ‘ $\pi$  to  $\pi$ -star transition’). Its energy is about 7 eV for an unconjugated double bond, which corresponds to an absorption at 180 nm (in the ultraviolet). When the double bond is part of a conjugated chain, the energies of the molecular orbitals lie closer together and the  $\pi^* \leftarrow \pi$  transition moves to longer wavelength; it may even lie in the visible region if the conjugated system is long enough.

**Figure 13A.13** A C=C double bond acts as a chromophore. One of its important transitions is the  $\pi^* \leftarrow \pi$  transition illustrated here, in which an electron is promoted from a  $\pi$  orbital to the corresponding antibonding orbital.

**Figure 13A.14** A carbonyl group (C=O) acts as a chromophore partly on account of the excitation of a nonbonding O lone-pair electron to an antibonding CO  $\pi$  orbital.

One of the transitions responsible for absorption in carbonyl compounds can be traced to the lone pairs of electrons on the O atom. The Lewis concept of a 'lone pair' of electrons is represented in molecular orbital theory by a pair of electrons in an orbital confined largely to one atom and not appreciably involved in bond formation. One of these electrons may be excited into an empty  $\pi^*$  orbital of the carbonyl group (Fig. 13A.14), which gives rise to an  $\pi^* \leftarrow n$  transition (an 'n to  $\pi$ -star transition'). Typical absorption energies are about 4eV (290 nm). Because  $\pi^* \leftarrow n$  transitions in carbonyls are symmetry forbidden, the absorptions are weak. By contrast, the  $\pi^* \leftarrow \pi$  transition in a carbonyl, which corresponds to excitation of a  $\pi$  electron of the C=O double bond, is allowed by symmetry and results in relatively strong absorption.

#### Brief illustration 13A.7 $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions

The compound  $\text{CH}_3\text{CH}=\text{CHCHO}$  has a strong absorption in the ultraviolet at  $46\,950\text{ cm}^{-1}$  (213 nm) and a weak absorption at  $30\,000\text{ cm}^{-1}$  (330 nm). The former is a  $\pi^* \leftarrow \pi$  transition associated with the delocalized  $\pi$  system  $\text{C}=\text{C}-\text{C}=\text{O}$ . Delocalization extends the range of the  $\text{C}=\text{O } \pi^* \leftarrow \pi$  transition to lower wavenumbers (longer wavelengths). The latter is an  $\pi^* \leftarrow n$  transition associated with the carbonyl chromophore.

**Self-test 13A.9** Account for the observation that propanone (acetone,  $(\text{CH}_3)_2\text{CO}$ ) has a strong absorption at 189 nm and a weaker absorption at 280 nm.

Answer: Both transitions are associated with the C=O chromophore, with the weaker being an  $\pi^* \leftarrow n$  transition and the stronger a  $\pi^* \leftarrow \pi$  transition.

### (c) Circular dichroism

Electronic spectra can reveal additional details of molecular structure when experiments are conducted with **polarized light**, electromagnetic radiation with electric and magnetic fields that oscillate only in certain directions. A mode of polarization is **circular polarization**, in which the electric and magnetic fields rotate around the direction of propagation in either a clockwise or a counter-clockwise sense but remain perpendicular to it and each other (Fig. 13A.15). Chiral molecules exhibit **circular dichroism**, meaning that they absorb left and right circularly polarized light to different extents. For example, the circular dichroism (CD) spectra of the enantiomeric pairs of chiral d-metal complexes are distinctly different, whereas there is little difference between their absorption spectra (Fig. 13A.16).

**Figure 13A.15** In circularly polarized light, the electric field rotates at different angles around the direction of propagation. The arrays of arrows in these illustrations show the view of the electric field (a) right-circularly polarized, (b) left-circularly polarized light.

**Figure 13A.16** (a) The absorption spectra of two isomers, denoted mer and fac, of  $[\text{Co}(\text{ala})_3]$ , where ala is the conjugate base of alanine, and (b) the corresponding CD spectra. The left- and right-handed forms of these isomers give identical absorption spectra. However, the CD spectra are distinctly different, and the absolute configurations (denoted  $\Delta$  and  $\Lambda$ ) have been assigned by comparison with the CD spectra of a complex of known absolute configuration.

## Checklist of concepts

- 1. The term symbols of diatomic molecules express the components of electronic angular momentum around the internuclear axis.
- 2. Selection rules for electronic transitions are based on considerations of angular momentum and symmetry.
- 3. The **Laporte selection rule** states that, for centrosymmetric molecules, only  $u \rightarrow g$  and  $g \rightarrow u$  transitions are allowed.
- 4. The **Franck–Condon principle** provides a basis for explaining the vibrational structure of electronic transitions.
- 5. In gas phase samples, rotational structure is present too and can give rise to **band heads**.
- 6. **Chromophores** are groups with characteristic optical absorptions.
- 7. In d-metal complexes, the presence of ligands removes the degeneracy of d orbitals and vibrationally allowed **d–d transitions** can occur between them.
- 8. **Charge-transfer transitions** typically involve the migration of electrons between the ligands and the central metal atom.
- 9. Other chromophores include double bonds ( $\pi^* \leftarrow \pi$  transitions) and carbonyl groups ( $\pi^* \leftarrow n$  transitions).
- 10. **Circular dichroism** is the differential absorption of left and right circularly polarized light.

## Checklist of equations

Property	Equation	Comment	Equation number
Selection rules (angular momentum)	$\Delta A = 0, \pm 1; \Delta S = 0; \Delta \Sigma = 0; \Delta \Omega = 0, \pm 1$	Linear molecules	13A.4
Franck–Condon factor	$ S(\nu_f, \nu_i) ^2 = \left( \int \psi_{\nu_f}^* \psi_{\nu_i} d\tau_n \right)^2$	Assumes Franck–Condon principle applies	13A.6
Rotational structure of electronic spectra (diatomic molecules)	$\tilde{\nu}_P(J) = \tilde{\nu} - (\tilde{B}' + \tilde{B})J + (\tilde{B}' - \tilde{B})J^2$	P branch ( $\Delta J = -1$ )	13A.8a
	$\tilde{\nu}_Q(J) = \tilde{\nu} + (\tilde{B}' - \tilde{B})J(J+1)$	Q branch ( $\Delta J = 0$ )	13A.8b

### ► Why do you need to know this material?

Considerable information about the electronic structure of a molecule can be obtained from the photons emitted when excited electronic states decay radiatively back to the ground state.

### ► What is the key idea?

Molecules in excited electronic states discard their excess energy by emission of electromagnetic radiation, transfer as heat to the surroundings, or fragmentation.

### ► What do you need to know already?

You need to be familiar with electronic transitions in molecules (Topic 13A), the difference between spontaneous and stimulated emission of radiation (Topic 12A), and the general features of spectroscopy (Topic 12A). You need to be aware of the difference between singlet and triplet states (Topic 9C) and of the Franck–Condon principle (Topic 13A).

A **radiative decay process** is a process in which a molecule discards its excitation energy as a photon (Topic 12A). In this Topic we pay particular attention to spontaneous radiative decay processes, which include fluorescence and phosphorescence. A more common fate of an electronically excited molecule is **non-radiative decay**, in which the excess energy is transferred into the vibration, rotation, and translation of the surrounding molecules. This thermal degradation converts the excitation energy into thermal motion of the environment (that is, to ‘heat’). An excited molecule may also dissociate or take part in a chemical reaction (Topic 20G).

## 13B.1 Fluorescence and phosphorescence

In **fluorescence**, spontaneous emission of radiation occurs while the sample is being irradiated and ceases within nanoseconds to milliseconds of the exciting radiation being extinguished (Fig. 13B.1). In **phosphorescence**, the spontaneous emission may persist for long periods (even hours, but characteristically seconds or fractions of seconds). The difference suggests that fluorescence is a fast conversion of absorbed radiation into re-emitted energy, and that phosphorescence involves the storage of energy in a reservoir from which it slowly leaks.

Figure 13B.2 shows the sequence of steps involved in fluorescence of chromophores in solution. The initial stimulated absorption takes the molecule to an excited electronic state, and if the absorption spectrum were monitored it would look like the one shown in Fig. 13B.3a. The excited molecule is subjected to collisions with the surrounding molecules, and as it gives up energy nonradiatively it steps down (typically within picoseconds) the ladder of vibrational levels to the lowest vibrational level of the electronically excited molecular state. The surrounding molecules, however, might now be unable to accept the larger energy difference needed to lower the molecule to the ground electronic state. It might therefore survive long enough to undergo spontaneous emission and emit the remaining excess energy as radiation. The downward electronic transition is vertical, in accord with the Franck–Condon principle (Topic

**Figure 13B.1** The empirical (observation-based) distinction between fluorescence and phosphorescence is that the former is extinguished very quickly after the exciting source is removed, whereas the latter continues with relatively slowly diminishing intensity.

**Figure 13B.2** The sequence of steps leading to fluorescence by chromophores in solution. After the initial absorption, the upper vibrational states undergo radiationless decay by giving up energy to the surrounding molecules. A radiative transition then occurs from the vibrational ground state of the upper electronic state.

**Figure 13B.3** An absorption spectrum (a) shows a vibrational structure characteristic of the upper state. A fluorescence spectrum (b) shows a structure characteristic of the lower state; it is also displaced to lower frequencies (but the 0–0 transitions are coincident) and resembles a mirror image of the absorption.

13A), and the fluorescence spectrum has a vibrational structure characteristic of the *lower* electronic state (Fig. 13B.3b).

Provided they can be seen, the 0–0 absorption and fluorescence transitions can be expected to be coincident. The absorption spectrum arises from  $1 \leftarrow 0$ ,  $2 \leftarrow 0$ , ... transitions that occur at progressively higher wavenumber and with intensities governed by the Franck–Condon principle. The fluorescence spectrum arises from  $0 \rightarrow 0$ ,  $0 \rightarrow 1$ , ... *downward* transitions that occur with decreasing wavenumbers. The 0–0 absorption and fluorescence peaks are not always exactly coincident, however, because the solvent may interact differently with the solute in the ground and excited states (for instance, the hydrogen bonding pattern might differ). Because the solvent molecules do not have time to rearrange during the transition, the absorption occurs in an environment characteristic

**Figure 13B.4** The solvent can shift the fluorescence spectrum relative to the absorption spectrum. On the left we see that the absorption occurs with the solvent (depicted by the ellipses) in the arrangement characteristic of the ground electronic state of the molecule (the sphere). However, before fluorescence occurs, the solvent molecules relax into a new arrangement, and that arrangement is preserved during the subsequent radiative transition.

of the solvated ground state; however, the fluorescence occurs in an environment characteristic of the solvated excited state (Fig. 13B.4).

Fluorescence occurs at lower frequencies (longer wavelengths) than the incident radiation because the emissive transition occurs after some vibrational energy has been discarded into the surroundings. The vivid oranges and greens of fluorescent dyes are an everyday manifestation of this effect: they absorb in the ultraviolet and blue, and fluoresce in the visible. The mechanism also suggests that the intensity of the fluorescence ought to depend on the ability of the solvent molecules to accept the electronic and vibrational quanta. It is indeed found that a solvent composed of molecules with widely spaced vibrational levels (such as water) can in some cases accept the large quantum of electronic energy and so extinguish, or ‘quench’, the fluorescence. The rate at which fluorescence is quenched by other molecules also gives valuable kinetic information (Topic 20G).

Figure 13B.5 shows the sequence of events leading to phosphorescence for a molecule with a singlet ground state. The first steps are the same as in fluorescence, but the presence of a triplet excited state at an energy close to that of the singlet excited state plays a decisive role. The singlet and triplet excited states share a common geometry at the point where their potential energy curves intersect. Hence, if there is a mechanism for unpairing two electron spins (and achieving the conversion of  $\uparrow\downarrow$  to  $\uparrow\uparrow$ ), the molecule may undergo **intersystem crossing**, a non-radiative transition between states of different multiplicity, and become a triplet state. As in the discussion of atomic spectra (Topic 9C), singlet–triplet transitions may occur in the presence of spin–orbit coupling. Intersystem crossing is expected to be important when a molecule contains a moderately heavy atom (such as sulfur), because then the spin–orbit coupling is large.

**Figure 13B.5** The sequence of steps leading to phosphorescence. The important step is the intersystem crossing (ISC), the switch from a singlet state to a triplet state brought about by spin–orbit coupling. The triplet state acts as a slowly radiating reservoir because the return to the ground state is spin-forbidden.

If an excited molecule crosses into a triplet state, it continues to discard energy into the surroundings. However, it is now stepping down the triplet's vibrational ladder, and at the lowest energy level it is trapped because the triplet state is at a lower energy than the corresponding singlet (Hund's rule, Topic 9B). The solvent cannot absorb the final, large quantum of electronic excitation energy, and the molecule cannot radiate its energy because return to the ground state is spin-forbidden. The radiative transition, however, is not totally forbidden because the spin–orbit coupling that was responsible for the intersystem crossing also breaks the selection rule. The molecules are therefore able to emit weakly, and the emission may continue long after the original excited state was formed.

The mechanism accounts for the observation that the excitation energy seems to get trapped in a slowly leaking reservoir. It also suggests (as is confirmed experimentally) that phosphorescence should be most intense from solid samples: energy transfer is then less efficient and intersystem crossing has time to occur as the singlet excited state steps slowly past the intersection point. The mechanism also suggests that the phosphorescence efficiency should depend on the presence of a moderately heavy atom (with strong spin–orbit coupling), which is in fact the case.

The various types of non-radiative and radiative transitions that can occur in molecules are often represented on a schematic **Jablonski diagram** of the type shown in Fig. 13B.6.

#### Brief illustration 13B.1 Fluorescence and phosphorescence of organic molecules

Fluorescence efficiency decreases, and the phosphorescence efficiency increases, in the series of compounds: naphthalene, 1-chloronaphthalene, 1-bromonaphthalene,

1-iodonaphthalene. The replacement of an H atom by successively heavier atoms enhances both intersystem crossing from the first excited singlet state to the first excited triplet state (thereby decreasing the efficiency of fluorescence) and the radiative transition from the first excited triplet state to the ground singlet state (thereby increasing the efficiency of phosphorescence).

**Self-test 13B.1** Consider an aqueous solution of a chromophore that fluoresces strongly. Is the addition of iodide ion to the solution likely to increase or decrease the efficiency of phosphorescence the chromophore?

Answer: increase

**Figure 13B.6** A Jablonski diagram (here, for naphthalene) is a simplified portrayal of the relative positions of the electronic energy levels of a molecule. Vibrational levels of states of a given electronic state lie above each other, but the relative horizontal locations of the columns bear no relation to the nuclear separations in the states. The ground vibrational states of each electronic state are correctly located vertically but the other vibrational states are shown only schematically. (IC: internal conversion; ISC: intersystem crossing.)

## 13B.2 Dissociation and predissociation

Another fate for an electronically excited molecule is **dissociation**, the breaking of bonds (Fig. 13B.7). The onset of dissociation can be detected in an absorption spectrum by seeing that the vibrational structure of a band terminates at a certain energy. Absorption occurs in a continuous band above this **dissociation limit** because the final state is an unquantized translational motion of the fragments. Locating the dissociation limit is a valuable way of determining the bond dissociation energy.

In some cases, the vibrational structure disappears but resumes at higher photon energies. This effect provides evidence of **predissociation**, which can be interpreted in terms of the molecular potential energy curves shown in Fig. 13B.8. When a molecule is excited to a vibrational level, its electrons

**Figure 13B.7** When absorption occurs to unbound states of the upper electronic state, the molecule dissociates and the absorption is a continuum. Below the dissociation limit the electronic spectrum shows a normal vibrational structure.

**Figure 13B.8** When a dissociative state crosses a bound state, molecules excited to levels near the crossing may dissociate. This process is called predissociation, and is detected in the spectrum as a loss of vibrational structure that resumes at higher frequencies.

may undergo a redistribution that results in it undergoing an **internal conversion**, a radiationless conversion to another state of the same multiplicity. An internal conversion occurs most readily at the point of intersection of the two molecular potential energy curves, because there the nuclear geometries of the two electronic states are the same. The state into which the molecule converts may be dissociative, so the states near the intersection have a finite lifetime and hence their energies are imprecisely defined (lifetime broadening, Topic 12A). As a result, the absorption spectrum is blurred in the vicinity of the intersection. When the incoming photon brings enough energy to excite the molecule to a vibrational level high above the intersection, the internal conversion does not occur (the nuclei are unlikely to have the same geometry). Consequently, the levels resume their well-defined, vibrational character with correspondingly well-defined energies, and the line structure resumes on the high-frequency side of the blurred region.

#### Brief illustration 13B.2 The effect of predissociation on an electronic spectrum

The  $\text{O}_2$  molecule absorbs ultraviolet radiation in a transition from its  $^3\Sigma_g^-$  ground electronic state to a  $^3\Sigma_u^-$  excited state that is energetically close to a dissociative  $^3\Pi_u$  state. In this case, the effect of predissociation is more subtle than the abrupt loss of vibrational–rotational structure in the spectrum; instead, the vibrational structure simply broadens rather than being lost completely. As before, the broadening is explained by short lifetimes of the excited vibrational states near the intersection of the curves describing the bound and dissociative excited electronic states.

**Self-test 13B.2** What can be estimated from the wavenumber of onset of predissociation?

Answer: See Fig. 13B.8; an upper limit on the dissociation energy of the ground electronic state

## Checklist of concepts

1. **Fluorescence** is radiative decay between states of the same multiplicity; it ceases as soon as the exciting source is removed.
2. **Phosphorescence** is radiative decay between states of different multiplicity; it persists after the exciting radiation is removed.
3. **Intersystem crossing** is the non-radiative conversion to a state of different multiplicity.
4. A **Jablonski diagram** is a schematic diagram of the types of non-radiative and radiative transitions that can occur in molecules.
5. An additional fate of an electronically excited species is **dissociation**.
6. **Internal conversion** is a non-radiative conversion to a state of the same multiplicity.
7. **Predissociation** is the observation of the effects of dissociation before the dissociation limit is reached.

### ► Why do you need to know this material?

Radiative decay has great technological importance: lasers have brought unprecedented precision to spectroscopy and are used in medicine, telecommunications, and many aspects of everyday life.

### ► What is the key idea?

Laser action is the stimulated emission of coherent radiation taking place between states related by a population inversion.

### ► What do you need to know already?

You need to be familiar with electronic transitions in molecules (Topic 13A), the difference between spontaneous and stimulated emission of radiation (Topic 12A), and the general features of spectroscopy (Topics 12A and 13B).

The word laser is an acronym formed from light amplification by stimulated emission of radiation. In stimulated emission (Topic 12A), an excited state is stimulated to emit a photon by radiation of the same frequency: the more photons that are

present, the greater the probability of the emission. The essential feature of laser action is positive-feedback: the greater the number of photons present of the appropriate frequency, the greater the rate at which even more photons of that frequency will be stimulated to form.

Laser radiation has a number of striking characteristics (Table 13C.1). Each of them (sometimes in combination with the others) opens up interesting opportunities in physical chemistry. Raman spectroscopy has flourished on account of the high intensity monochromatic radiation available from lasers (Topic 12A), and the ultra-short pulses that lasers can generate make possible the study of light-initiated reactions on timescales of femtoseconds and even attoseconds.

## 13C.1 Population inversion

One requirement of laser action is the existence of a **metastable excited state**, an excited state with a long enough lifetime for it to participate in stimulated emission. Another requirement is the existence of a greater population in the metastable state than in the lower state where the transition terminates, for

**Table 13C.1** Characteristics of laser radiation and their chemical applications

Characteristic	Advantage	Application
High power	Multiphoton process	Spectroscopy
	Low detector noise	Improved sensitivity
	High scattering intensity	Raman spectroscopy (Topics 12C–12E)
Monochromatic	High resolution	Spectroscopy
	State selection	Photochemical studies (Topic 20G) Reaction dynamics (Topic 21D)
Collimated beam	Long path lengths	Improved sensitivity
	Forward-scattering observable	Raman spectroscopy (Topics 12C–12E)
Coherent	Interference between separate beams	CARS (Topic 12E)
Pulsed	Precise timing of excitation	Fast reactions (Topics 13C, 20G, and 21C)
		Relaxation (Topic 20C)
		Energy transfer (Topic 20C)

then there will be a net emission of radiation. Because at thermal equilibrium the opposite is true, it is necessary to achieve a **population inversion** in which there are more molecules in the upper state than in the lower.

One way of achieving population inversion is illustrated in Fig. 13C.1. The molecule is excited to an intermediate state I, which then gives up some of its energy non-radiatively and changes into a lower state A; the laser transition is the return of A to the ground state X. Because three energy levels are involved overall, this arrangement leads to a **three-level laser**. In practice, I consists of many states, all of which can convert to the upper of the two laser states A. The  $I \leftarrow X$  transition is stimulated with an intense flash of light in the process called **pumping**. The pumping is often achieved with an electric discharge through xenon or with the light of another laser. The conversion of I to A should be rapid, and the laser transitions from A to X should be relatively slow.

The disadvantage of the three-level arrangement is that it is difficult to achieve population inversion, because so many ground-state molecules must be converted to the excited state by the pumping action. The arrangement adopted in a **four-level laser** simplifies this task by having the laser transition terminate in a state  $A'$  other than the ground state (Fig. 13C.2).

**Figure 13C.1** The transitions involved in one kind of three-level laser. The pumping pulse populates the intermediate state I, which in turn populates the metastable state A. The laser transition is the stimulated emission  $A \rightarrow X$ .

**Figure 13C.2** The transitions involved in a four-level laser. Because the laser transition terminates in an excited state ( $A'$ ), the population inversion between A and  $A'$  is much easier to achieve.

Because  $A'$  is unpopulated initially, any population in A corresponds to a population inversion and we can expect laser action if A is sufficiently metastable. Moreover, this population inversion can be maintained if the  $A' \rightarrow X$  transitions are rapid, for these transitions will deplete any population in  $A'$  that stems from the laser transition, and keep the state  $A'$  relatively empty.

### Brief illustration 13C.1 Simple lasers

The ruby laser is an example of a three-level laser (Fig. 13C.3). Ruby is  $\text{Al}_2\text{O}_3$  containing a small proportion of  $\text{Cr}^{3+}$  ions. The lower level of the laser transition is the  ${}^4A_2$  ground state of the  $\text{Cr}^{3+}$  ion. The process of pumping a majority of the  $\text{Cr}^{3+}$  ions into the  ${}^4T_2$  and  ${}^4T_1$  excited states is followed by a radiationless transition to the  ${}^2E$  excited state. The laser transition is  ${}^2E \rightarrow {}^4A_2$ , and gives rise to red 694 nm radiation.

**Figure 13C.3** The transitions involved in a ruby laser.

The neodymium laser is an example of a four-level laser (Fig. 13C.4). In one form it consists of  $\text{Nd}^{3+}$  ions at low concentration in yttrium aluminium garnet (YAG, specifically  $\text{Y}_3\text{Al}_5\text{O}_{12}$ ), and is then known as a Nd:YAG laser. A neodymium laser operates at a number of wavelengths in the infrared, the band at 1064 nm being most common.

**Figure 13C.4** The transitions involved in a neodymium laser.

**Self-test 13C.1** In the arrangement discussed here, does a ruby laser generate pulses of light or a continuous beam of light?

Answer: Pulses

## 13C.2 Cavity and mode characteristics

The laser medium is confined to a cavity that ensures that only certain photons of a particular frequency, direction of travel, and state of polarization are generated abundantly. The cavity is essentially a region between two mirrors, which reflect the light back and forth. This arrangement can be regarded as a version of the particle in a box, with the particle now being a photon. As in the treatment of a particle in a box (Topic 8A), the only wavelengths that can be sustained satisfy

$$n \times \frac{1}{2} \lambda = L \quad \text{Resonant modes} \quad (13C.1)$$

where  $n$  is an integer and  $L$  is the length of the cavity. That is, only an integral number of half-wavelengths fit into the cavity; all other waves undergo destructive interference with themselves. In addition, not all wavelengths that can be sustained by the cavity are amplified by the laser medium (many fall outside the range of frequencies of the laser transitions), so only a few contribute to the laser radiation. These wavelengths are the **resonant modes** of the laser.

### Brief illustration 13C.2 Resonant modes

It follows from eqn 13C.1 that the frequencies of the resonant modes are  $\nu = c/\lambda = (c/2L) \times n$ . For a laser cavity of length 30.0 cm, the allowed frequencies are

$$\nu = \frac{c}{2 \times (0.300 \text{ m})} \times n = (5.00 \times 10^8 \text{ s}^{-1}) \times n = (500 \text{ MHz}) \times n$$

with  $n = 1, 2, \dots$ , and therefore  $\nu = 500 \text{ MHz}, 1000 \text{ MHz}, \dots$

**Self-test 13C.2** Consider a laser cavity of length 1.0 m. What is the frequency difference between successive resonant modes?

Answer: 150 MHz

Photons with the correct wavelength for the resonant modes of the cavity and the correct frequency to stimulate the laser transition are highly amplified. One photon might be generated spontaneously and travel through the medium. It stimulates the emission of another photon, which in turn stimulates more (Fig. 13C.5). The cascade of energy builds up rapidly, and soon the cavity is an intense reservoir of radiation at all the resonant modes it can sustain. Some of this radiation can be withdrawn if one of the mirrors is partially transmitting.

The resonant modes of the cavity have various natural characteristics, and to some extent may be selected. Only photons that are travelling strictly parallel to the axis of the cavity undergo more than a couple of reflections, so only they are amplified, all others simply vanishing into the surroundings. Hence, laser light generally forms a beam with very low divergence. It may

**Figure 13C.5** A schematic illustration of the steps leading to laser action. (a) The Boltzmann population of states, with more atoms in the ground state. (b) When the initial state absorbs, the populations are inverted (the atoms are pumped to the excited state). (c) A cascade of radiation then occurs, as one emitted photon stimulates another atom to emit, and so on. The radiation is coherent (phases in step).

also be polarized, with its electric vector in a particular plane (or in some other state of polarization), by including a polarizing filter into the cavity or by making use of polarized transitions in a solid medium.

Laser radiation is **coherent** in the sense that the electromagnetic waves are all in step. In **spatial coherence** the waves are in step across the cross-section of the beam emerging from the cavity. In **temporal coherence** the waves remain in step along the beam. The former is normally expressed in terms of a **coherence length**,  $l_c$ , the distance across the beam over which the waves remain coherent, and is related to the range of wavelengths,  $\Delta\lambda$ , present in the beam:

$$l_c = \frac{\lambda^2}{2\Delta\lambda} \quad \text{Coherence length} \quad (13C.2)$$

When many wavelengths are present, and  $\Delta\lambda$  is large, the waves get out of step in a short distance and the coherence length is small.

### Brief illustration 13C.3 Coherence length

A typical light bulb gives out light with a coherence length of only about 400 nm. By contrast, a He–Ne laser with  $\lambda = 633 \text{ nm}$  and  $\Delta\lambda = 2.0 \text{ pm}$  has a coherence length of

$$l_c = \frac{\lambda^2}{2 \times (0.0020 \text{ nm})} = 1.0 \times 10^8 \text{ nm} = 0.10 \text{ m} = 10 \text{ cm}$$

**Self-test 13C.3** What is the condition that would lead to an infinite coherence length?

Answer: A perfectly monochromatic beam, or  $\Delta\lambda = 0$

### 13C.3 Pulsed lasers

A laser can generate radiation for as long as the population inversion is maintained. A laser can operate continuously when heat is easily dissipated, for then the population of the upper level can be replenished by pumping. When overheating is a problem, the laser can be operated only in pulses, perhaps of microsecond or millisecond duration, so that the medium has a chance to cool or the lower state discard its population. However, it is sometimes desirable to have pulses of radiation rather than a continuous output, with a lot of power concentrated into a brief pulse. One way of achieving pulses is by **Q-switching**, the modification of the resonance characteristics of the laser cavity. The name comes from the ‘Q-factor’ used as a measure of the quality of a resonance cavity in microwave engineering.

#### Example 13C.1 Relating the power and energy of a laser

A certain laser can generate radiation in 3.0 ns pulses, each of which delivers an energy of 0.10 J, at a pulse repetition frequency of 10 Hz. Assuming that the pulses are rectangular, calculate the peak power and the average power of this laser.

**Method** Power is the energy released in an interval divided by the duration of the interval, and is expressed in watts ( $1 \text{ W} = 1 \text{ J s}^{-1}$ ). The peak power,  $P_{\text{peak}}$ , of a rectangular pulse is defined as the energy delivered in a pulse divided by its duration. The average power,  $P_{\text{average}}$ , is the total energy delivered by a large number of pulses divided by the duration of the time interval over which that total energy is measured. If each pulse delivers an energy  $E_{\text{pulse}}$  and in an interval  $\Delta t$  there are  $N$  pulses, the total energy delivered is  $NE_{\text{pulse}}$  and the average power is  $P_{\text{average}} = NE_{\text{pulse}}/\Delta t$ . However,  $\Delta t/N$  is the interval between pulses and therefore the inverse of the pulse repetition frequency,  $\nu_{\text{repetition}}$ . It follows that  $P_{\text{average}} = E_{\text{pulse}}\nu_{\text{repetition}}$ .

**Answer** From the data,

$$P_{\text{peak}} = \frac{0.10 \text{ J}}{3.0 \times 10^{-9} \text{ s}} = 3.3 \times 10^7 \text{ J s}^{-1} = 33 \text{ MJ s}^{-1} = 33 \text{ MW}$$

The pulse repetition frequency rate is 10 Hz. It follows that the average power is

$$P_{\text{average}} = 0.10 \text{ J} \times 10 \text{ s}^{-1} = 1.0 \text{ J s}^{-1} = 1.0 \text{ W}$$

The peak power is much higher than the average power because this laser emits light for only 30 ns during each second of operation.

**Self-test 13C.4** Calculate the peak power and average power of a laser with a pulse energy of 2.0 mJ, a pulse duration of 30 ps, and a pulse repetition rate of 38 MHz.

$$\text{Answer: } P_{\text{peak}} = 67 \text{ MW}, P_{\text{average}} = 76 \text{ kW}$$

The aim of Q-switching is to achieve a healthy population inversion in the absence of the resonant cavity, then to plunge the population-inverted medium into a cavity and hence to obtain a sudden pulse of radiation. The switching may be achieved by impairing the resonance characteristics of the cavity in some way while the pumping pulse is active and then suddenly to improve them (Fig. 13C.6). One technique is to use the ability of some crystals to change their optical properties when an electrical potential difference is applied. For example, a crystal of potassium dihydrogenphosphate ( $\text{KH}_2\text{PO}_4$ ) rotates the plane of polarization of light to different extents when a potential difference is switched on and off. In this way energy can be stored or released in a laser cavity, resulting in an intense pulse of stimulated emission.

The technique of **mode locking** can produce pulses of picosecond duration and less. A laser radiates at a number of different frequencies, depending on the precise details of the resonance characteristics of the cavity and in particular on the number of half-wavelengths of radiation that can be trapped between the mirrors (the cavity modes). The resonant modes differ in frequency by multiples of  $c/2L$  (Brief illustration 13C.4). Normally, these modes have random phases relative to each other. However, it is possible to lock their phases together. As we show in the following *Justification*, interference then occurs to give a series of sharp peaks, and the energy of the laser is obtained in short bursts (Fig. 13C.7). More specifically, the intensity,  $I$ , of the radiation varies with time as

$$I(t) \propto \mathcal{E}_0^2 \frac{\sin^2(N\pi ct/2L)}{\sin^2(\pi ct/2L)} \quad \text{Mode-locked laser output} \quad (13C.3)$$

where  $\mathcal{E}_0$  is the amplitude of the electromagnetic wave describing the laser beam and  $N$  is the number of locked modes. This function is shown in Fig. 13C.8. We see that it is a series of peaks with maxima separated by  $t = 2L/c$ , the round-trip transit time of the light in the cavity, and that the peaks become sharper as  $N$  is increased. In a laser with a cavity of length 30 cm, the peaks are separated by 2 ns. If 1000 modes contribute, the width of the pulses is 4 ps.

**Figure 13C.6** The principle of Q-switching. (a) The excited state is populated while the cavity is non-resonant. (b) Then the resonance characteristics are suddenly restored, and the stimulated emission emerges in a giant pulse.

**Figure 13C.7** The output of a mode-locked laser consists of a stream of very narrow pulses (here 1 ps in duration) separated by an interval equal to the time it takes for light to make a round trip inside the cavity (here 1 ns).

**Figure 13C.8** The structure of the pulses generated by a mode-locked laser.

**Justification 13C.1** The origin of mode locking

The general expression for a (complex) wave of amplitude  $\mathcal{E}_0$  and frequency  $\omega$  is  $\mathcal{E}_0 e^{i\omega t}$ . Therefore, each wave that can be supported by a cavity of length  $L$  has the form

$$\mathcal{E}_n(t) = \mathcal{E}_0 e^{2\pi i(\nu + nc/2L)t}$$

where  $\nu$  is the lowest frequency. A wave formed by superimposing  $N$  modes with  $n = 0, 1, \dots, N - 1$  has the form

$$\mathcal{E}(t) = \sum_{n=0}^{N-1} \mathcal{E}_n(t) = \mathcal{E}_0 e^{2\pi i \nu t} \sum_{n=0}^{N-1} e^{i\pi n c t / L} = \mathcal{E}_0 e^{2\pi i \nu t} S(N)$$

The sum simplifies to:

$$S(N) = 1 + e^{i\pi c t / L} + e^{2i\pi c t / L} + \dots + e^{(N-1)i\pi c t / L}$$

The sum of a geometric series is

$$1 + e^x + e^{2x} + \dots + e^{(N-1)x} = \frac{e^{Nx} - 1}{e^x - 1}$$

so, with  $x = i\pi c t / L$ ,

$$S(N) = \frac{e^{N i\pi c t / L} - 1}{e^{i\pi c t / L} - 1}$$

On multiplication of both the numerator and denominator by  $e^{-i\pi c t / 2L}$  and a little rearrangement this expression becomes

$$S(N) = \frac{e^{N i\pi c t / 2L} - e^{-N i\pi c t / 2L}}{e^{i\pi c t / 2L} - e^{-i\pi c t / 2L}} \times e^{(N-1)i\pi c t / 2L}$$

At this point we use  $\sin x = (1/2i)(e^{ix} - e^{-ix})$ , and obtain

$$S(N) = \frac{\sin(N\pi c t / 2L)}{\sin(\pi c t / 2L)} \times e^{(N-1)i\pi c t / 2L}$$

The intensity,  $I(t)$ , of the radiation is proportional to the square modulus of the total amplitude, so

$$I(t) \propto \mathcal{E}^* \mathcal{E} = \mathcal{E}_0^2 \frac{\sin^2(N\pi c t / 2L)}{\sin^2(\pi c t / 2L)}$$

which is eqn 13C.3.

Mode locking is achieved by varying the Q-factor of the cavity periodically at the frequency  $c/2L$ . The modulation can be pictured as the opening of a shutter in synchrony with the round-trip travel time of the photons in the cavity, so only photons making the journey in that time are amplified. The modulation can be achieved by linking a prism in the cavity to a transducer driven by a radiofrequency source at a frequency  $c/2L$ . The transducer sets up standing-wave vibrations in the prism and modulates the loss it introduces into the cavity.

Another mechanism for mode-locking lasers is based on the **optical Kerr effect**, which arises from a change in refractive index of a well-chosen medium, the **Kerr medium**, when it is exposed to intense laser pulses. Because a beam of light changes direction when it passes from a region of one refractive index to a region with a different refractive index, changes in refractive index result in the self-focussing of an intense laser pulse as it travels through the Kerr medium (Fig. 13C.9).

To bring about mode-locking, a Kerr medium is included in the laser cavity and next to it is a small aperture. The procedure makes use of the fact that the **gain**, the growth in intensity, of a frequency component of the radiation in the cavity is very sensitive to amplification, and once a particular frequency begins to grow, it can quickly dominate. When the power inside the cavity is low, a portion of the photons will be blocked by the aperture, creating a significant loss. A spontaneous fluctuation in intensity—a bunching of photons—may begin to turn on the optical Kerr effect and the changes in the refractive index of the Kerr medium will result in a **Kerr lens**, which is the self-focussing of the laser beam. The bunch of photons can pass through and travel to the far end of the cavity, amplifying as it goes.

**Figure 13C.9** An illustration of the Kerr effect. An intense laser beam is focused inside a Kerr medium and passes through a small aperture in the laser cavity. This effect may be used to mode-lock a laser, as explained in the text.

The Kerr lens immediately disappears (if the medium is well chosen), but is re-created when the intense pulse returns from the mirror at the far end. In this way, that particular bunch of photons may grow to considerable intensity because it alone is stimulating emission in the cavity.

### 13C.4 Time-resolved spectroscopy

The ability of lasers to produce pulses of very short duration is particularly useful in chemistry when we want to monitor processes in time. In **time-resolved spectroscopy**, laser pulses are used to obtain the absorption, emission, or Raman spectrum of reactants, intermediates, products, and even transition states of reactions. It is also possible to study energy transfer, molecular rotations, vibrations, and conversion from one mode of motion to another.

The arrangement shown in Fig. 13C.10 is often used to study ultrafast chemical reactions that can be initiated by light (Topic 20G). A strong and short laser pulse, the *pump*, promotes a molecule A to an excited electronic state  $A^*$  that can either emit a photon (as fluorescence or phosphorescence) or react with another species B to yield a product C:

Here [AB] denotes either an intermediate or an activated complex. The rates of appearance and disappearance of the various species are determined by observing time-dependent changes in the absorption spectrum of the sample during the course of the reaction. This monitoring is done by passing a weak pulse of white light, the *probe*, through the sample at different times after the laser pulse. Pulsed 'white' light can be generated directly from the laser pulse by the phenomenon of **continuum generation**, in which focusing a short laser pulse on a vessel containing water, carbon tetrachloride, or sapphire

**Figure 13C.10** A configuration used for time-resolved absorption spectroscopy, in which the same pulsed laser is used to generate a monochromatic pump pulse and, after continuum generation in a suitable liquid, a 'white' light probe pulse. The time delay between the pump and probe pulses may be varied.

results in an outgoing beam with a wide distribution of frequencies. A time delay between the strong laser pulse and the 'white' light pulse can be introduced by allowing one of the beams to travel a longer distance before reaching the sample. For example, a difference in travel distance of  $\Delta d = 3 \text{ mm}$  corresponds to a time delay  $\Delta t = \Delta d/c \approx 10 \text{ ps}$  between two beams, where  $c$  is the speed of light. The relative distances travelled by the two beams in Fig 13C.10 are controlled by directing the 'white' light beam to a motorized stage carrying a pair of mirrors.

Variations of the arrangement in Fig 13C.10 can be used for the observation of the decay of an excited state and of time-resolved Raman spectra during the course of the reaction. The lifetime of  $A^*$  can be determined by exciting A as before and measuring the decay of the fluorescence intensity after the pulse with a fast photodetector system. In this case, continuum generation is not necessary. Time-resolved resonance Raman spectra of A,  $A^*$ , B, [AB], or C can be obtained by initiating the reaction with a strong laser pulse of a certain wavelength and then, sometime later, irradiating the sample with another laser pulse that can excite the resonance Raman spectrum of the desired species. Also in this case continuum generation is not necessary.

### 13C.5 Examples of practical lasers

Figure 13C.11 summarizes the requirements for an efficient laser. In practice, the requirements can be satisfied by using a variety of different systems. We have already considered the ruby and neodymium lasers, and here we review other arrangements that are commonly available. We also include some lasers that operate by using other than electronic transitions. Noticeably absent from this discussion are the ubiquitous diode lasers, which we discuss in Topic 18D.

Figure 13C.11 A summary of the features needed for efficient laser action.

### (a) Gas lasers

Because gas lasers can be cooled by a rapid flow of the gas through the cavity, they can be used to generate high powers. The pumping is normally achieved using a gas that is different from the gas responsible for the laser emission itself.

In the **helium–neon laser** the active medium is a mixture of helium and neon in a mole ratio of about 5:1 (Fig. 13C.12). The initial step is the excitation of an He atom to the metastable  $1s^1 2s^1$  configuration by using an electric discharge (the collisions of electrons and ions cause transitions that are not restricted by electric-dipole selection rules). The excitation energy of this transition happens to match an excitation energy of neon, and during an He–Ne collision efficient transfer of energy may occur, leading to the production of highly excited, metastable Ne atoms with unpopulated intermediate states. Laser action generating 633 nm radiation (among about 100 other lines) then occurs.

The **argon-ion laser** (Fig. 13C.13), one of a number of ‘ion lasers’, consists of argon at about 1 Torr, through which is passed an electric discharge. The discharge results in the formation of  $\text{Ar}^+$  and  $\text{Ar}^{2+}$  ions in excited states, which undergo a laser transition to a lower state. These ions then revert to their ground

Figure 13C.12 The transitions involved in a helium–neon laser. The pumping (of the neon) depends on a coincidental matching of the helium and neon energy separations, so excited He atoms can transfer their excess energy to Ne atoms during a collision.

Figure 13C.13 The transitions involved in an argon-ion laser.

states by emitting hard (short wavelength) ultraviolet radiation (at 72 nm), and are then neutralized by a series of electrodes in the laser cavity. One of the design problems is to find materials that can withstand this damaging residual radiation. There are many lines in the laser transition because the excited ions may make transitions to many lower states, but two strong emissions from  $\text{Ar}^+$  are at 488 nm (blue) and 514 nm (green); other transitions occur elsewhere in the visible region, in the infrared, and in the ultraviolet. The **krypton-ion laser** works similarly. It is less efficient, but gives a wider range of wavelengths, the most intense being at 647 nm (red), but it can also generate yellow, green, and violet light.

The **carbon dioxide laser** works on a slightly different principle (Fig. 13C.14), for its radiation (between  $9.2\ \mu\text{m}$  and  $10.8\ \mu\text{m}$ , with the strongest emission at  $10.6\ \mu\text{m}$ , in the infrared) arises from vibrational transitions. Most of the working gas is nitrogen, which becomes vibrationally excited by electronic and ionic collisions in an electric discharge. The vibrational levels happen to coincide with the ladder of antisymmetric stretch ( $\nu_3$ , see Fig. 12E.2) energy levels of  $\text{CO}_2$ , which pick up the energy during a collision. Laser action then occurs from the lowest excited level of  $\nu_3$  to the lowest excited level of the symmetric stretch ( $\nu_1$ ), which has remained unpopulated during

Figure 13C.14 The transitions involved in a carbon dioxide laser. The pumping also depends on the coincidental matching of energy separations; in this case the vibrationally excited  $\text{N}_2$  molecules have excess energies that correspond to a vibrational excitation of the antisymmetric stretch of  $\text{CO}_2$ . The laser transition is from  $\nu=1$  of mode  $\nu_3$  to  $\nu=1$  of mode  $\nu_1$ .

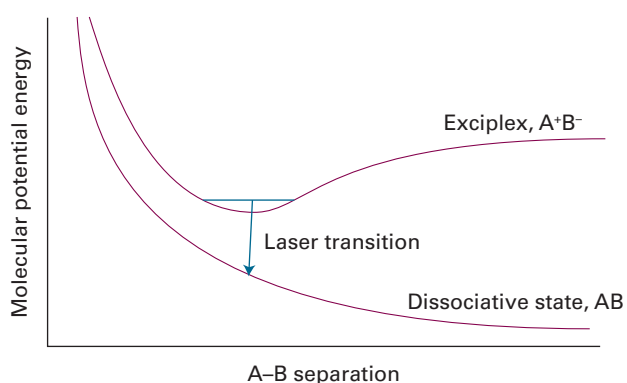

the collisions. This transition is allowed by anharmonicities in the molecular potential energy. Some helium is included in the gas to help remove energy from this state and maintain the population inversion.

In a **nitrogen laser**, the efficiency of the stimulated transition (at 337 nm, in the ultraviolet, the transition  $C^3\Pi_u \rightarrow B^3\Pi_g$ ) is so great that a single passage of a pulse of radiation is enough to generate laser radiation and mirrors are unnecessary: such lasers are said to be **superradiant**.

### (b) Exciplex lasers

The population inversion needed for laser action is achieved in an underhand way in **exciplex lasers**, for in these (as we shall see) the lower state does not effectively exist. This odd situation is achieved by forming an **exciplex**, a combination of two atoms that survives only in an excited state and which dissociates as soon as the excitation energy has been discarded. An exciplex can be formed in a mixture of xenon, chlorine, and neon (which acts as a buffer gas). An electric discharge through the mixture produces excited Cl atoms, which attach to the Xe atoms to give the exciplex  $XeCl^*$ . The exciplex survives for about 10 ns, which is time for it to participate in laser action at 308 nm (in the ultraviolet). As soon as  $XeCl^*$  has discarded a photon, the atoms separate because the molecular potential energy curve of the ground state is dissociative, and the ground state of the exciplex cannot become populated (Fig. 13C.15). The  $KrF^*$  exciplex laser is another example: it produces radiation at 249 nm.

The term ‘excimer laser’ is also widely encountered and used loosely when ‘exciplex laser’ is more appropriate. An exciplex has the form  $AB^*$  whereas an excimer, an excited dimer, is  $AA^*$ .

**Figure 13C.15** The molecular potential energy curves for an exciplex. The species can survive only as an excited state (in this case a charge-transfer complex,  $A^+B^-$ ), because on discarding its energy it enters the lower, dissociative state. Because only the upper state can exist, there is never any population in the lower state.

### (c) Dye lasers

Gas lasers and most solid state lasers operate at discrete frequencies and, although the frequency required may be selected by suitable optics, the laser cannot be tuned continuously. The tuning problem is overcome by using a titanium–sapphire laser (see below) or a **dye laser**, which has broad spectral characteristics because the solvent broadens the vibrational structure of the transitions into bands. Hence, it is possible to scan the wavelength continuously (by rotating the diffraction grating in the cavity) and achieve laser action at any chosen wavelength. A commonly used dye is rhodamine 6G in methanol (Fig. 13C.16). As the gain is very high, only a short length of the optical path need be through the dye. The excited states of the active medium, the dye, are sustained by another laser or a flash lamp, and the dye solution is flowed through the laser cavity to avoid thermal degradation.

### (d) Vibronic lasers

The **titanium–sapphire laser** (‘Ti:sapphire laser’), which consists of  $Ti^{3+}$  ions at low concentration in an alumina ( $Al_2O_3$ ) crystal. The electronic absorption spectrum of  $Ti^{3+}$  ion in sapphire is very similar to that shown in Fig. 13A.12, with a broad absorption band centred at around 500 nm that arises from vibronically allowed d–d transitions of the  $Ti^{3+}$  ion in an octahedral environment provided by oxygen atoms of the host lattice. As a result, the emission spectrum of  $Ti^{3+}$  in sapphire is also broad and laser action occurs over a wide range of wavelengths (Fig. 13C.17). Therefore, the titanium sapphire laser is an example of a **vibronic laser**, in which the laser transitions originate from vibronic transitions in the laser medium. The titanium sapphire laser is usually pumped by another laser, such as a Nd:YAG laser or an argon-ion laser, and can be operated in either a continuous or pulsed fashion.

**Figure 13C.16** The optical absorption spectrum of the dye rhodamine 6G and the region used for laser action.

**Figure 13C.17** The transitions involved in a Ti:sapphire laser. Monochromatic light from a pump laser induces a  ${}^2E \leftarrow {}^2T_2$  transition in a  $\text{Ti}^{3+}$  ion that resides in a site with octahedral symmetry. After radiationless vibrational excitation in the  ${}^2E$  state, laser emission occurs from a very large number of closely spaced vibronic states of the medium. As a result, the laser emits radiation over a broad spectrum that spans from about 700 nm to about 1000 nm.

Sapphire is an example of a Kerr medium that facilitates the mode locking of titanium sapphire lasers, resulting in very short (20–100 fs,  $1 \text{ fs} = 10^{-15} \text{ s}$ ) pulses. When considered together with broad wavelength tunability (700–1000 nm), these features of the titanium sapphire laser justify its wide use in modern spectroscopy and photochemistry.

## Checklist of concepts

- 1. **Laser action** is the stimulated emission of coherent radiation between states related by a population inversion.
- 2. A **population inversion** is a condition in which the population of an upper state is greater than that of a relevant lower state.
- 3. The **resonant modes** of a laser are the wavelengths of radiation sustained inside a laser cavity.
- 4. Laser pulses are generated by the techniques of **Q-switching** and **mode locking**.
- 5. In **time-resolved spectroscopy**, laser pulses are used to obtain the absorption, emission, or Raman spectrum of reactants, intermediates, products, and even transition states of reactions.
- 6. Practical lasers include **gas**, **dye**, **exciplex**, and **vibronic lasers**.

## Checklist of equations

Property	Equation	Comment	Equation number
Resonant modes	$n \times \frac{1}{2} \lambda = L$	Laser cavity of length $L$	13C.1
Coherence length	$l_c = \lambda^2 / 2\Delta\lambda$		13C.2
Mode-locked laser output	$I(t) \propto E_0^2 \{ \sin^2(N\pi ct/2L) / \sin^2(\pi ct/2L) \}$	$N$ locked modes	13C.3

# CHAPTER 13 Electronic transitions

## TOPIC 13A Electronic spectra

### Discussion questions

**13A.1** Explain the origin of the term symbol  ${}^3\Sigma_g^-$  for the ground state of dioxygen.

**13A.2** Explain the basis of the Franck–Condon principle and how it leads to the formation of a vibrational progression.

**13A.3** How do the band heads in P and R branches arise? Could the Q branch show a head?

### Exercises

**13A.1(a)** One of the excited states of the  $C_2$  molecule has the valence electron configuration  $1\sigma_g^2 1\sigma_u^2 1\pi_u^3 1\pi_g^1$ . Give the multiplicity and parity of the term.

**13A.1(b)** Another of the excited states of the  $C_2$  molecule has the valence electron configuration  $1\sigma_g^2 1\sigma_u^2 1\pi_u^2 1\pi_g^2$ . Give the multiplicity and parity of the term.

**13A.2(a)** Which of the following transitions are electric-dipole allowed?

(i)  ${}^2\Pi \leftrightarrow {}^2\Pi$ , (ii)  ${}^1\Sigma \leftrightarrow {}^1\Sigma$ , (iii)  $\Sigma \leftrightarrow \Delta$ , (iv)  $\Sigma^+ \leftrightarrow \Sigma^-$ , (v)  $\Sigma^+ \leftrightarrow \Sigma^+$ .

**13A.2(b)** Which of the following transitions are electric-dipole allowed?

(i)  ${}^1\Sigma_g^+ \leftrightarrow {}^1\Sigma_u^+$ , (ii)  ${}^3\Sigma_g^+ \leftrightarrow {}^3\Sigma_u^+$ , (iii)  $\pi^* \leftrightarrow n$ .

**13A.3(a)** The ground-state wavefunction of a certain molecule is described by the vibrational wavefunction  $\psi_0 = N_0 e^{-ax^2}$ . Calculate the Franck–Condon factor for a transition to a vibrational state described by the wavefunction  $\psi_v = N_v e^{-a(x-x_0)^2/2}$ .

**13A.3(b)** The ground-state wavefunction of a certain molecule is described by the vibrational wavefunction  $\psi_0 = N_0 e^{-ax^2}$ . Calculate the Franck–Condon factor for a transition to a vibrational state described by the wavefunction  $\psi_v = N_v x e^{-a(x-x_0)^2/2}$ .

**13A.4(a)** Suppose that the ground vibrational state of a molecule is modelled by using the particle-in-a-box wavefunction  $\psi_0 = (2/L)^{1/2} \sin(\pi x/L)$  for  $0 \leq x \leq L$  and 0 elsewhere. Calculate the Franck–Condon factor for a transition to a vibrational state described by the wavefunction  $\psi' = (2/L)^{1/2} \sin\{\pi(x-L/4)/L\}$  for  $L/4 \leq x \leq 5L/4$  and 0 elsewhere.

**13A.4(b)** Suppose that the ground vibrational state of a molecule is modelled by using the particle-in-a-box wavefunction  $\psi_0 = (2/L)^{1/2} \sin(\pi x/L)$  for  $0 \leq x \leq L$  and 0 elsewhere. Calculate the Franck–Condon factor for a transition to a vibrational state described by the wavefunction  $\psi' = (2/L)^{1/2} \sin\{\pi(x-L/2)/L\}$  for  $L/2 \leq x \leq 3L/2$  and 0 elsewhere.

**13A.5(a)** Use eqn 13A.8a to infer the value of  $J$  corresponding to the location of the band head of the P branch of a transition.

**13A.5(b)** Use eqn 13A.8c to infer the value of  $J$  corresponding to the location of the band head of the R branch of a transition.

**13A.6(a)** The following parameters describe the electronic ground state and an excited electronic state of SnO:  $\tilde{B} = 0.3540 \text{ cm}^{-1}$ ,  $\tilde{B}' = 0.3101 \text{ cm}^{-1}$ . Which branch of the transition between them shows a head? At what value of  $J$  will it occur?

**13A.6(b)** The following parameters describe the electronic ground state and an excited electronic state of BeH:  $\tilde{B} = 10.308 \text{ cm}^{-1}$ ,  $\tilde{B}' = 10.470 \text{ cm}^{-1}$ . Which branch of the transition between them shows a head? At what value of  $J$  will it occur?

**13A.7(a)** The R-branch of the  ${}^1\Pi_u \leftarrow {}^1\Sigma_g^+$  transition of  $H_2$  shows a band head at the very low value of  $J=1$ . The rotational constant of the ground state is

**13A.4** Explain how colour can arise from molecules.

**13A.5** Suppose that you are a colour chemist and had been asked to intensify the colour of a dye without changing the type of compound, and that the dye in question was a conjugated polyene. (a) Would you choose to lengthen or to shorten the chain? (b) Would the modification to the length shift the apparent colour of the dye towards the red or the blue?

$60.80 \text{ cm}^{-1}$ . What is the rotational constant of the upper state? Has the bond length increased or decreased in the transition?

**13A.7(b)** The P-branch of the  ${}^2\Pi \leftarrow {}^2\Sigma^+$  transition of CdH shows a band head at  $J=25$ . The rotational constant of the ground state is  $5.437 \text{ cm}^{-1}$ . What is the rotational constant of the upper state? Has the bond length increased or decreased in the transition?

**13A.8(a)** The complex ion  $[\text{Fe}(\text{OH}_2)_6]^{3+}$  has an electronic absorption spectrum with a maximum at 700 nm. Estimate a value of  $\Delta_O$  for the complex.

**13A.8(b)** The complex ion  $[\text{Fe}(\text{CN})_6]^{3-}$  has an electronic absorption spectrum with a maximum at 305 nm. Estimate a value of  $\Delta_O$  for the complex.

**13A.9(a)** Suppose that we can model a charge-transfer transition in a one-dimensional system as a process in which a rectangular wavefunction that is nonzero in the range  $0 \leq x \leq a$  makes a transition to another rectangular wavefunction that is nonzero in the range  $\frac{1}{2}a \leq x \leq b$ . Evaluate the transition moment  $\int \psi_f x \psi_i dx$ . (Assume  $a < b$ .)

**13A.9(b)** Suppose that we can model a charge-transfer transition in a one-dimensional system as a process in which an electron described by a rectangular wavefunction that is nonzero in the range  $0 \leq x \leq a$  makes a transition to another rectangular wavefunction that is nonzero in the range  $ca \leq x \leq a$  where  $0 \leq c \leq 1$ . Evaluate the transition moment  $\int \psi_f x \psi_i dx$  and explore its dependence on  $c$ .

**13A.10(a)** Suppose that we can model a charge-transfer transition in a one-dimensional system as a process in which a Gaussian wavefunction centred on  $x=0$  and width  $a$  makes a transition to another Gaussian wavefunction of the same width centred on  $x=\frac{1}{2}a$ . Evaluate the transition moment  $\int \psi_f x \psi_i dx$ .

**13A.10(b)** Suppose that we can model a charge-transfer transition in a one-dimensional system as a process in which an electron described by a Gaussian wavefunction centred on  $x=0$  and width  $a$  makes a transition to another Gaussian wavefunction of width  $a/2$  and centred on  $x=0$ . Evaluate the transition moment  $\int \psi_f x \psi_i dx$ .

**13A.11(a)** The two compounds 2,3-dimethyl-2-butene (1) and 2,5-dimethyl-2,4-hexadiene (2) are to be distinguished by their ultraviolet absorption spectra. The maximum absorption in one compound occurs at 192 nm and in the other at 243 nm. Match the maxima to the compounds and justify the assignment.

1 2,3-Dimethyl-2-butene

2 2,5-Dimethyl-2,4-hexadiene

**13A.11(b)** 3-Buten-2-one (3) has a strong absorption at 213 nm and a weaker absorption at 320 nm. Justify these features and assign the ultraviolet absorption transitions.

**3** 3-Buten-2-one

## Problems

**13A.1\*** J.G. Dojahn et al. (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of the ground and electronic states of homonuclear diatomic halogen anions. These anions have a  ${}^2\Sigma_u^+$  ground state and  ${}^2\Pi_g$ ,  ${}^2\Pi_u$ , and  ${}^2\Sigma_g^+$  excited states. To which of the excited states are electric-dipole transitions allowed? Explain your conclusion.

**13A.2** The vibrational wavenumber of the oxygen molecule in its electronic ground state is  $1580\text{ cm}^{-1}$ , whereas that in the excited state ( $B^3\Sigma_u^-$ ), to which there is an allowed electronic transition, is  $700\text{ cm}^{-1}$ . Given that the separation in energy between the minima in their respective potential energy curves of these two electronic states is  $6.175\text{ eV}$ , what is the wavenumber of the lowest energy transition in the band of transitions originating from the  $\nu=0$  vibrational state of the electronic ground state to this excited state? Ignore any rotational structure or anharmonicity.

**13A.3** A transition of particular importance in  $\text{O}_2$  gives rise to the Schumann–Runge band in the ultraviolet region. The wavenumbers (in  $\text{cm}^{-1}$ ) of transitions from the ground state to the vibrational levels of the first excited state ( ${}^3\Sigma_u^-$ ) are 50 062.6, 50 725.4, 51 369.0, 51 988.6, 52 579.0, 53 143.4, 53 679.6, 54 177.0, 54 641.8, 55 078.2, 55 460.0, 55 803.1, 56 107.3, 56 360.3, 56 570.6. What is the dissociation energy of the upper electronic state? (Use a Birge–Spencer plot, Topic 12D.) The same excited state is known to dissociate into one ground state O atom and one excited state atom with an energy  $190\text{ kJ mol}^{-1}$  above the ground state. (This excited atom is responsible for a great deal of photochemical mischief in the atmosphere.) Ground state  $\text{O}_2$  dissociates into two ground state atoms. Use this information to calculate the dissociation energy of ground-state  $\text{O}_2$  from the Schumann–Runge data.

**13A.4** You are now ready to understand more deeply the features of photoelectron spectra (Topic 10B). Figure 13.1 shows the photoelectron spectra of HBr. Disregarding for now the fine structure, the HBr lines fall into two main groups. The least tightly bound electrons (with the lowest ionization energies and hence highest kinetic energies when ejected) are those in the lone pairs of the Br atom. The next ionization energy lies at  $15.2\text{ eV}$ , and corresponds to the removal of an electron from the HBr  $\sigma$  bond. (a) The spectrum shows that ejection of a  $\sigma$  electron is accompanied by a considerable amount of vibrational excitation. Use the Franck–Condon principle to account for this observation. (b) Go on to explain why the lack of much vibrational structure in the other band is consistent with the nonbonding role of the  $\text{Br}4p_x$  and  $\text{Br}4p_y$  lone-pair electrons.

**13A.5** The highest kinetic energy electrons in the photoelectron spectrum of  $\text{H}_2\text{O}$  using  $21.22\text{ eV}$  radiation are at about  $9\text{ eV}$  and show a large vibrational spacing of  $0.41\text{ eV}$ . The symmetric stretching mode of the neutral  $\text{H}_2\text{O}$  molecule lies at  $3652\text{ cm}^{-1}$ . (a) What conclusions can be drawn from the nature of the orbital from which the electron is ejected? (b) In the same spectrum of  $\text{H}_2\text{O}$ , the band near  $7.0\text{ eV}$  shows a long vibrational series with spacing  $0.125\text{ eV}$ . The bending mode of  $\text{H}_2\text{O}$  lies at  $1596\text{ cm}^{-1}$ . What conclusions can you draw about the characteristics of the orbital occupied by the photoelectron?

**13A.6** A lot of information about the energy levels and wavefunctions of small inorganic molecules can be obtained from their ultraviolet spectra. An example of a spectrum with considerable vibrational structure, that of gaseous  $\text{SO}_2$  at  $25^\circ\text{C}$ , is shown in Fig. 13A.5. Estimate the integrated absorption coefficient for the transition. What electronic states are accessible from the  $A_1$  ground state of this  $C_{2v}$  molecule by electric dipole transitions?

\* These problems were supplied by Charles Trapp and Carmen Giunta.

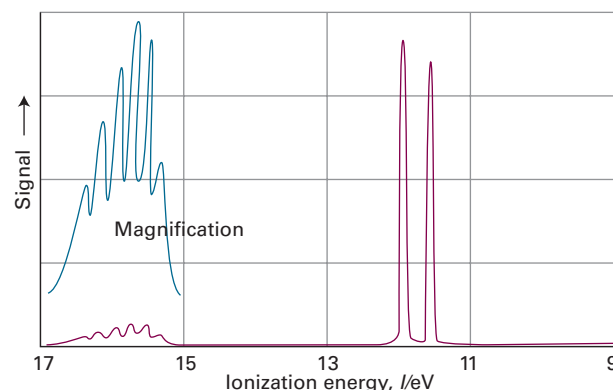

Figure 13.1 The photoelectron spectrum of HBr.

**13A.7** Assume that the electronic states of the  $\pi$  electrons of a conjugated molecule can be approximated by the wavefunctions of a particle in a one-dimensional box, and that the magnitude of the dipole moment can be related to the displacement along this length by  $\mu = -ex$ . Show that the transition probability for the transition  $n=1 \rightarrow n=2$  is nonzero, whereas that for  $n=1 \rightarrow n=3$  is zero. *Hints:* The following relation will be useful:  $\sin x \sin y = \frac{1}{2} \cos(x-y) - \frac{1}{2} \cos(x+y)$ . Relevant integrals are found in the Resource section.

**13A.8** 1,3,5-Hexatriene (a kind of ‘linear’ benzene) was converted into benzene itself. On the basis of a free-electron molecular orbital model (in which hexatriene is treated as a linear box and benzene as a ring), would you expect the lowest energy absorption to rise or fall in energy?

**13A.9** Estimate the magnitude of the transition dipole moment of a charge-transfer transition modelled as the migration of an electron from a  $\text{H}1s$  orbital on one atom to another  $\text{H}1s$  orbital on an atom a distance  $R$  away. Approximate the transition moment by  $-eRS$  where  $S$  is the overlap integral of the two orbitals. Sketch the transition moment as a function of  $R$  using the curve for  $S$  given in Fig. 10C.7. Why does the intensity of a charge-transfer transition fall to zero as  $R$  approaches 0 and infinity?

**13A.10** Figure 13.2 shows the UV-visible absorption spectra of a selection of amino acids. Suggest reasons for their different appearances in terms of the structures of the molecules.

Figure 13.2 Electronic absorption spectra of selected amino acids.

## TOPIC 13B Decay of excited states

### Discussion questions

**13B.1** Describe the mechanism of fluorescence. In what respects is a fluorescence spectrum not the exact mirror image of the corresponding absorption spectrum?

**13B.2** What is the evidence for the correctness of the mechanism of fluorescence?

### Exercises

**13B.1(a)** The line marked A in Fig. 13.3 is the fluorescence spectrum of benzophenone in solid solution in ethanol at low temperatures observed when the sample is illuminated with 360 nm ultraviolet radiation. What can be said about the vibrational energy levels of the carbonyl group in (i) its ground electronic state and (ii) its excited electronic state?

**13B.1(b)** When naphthalene is illuminated with 360 nm ultraviolet radiation it does not absorb, but the line marked B in Fig. 13.3 is the phosphorescence spectrum of a solid solution of a mixture of naphthalene and benzophenone in ethanol. Now a component of fluorescence from naphthalene can be detected. Account for this observation.

**13B.2(a)** The oxygen molecule absorbs ultraviolet radiation in a transition from its  $^3\Sigma_g^-$  ground electronic state to an excited state that is energetically close to a dissociative  $^5\Pi_u$  state. The absorption band has a relatively large experimental linewidth. Account for this observation.

**13B.2(b)** The hydrogen molecule absorbs ultraviolet radiation in a transition from its  $^1\Sigma_g^+$  ground electronic state to an excited state that is energetically close to a dissociative  $^1\Sigma_u^+$  state. The absorption band has a relatively large experimental linewidth. Account for this observation.

Figure 13.3 The fluorescence and phosphorescence spectra of two solutions.

### Problem

**13B.1** The fluorescence spectrum of anthracene vapour shows a series of peaks of increasing intensity with individual maxima at 440 nm, 410 nm, 390 nm, and 370 nm followed by a sharp cut-off at shorter wavelengths. The absorption

spectrum rises sharply from zero to a maximum at 360 nm with a trail of peaks of lessening intensity at 345 nm, 330 nm, and 305 nm. Account for these observations.

## TOPIC 13C Lasers

### Discussion questions

**13C.1** Describe the principles of (a) continuous-wave and (b) pulsed laser action.

**13C.2** How might you use a Q-switched or mode-locked laser in the study of a very fast chemical reaction that can be initiated by absorption of light?

### Exercises

**13C.1(a)** Consider an evacuated laser cavity of length 1.0 cm. What are the allowed wavelengths and frequencies of the resonant modes?

**13C.1(b)** Consider an evacuated laser cavity of length 3.0 m. What are the allowed wavelengths and frequencies of the resonant modes?

**13C.2(a)** A certain laser can generate radiation in pulses, each of which delivers an energy of 0.10 mJ, with peak power of 5.0 MW and average power of 7.0 kW. What are the pulse duration and repetition frequency?

**13C.2(b)** A certain laser can generate radiation in pulses, each of which delivers an energy of 20.0 μJ, with peak power of 100 kW and average power of 0.40 mW. What are the pulse duration and repetition frequency?

### Problems

**13C.1** Light-induced degradation of molecules, also called *photobleaching*, is a serious problem in fluorescence microscopy. A molecule of a fluorescent dye

commonly used to label biopolymers can withstand about  $10^6$  excitations by photons before light-induced reactions destroy its  $\pi$  system and the molecule

no longer fluoresces. For how long will a single dye molecule fluoresce while being excited by 1.0 mW of 488 nm radiation from a continuous-wave argon ion laser? You may assume that the dye has an absorption spectrum that peaks at 488 nm and that every photon delivered by the laser is absorbed by the molecule.

## Integrated activities

**13.1\*** One of the principal methods for obtaining the electronic spectra of unstable radicals is to study the spectra of comets, which are almost entirely due to radicals. Many radical spectra have been detected in comets, including that due to CN. These radicals are produced in comets by the absorption of far-ultraviolet solar radiation by their parent compounds. Subsequently, their fluorescence is excited by sunlight of longer wavelength. The spectra of comet Hale-Bopp (C/1995 O1) have been the subject of many recent studies. One such study is that of the fluorescence spectrum of CN in the comet at large heliocentric distances by R.M. Wagner and D.G. Schleicher (*Science* 275, 1918 (1997)), in which the authors determine the spatial distribution and rate of production of CN in the coma (the cloud constituting the major part of the head of the comet). The (0–0) vibrational band is centred on 387.6 nm and the weaker (1–1) band with relative intensity 0.1 is centred on 386.4 nm. The band heads for (0–0) and (0–1) are known to be 388.3 and 421.6 nm, respectively. From these data, calculate the energy of the excited  $S_1$  state relative to the ground  $S_0$  state, the vibrational wavenumbers and the difference in the vibrational wavenumbers of the two states, and the relative populations of the  $\nu=0$  and  $\nu=1$  vibrational levels of the  $S_1$  state. Also estimate the effective temperature of the molecule in the excited  $S_1$  state. Only eight rotational levels of the  $S_1$  state are thought to be populated. Is that observation consistent with the effective temperature of the  $S_1$  state?

**13.2** Use a group theoretical argument to decide which of the following transitions are electric-dipole allowed: (a) the  $\pi^* \leftarrow \pi$  transition in ethene, (b) the  $\pi^* \leftarrow n$  transition in a carbonyl group in a  $C_{2v}$  environment.

**13.3** Use molecule (4) as a model of the *trans* conformation of the chromophore found in rhodopsin. In this model, the methyl group bound to the nitrogen atom of the protonated Schiff's base replaces the protein. (a) Using molecular modelling software and the computational method of your instructor's choice, calculate the energy separation between the HOMO and

**13C.2** Use mathematical software or an electronic spreadsheet to simulate the output of a mode-locked laser (that is, plots such as that shown in Fig. 13C.8) for  $L=30$  cm and  $N=100$  and 1000.

LUMO of (4). (b) Repeat the calculation for the 11-*cis* form of (4).

(c) Based on your results from parts (a) and (b), do you expect the experimental frequency for the  $\pi^* \leftarrow \pi$  visible absorption of the *trans* form of (4) to be higher or lower than that for the 11-*cis* form of (4)?

**13.4** Aromatic hydrocarbons and  $I_2$  form complexes from which charge-transfer electronic transitions are observed. The hydrocarbon acts as an electron donor and  $I_2$  as an electron acceptor. The energies  $h\nu_{\max}$  of the charge-transfer transitions for a number of hydrocarbon- $I_2$  complexes are given below:

Hydrocarbon	benzene	biphenyl	naphthalene	phenanthrene	pyrene	anthracene
$h\nu_{\max}/\text{eV}$	4.184	3.654	3.452	3.288	2.989	2.890

Investigate the hypothesis that there is a correlation between the energy of the HOMO of the hydrocarbon (from which the electron comes in the charge-transfer transition) and  $h\nu_{\max}$ . Use one of the computational methods discussed in Topic 10E to determine the energy of the HOMO of each hydrocarbon in the data set.

**13.5** Spin angular momentum is conserved when a molecule dissociates into atoms. What atom multiplicities are permitted when (a) an  $O_2$  molecule, (b) an  $N_2$  molecule dissociates into atoms?

# CHAPTER 14

## Magnetic resonance

The techniques of ‘magnetic resonance’ probe transitions between spin states of nuclei and electrons in molecules. ‘Nuclear magnetic resonance’ (NMR) spectroscopy, the focus of this chapter, is one of the most widely used procedures in chemistry for the exploration of structural and dynamical properties of molecules of all sizes, up to as large as biopolymers.

### 14A General principles

The chapter begins with an account of the principles that govern spectroscopic transitions between spin states of nuclei and electrons in molecules. It also describes simple experimental arrangements for the detection of these transitions. The concepts developed in this Topic prepare the ground for a discussion of the chemical applications of NMR and ‘electron paramagnetic resonance’ (EPR).

### 14B Features of NMR spectra

This Topic contains a discussion of conventional NMR, showing how the properties of a magnetic nucleus are affected by its electronic environment and the presence of magnetic nuclei in its vicinity. These concepts lead to understanding of how molecular structure governs the appearance of NMR spectra.

### 14C Pulse techniques in NMR

In this Topic we turn to the modern versions of NMR, which are based on the use of pulses of electromagnetic radiation and the processing of the resulting signal by ‘Fourier transform’ techniques. It is through the application of these pulse

techniques that NMR spectroscopy can probe a vast array of small and large molecules in a variety of environments.

### 14D Electron paramagnetic resonance

The experimental techniques for EPR resemble those used in the early days of NMR. The information obtained is used to investigate species with unpaired electrons. This Topic includes a brief survey of the applications of EPR to the study of organic radicals and d-metal complexes.

### What is the impact of this material?

Magnetic resonance techniques are ubiquitous in chemistry, as they are an enormously powerful analytical and structural technique, especially in organic chemistry and biochemistry. One of the most striking applications of nuclear magnetic resonance is in medicine. ‘Magnetic resonance imaging’ (MRI) is a portrayal of the concentrations of protons in a solid object (*Impact* I14.1). The technique is particularly useful for diagnosing disease. In *Impact* I14.2 we highlight an application of electron paramagnetic resonance in materials science and biochemistry: the use of a ‘spin probe’, a radical that interacts with biopolymer or a nanostructure and has an EPR spectrum that reveals its structural and dynamical properties.

### ► Why do you need to know this material?

Nuclear magnetic resonance spectroscopy is used widely in chemistry and medicine. To understand the power of magnetic resonance, you need to understand the principles that govern spectroscopic transitions between spin states of electrons and nuclei in molecules.

### ► What is the key idea?

Resonant absorption occurs when the separation of the energy levels of spins in a magnetic field matches the energy of incident photons.

### ► What do you need to know already?

You need to be familiar with the quantum mechanical concept of spin (Topic 9B), the Boltzmann distribution (*Foundations* B and Topic 15A), and the general features of spectroscopy (Topic 12A).

When two pendulums share a slightly flexible support and one is set in motion, the other is forced into oscillation by the motion of the common axle. As a result, energy flows between the two pendulums. The energy transfer occurs most efficiently when the frequencies of the two pendulums are identical. The

condition of strong effective coupling when the frequencies of two oscillators are identical is called **resonance**. Resonance is the basis of a number of everyday phenomena, including the response of radios to the weak oscillations of the electromagnetic field generated by a distant transmitter. Historically, spectroscopic techniques that measure transitions between nuclear and electron spin states have carried the term ‘resonance’ in their names because they have depended on matching a set of energy levels to a source of monochromatic radiation and observing the strong absorption that occurs at resonance. In fact, all spectroscopy is a form of resonant coupling between the electromagnetic field and the molecules; what distinguishes **magnetic resonance** is that the energy levels themselves are modified by the application of a magnetic field.

The Stern–Gerlach experiment (Topic 9B) provided evidence for electron spin. It turns out that many nuclei also possess spin angular momentum. Orbital and spin angular momenta give rise to magnetic moments, and to say that electrons and nuclei have magnetic moments means that, to some extent, they behave like small bar magnets with energies that depend on their orientation in an applied magnetic field. Here we establish how the energies of electrons and nuclei depend on the applied field. This material sets the stage for the exploration of the structure and dynamics of many kinds of molecules by magnetic resonance spectroscopy (Topics 14B–14D).

## 14A.1 Nuclear magnetic resonance

The application of resonance that we describe here depends on the fact that many nuclei possess spin angular momentum characterized by a **nuclear spin quantum number**  $I$  (the analogue of  $s$  for electrons). To understand the **nuclear magnetic resonance** (NMR) experiment we need to describe the behaviour of nuclei in magnetic fields and then the basic techniques for detecting spectroscopic transitions.

### (a) The energies of nuclei in magnetic fields

The nuclear spin quantum number,  $I$ , is a fixed characteristic property of a nucleus in its ground state (the only state we consider) and, depending on the nuclide, is either an integer or a half-integer (Table 14A.1). A nucleus with spin quantum number  $I$  has the following properties:

**Table 14A.1** Nuclear constitution and the nuclear spin quantum number\*

Number of protons	Number of neutrons	$I$
Even	Even	0
Odd	Odd	Integer (1, 2, 3, ...)
Even	Odd	Half-integer ( $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$ )
Odd	Even	Half-integer ( $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots$ )

\* The spin of a nucleus may be different if it is in an excited state; throughout this chapter we deal only with the ground state of nuclei.

- An angular momentum of magnitude  $\{I(I+1)\}^{1/2}\hbar$ .
- A component of angular momentum  $m_I\hbar$  on a specified axis ('the  $z$ -axis'), where  $m_I = I, I-1, \dots, -I$ .
- If  $I > 0$ , a magnetic moment with a constant magnitude and an orientation that is determined by the value of  $m_I$ .

Physical interpretation

According to the second property, the spin, and hence the magnetic moment, of the nucleus may lie in  $2I+1$  different orientations relative to an axis. A proton has  $I = \frac{1}{2}$  and its spin may adopt either of two orientations; a  $^{14}\text{N}$  nucleus has  $I = 1$  and its spin may adopt any of three orientations; both  $^{12}\text{C}$  and  $^{16}\text{O}$  have  $I = 0$  and hence zero magnetic moment.

Classically, the energy of a magnetic moment  $\mu$  in a magnetic field  $\mathcal{B}$  is equal to the scalar product (*Mathematical background 5* following Chapter 9)

$$E = -\boldsymbol{\mu} \cdot \mathcal{B} \quad (14A.1)$$

More formally,  $\mathcal{B}$  is the magnetic induction and is measured in tesla, T;  $1 \text{ T} = 1 \text{ kg s}^{-2} \text{ A}^{-1}$ . The (non-SI) unit gauss, G, is also occasionally used:  $1 \text{ T} = 10^4 \text{ G}$ . Quantum mechanically, we write the hamiltonian as

$$\hat{H} = -\hat{\boldsymbol{\mu}} \cdot \mathcal{B} \quad (14A.2)$$

To write an expression for  $\hat{\boldsymbol{\mu}}$ , we use the fact that, just as for electrons (Topic 9B), the magnetic moment of a nucleus is

proportional to its angular momentum. The operators in eqn 14A.2 are then:

$$\hat{\boldsymbol{\mu}} = \gamma_N \hat{\mathbf{I}} \quad \text{and} \quad \hat{H} = -\gamma_N \mathcal{B} \cdot \hat{\mathbf{I}} \quad (14A.3a)$$

where  $\gamma_N$  is the **nuclear magnetogyric ratio** of the specified nucleus, an empirically determined characteristic arising from its internal structure (Table 14A.2). For a magnetic field of magnitude  $\mathcal{B}_0$  along the  $z$ -direction, the hamiltonian in eqn 14A.3a becomes

$$\hat{H} = -\gamma_N \mathcal{B}_0 \hat{I}_z \quad (14A.3b)$$

Because the eigenvalues of the operator  $\hat{I}_z$  are  $m_I\hbar$ , the eigenvalues of this hamiltonian are

$$E_{m_I} = -\gamma_N \hbar \mathcal{B}_0 m_I \quad \text{Energies of a nuclear spin in a magnetic field} \quad (14A.4a)$$

When written in terms of the **nuclear magneton**,  $\mu_N$ ,

$$\mu_N = \frac{e\hbar}{2m_p} = 5.051 \times 10^{-27} \text{ J T}^{-1} \quad \text{Nuclear magneton} \quad (14A.4b)$$

(where  $m_p$  is the mass of the proton) and an empirical constant called the **nuclear  $g$ -factor**,  $g_I$ , the energy in eqn 14A.4a becomes

$$E_{m_I} = -g_I \mu_N \mathcal{B}_0 m_I \quad g_I = \frac{\gamma_N \hbar}{\mu_N} \quad \text{Energies of a nuclear spin in a magnetic field} \quad (14A.4c)$$

Nuclear  $g$ -factors are experimentally determined dimensionless quantities with values typically between  $-6$  and  $+6$  (Table 14A.2). Positive values of  $g_I$  and  $\gamma_N$  denote a magnetic moment that lies in the same direction as the spin angular momentum vector; negative values indicate that the magnetic moment and spin lie in opposite directions. A nuclear magnet is about 2000 times weaker than the magnet associated with electron spin.

For the remainder of our discussion of nuclear magnetic resonance we assume that  $\gamma_N$  is positive, as is the case for the majority of nuclei. In such cases, it follows from eqn 14A.4c

**Table 14A.2\*** Nuclear spin properties

Nuclide	Natural abundance/%	Spin $I$	$g$ -factor, $g_I$	Magnetogyric ratio, $\gamma_N/(10^7 \text{ T}^{-1} \text{ s}^{-1})$	NMR frequency at 1 T, $\nu/\text{MHz}$
$^1\text{n}$		$\frac{1}{2}$	-3.826	-18.32	29.164
$^1\text{H}$	99.98	$\frac{1}{2}$	5.586	26.75	42.576

\* More values are given in the *Resource section*.

that states with  $m_l > 0$  lie below states with  $m_l < 0$ . It follows that the energy separation between the lower  $m_l = +\frac{1}{2}$  ( $\alpha$ ) and upper  $m_l = -\frac{1}{2}$  ( $\beta$ ) states of a spin- $\frac{1}{2}$  nucleus, a nucleus with  $I = \frac{1}{2}$ , is

$$\Delta E = E_{-\frac{1}{2}} - E_{+\frac{1}{2}} = \frac{1}{2}\gamma_N \hbar B_0 - (-\frac{1}{2}\gamma_N \hbar B_0) = \gamma_N \hbar B_0 \quad (14A.5)$$

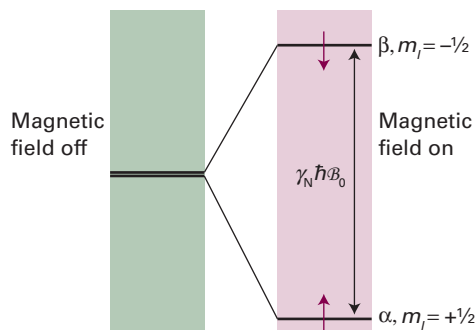

and resonant absorption occurs when the resonance condition

$$h\nu = \gamma_N \hbar B_0 \quad \text{or} \quad \nu = \frac{\gamma_N B_0}{2\pi} \quad \text{Spin-}\frac{1}{2} \text{ nuclei} \quad \text{Resonance condition} \quad (14A.6)$$

is fulfilled (Fig. 14A.1). At resonance there is strong coupling between the spins and the radiation, and absorption occurs as the spins flip from the lower energy state to the upper state.

It is sometimes useful to compare the quantum mechanical and classical pictures of magnetic nuclei pictured as tiny bar magnets. A bar magnet in an externally applied magnetic field undergoes the motion called **precession** as it twists round the direction of the field (Fig. 14A.2). The rate of precession  $\nu_L$  is called the **Larmor precession frequency**:

$$\nu_L = \frac{\gamma_N B_0}{2\pi} \quad \text{Definition} \quad \text{Larmor frequency of a nucleus} \quad (14A.7)$$

**Figure 14A.1** The nuclear spin energy levels of a spin- $\frac{1}{2}$  nucleus with positive magnetogyric ratio (for example,  $^1\text{H}$  or  $^{13}\text{C}$ ) in a magnetic field. Resonance occurs when the energy separation of the levels matches the energy of the photons in the electromagnetic field.

**Figure 14A.2** The interactions between the  $m_l$  states of a spin- $\frac{1}{2}$  nucleus and an external magnetic field may be visualized as the precession of the vectors representing the angular momentum.

It follows by comparing this expression with eqn 14A.6 that resonance absorption by spin- $\frac{1}{2}$  nuclei occurs when the Larmor precession frequency  $\nu_L$  is the same as the frequency of the applied electromagnetic field,  $\nu$ .

#### Brief illustration 14A.1 The resonance condition in NMR

To calculate the frequency at which radiation comes into resonance with proton ( $I = \frac{1}{2}$ ) spins in a 12.0 T magnetic field we use eqn 14A.6 as follows:

$$\nu = \frac{\overbrace{(2.6752 \times 10^8 \text{ T}^{-1} \text{ s}^{-1})}^{\gamma_N} \times \overbrace{(12.0 \text{ T})}^{B_0}}{2\pi} = 5.11 \times 10^8 \text{ s}^{-1} \\ = 511 \text{ MHz}$$

**Self-test 14A.1** Determine the resonance frequency for  $^{31}\text{P}$  nuclei, for which  $\gamma_N = 1.0841 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}$ , under the same conditions.

Answer: 207 MHz

### (b) The NMR spectrometer

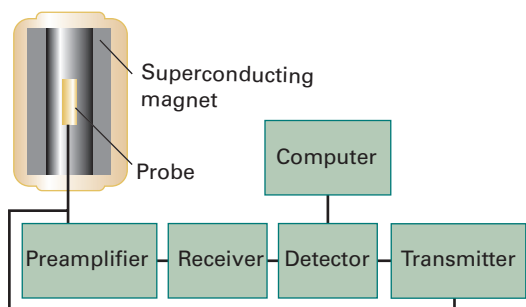

In its simplest form, NMR is the study of the properties of molecules containing magnetic nuclei by applying a magnetic field and observing the frequency of the resonant electromagnetic field. Larmor frequencies of nuclei at the fields normally employed (about 12 T) typically lie in the radiofrequency region of the electromagnetic spectrum (close to 500 MHz), so NMR is a radiofrequency technique. For much of our discussion we consider spin- $\frac{1}{2}$  nuclei, but NMR is applicable to nuclei with any non-zero spin. As well as protons, which are the most common nuclei studied by NMR, spin- $\frac{1}{2}$  nuclei include  $^{13}\text{C}$ ,  $^{19}\text{F}$ , and  $^{31}\text{P}$ .

An NMR spectrometer consists of the appropriate sources of radiofrequency radiation and a magnet that can produce a uniform, intense field. Most modern instruments use a superconducting magnet capable of producing fields of the order of 10 T and more (Fig. 14A.3). The sample is rotated rapidly to average out magnetic inhomogeneities; however, although sample spinning is essential for the investigation of small molecules, for large molecules it can lead to irreproducible results and is often avoided. Although a superconducting magnet (Topic 18C) operates at the temperature of liquid helium (4 K), the sample itself is normally at room temperature or held in a variable temperature enclosure between, typically,  $-150$  and  $+100$  °C.

Modern NMR spectroscopy uses pulses of radiofrequency radiation. These techniques of Fourier-transform (FT) NMR make possible the determination of structures of very large molecules in solution and in solids. They are discussed in Topic 14C.

The intensity of an NMR transition depends on a number of factors. We show in the following *Justification* that

$$\text{Intensity} \propto (N_\alpha - N_\beta) B_0 \quad (14A.8a)$$

**Figure 14A.3** The layout of a typical NMR spectrometer. The link from the transmitter to the detector indicates that the high frequency of the transmitter is subtracted from the high frequency received signal to give a low frequency signal for processing.

where

$$N_{\alpha} - N_{\beta} \approx \frac{N\gamma_N \hbar B_0}{2kT} \quad \text{Nuclei Population difference} \quad (14A.8b)$$

with  $N$  the total number of spins ( $N = N_{\alpha} + N_{\beta}$ ). It follows that decreasing the temperature increases the intensity by increasing the population difference.

#### Brief illustration 14A.2 Nuclear spin populations

For protons  $\gamma_N = 2.675 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}$ . Therefore, for 1 000 000 protons in a field of 10 T at 20 °C

$$N_{\alpha} - N_{\beta} \approx \frac{\overbrace{1000000}^N \times \overbrace{(2.675 \times 10^8 \text{ T}^{-1} \text{ s}^{-1})}^{\gamma_N} \times \overbrace{(1.055 \times 10^{-34} \text{ Js})}^{\hbar} \times \overbrace{10}^{B_0}}{2 \times \underbrace{(1.381 \times 10^{-23} \text{ JK}^{-1})}_k \times \underbrace{(293 \text{ K})}_T} \approx 35$$

Even in such a strong field there is only a tiny imbalance of population of about 35 in a million.

**Self-test 14A.2** For  $^{13}\text{C}$  nuclei,  $\gamma_N = 6.7283 \times 10^7 \text{ T}^{-1} \text{ s}^{-1}$ . Determine the magnetic field that would need to be achieved in order to induce the same imbalance in the distribution of  $^{13}\text{C}$  spins at 20 °C.

Answer: 40 T

#### Justification 14A.1 Intensities in NMR spectra

From the general considerations of transition intensities in Topic 12A, we know that the rate of absorption of electromagnetic radiation is proportional to the population of the lower energy state ( $N_{\alpha}$  in the case of a proton NMR transition) and the rate of stimulated emission is proportional to the population of the upper state ( $N_{\beta}$ ). At the low frequencies typical of magnetic resonance, spontaneous emission can be neglected

as it is very slow. Therefore, the net rate of absorption is proportional to the difference in populations, and we can write

$$\text{Rate of absorption} \propto N_{\alpha} - N_{\beta}$$

The intensity of absorption, the rate at which energy is absorbed, is proportional to the product of the rate of absorption (the rate at which photons are absorbed) and the energy of each photon. The latter is proportional to the frequency  $\nu$  of the incident radiation (through  $E = h\nu$ ). At resonance, this frequency is proportional to the applied magnetic field (through  $\nu = \gamma_N B_0 / 2\pi$ ), so we can write

$$\text{Rate of absorption} \propto (N_{\alpha} - N_{\beta}) B_0$$

as in eqn 14A.8a. To write an expression for the population difference, we use the Boltzmann distribution (*Foundations B* and Topic 15A) to write the ratio of populations as

$$\frac{N_{\beta}}{N_{\alpha}} = e^{-\frac{\Delta E}{\gamma_N \hbar B_0 / kT}} \approx e^{-x} = 1 - x + \dots \approx 1 - \frac{\gamma_N \hbar B_0}{kT}$$

The expansion of the exponential term is appropriate for  $\Delta E = \gamma_N \hbar B_0 \ll kT$ , a condition usually met for nuclear spins. It follows that

$$\begin{aligned} \frac{N_{\alpha} - N_{\beta}}{N_{\alpha} + N_{\beta}} &= \frac{N_{\alpha}(1 - N_{\beta}/N_{\alpha})}{N_{\alpha}(1 + N_{\beta}/N_{\alpha})} = \frac{1 - \overbrace{N_{\beta}/N_{\alpha}}^{1 - \gamma_N \hbar B_0 / kT}}{1 + \overbrace{N_{\beta}/N_{\alpha}}^{1 - \gamma_N \hbar B_0 / kT}} \\ &\approx \frac{1 - (1 - \gamma_N \hbar B_0 / kT)}{1 + (1 - \gamma_N \hbar B_0 / kT)} = \frac{\gamma_N \hbar B_0 / kT}{2} \end{aligned}$$

which is eqn 14A.8b.

By combining eqns 14A.8a and 14A.8b we see that the intensity is proportional to  $B_0^2$ , so NMR transitions can be enhanced significantly by increasing the strength of the applied magnetic field. The use of high magnetic fields also simplifies the appearance of spectra (a point explained in Topic 14B) and so allows them to be interpreted more readily. We can also conclude that absorptions of nuclei with large magnetogyric ratios ( $^1\text{H}$ , for instance) are more intense than those with small magnetogyric ratios ( $^{13}\text{C}$ , for instance).

## 14A.2 Electron paramagnetic resonance

**Electron paramagnetic resonance (EPR)**, or **electron spin resonance (ESR)**, is the study of molecules and ions containing unpaired electrons by observing the magnetic field at which they come into resonance with radiation of known frequency.

As we have done for NMR, we write expressions for the resonance condition in EPR and then describe the general features of EPR spectrometers.

### (a) The energies of electrons in magnetic fields

The spin magnetic moment of an electron, which has a spin quantum number  $s = \frac{1}{2}$  (Topic 9B), is proportional to its spin angular momentum. The spin magnetic moment and hamiltonian operators are, respectively,

$$\hat{\boldsymbol{\mu}} = \gamma_e \hat{\boldsymbol{s}} \quad \text{and} \quad \hat{H} = -\gamma_e \mathcal{B} \cdot \hat{\boldsymbol{s}} \quad (14A.9a)$$

where  $\hat{\boldsymbol{s}}$  is the spin angular momentum operator, and  $\gamma_e$  is the **magnetogyric ratio of the electron**:

$$\gamma_e = -\frac{g_e e}{2m_e} \quad \text{Electrons} \quad \text{Magnetogyric ratio} \quad (14A.9b)$$

with  $g_e = 2.002\,319\dots$  as the  **$g$ -value of the electron**. (Note that the current convention is to include the  $g$ -value in the definition of the magnetogyric ratio.) Dirac's relativistic theory, his modification of the Schrödinger equation to make it consistent with Einstein's special relativity, gives  $g_e = 2$ ; the additional  $0.002\,319\dots$  arises from interactions of the electron with the electromagnetic fluctuations of the vacuum that surrounds the electron. The negative sign of  $\gamma_e$  (arising from the sign of the electron's charge) shows that the magnetic moment is opposite in direction to the angular momentum vector.

For a magnetic field of magnitude  $\mathcal{B}_0$  in the  $z$ -direction,

$$\hat{H} = -\gamma_e \mathcal{B}_0 \hat{s}_z \quad (14A.10)$$

Because the eigenvalues of the operator  $\hat{s}_z$  are  $m_s \hbar$  with  $m_s = +\frac{1}{2}(\alpha)$  and  $m_s = -\frac{1}{2}(\beta)$ , it follows that the energies of an electron spin in a magnetic field are

$$E_{m_s} = -\gamma_e \hbar \mathcal{B}_0 m_s \quad \text{Energies of an electron spin in a magnetic field} \quad (14A.11a)$$

They can also be expressed in terms of the **Bohr magneton**,  $\mu_B$ , as

$$E_{m_s} = g_e \mu_B \mathcal{B}_0 m_s \quad \text{Energies of an electron spin in a magnetic field} \quad (14A.11b)$$

where

$$\mu_B = \frac{e\hbar}{2m_e} = 9.274 \times 10^{-24} \text{ J T}^{-1} \quad \text{Bohr magneton} \quad (14A.11c)$$

The Bohr magneton, a positive quantity, is often regarded as the fundamental quantum of magnetic moment.

In the absence of a magnetic field, the states with different values of  $m_s$  are degenerate. When a field is present, the

degeneracy is removed: the state with  $m_s = +\frac{1}{2}$  moves up in energy by  $\frac{1}{2} g_e \mu_B \mathcal{B}_0$  and the state with  $m_s = -\frac{1}{2}$  moves down by  $\frac{1}{2} g_e \mu_B \mathcal{B}_0$ . From eqn 14A.11b, the separation between the (upper)  $m_s = +\frac{1}{2}(\alpha)$  and (lower)  $m_s = -\frac{1}{2}(\beta)$  levels of an electron spin in a magnetic field of magnitude  $\mathcal{B}_0$  in the  $z$ -direction is

$$\Delta E = E_{+1/2} - E_{-1/2} = \frac{1}{2} g_e \mu_B \mathcal{B}_0 - (-\frac{1}{2} g_e \mu_B \mathcal{B}_0) = g_e \mu_B \mathcal{B}_0 \quad (14A.12a)$$

The energy separations come into resonance with the electromagnetic radiation of frequency  $\nu$  when

$$h\nu = g_e \mu_B \mathcal{B}_0 \quad \text{Electrons} \quad \text{Resonance condition} \quad (14A.12b)$$

This is the resonance condition for EPR (Fig. 14A.4). At resonance there is strong coupling between the electron spins and the radiation, and strong absorption occurs as the spins make the transition  $\alpha \leftarrow \beta$ .

#### Brief illustration 14A.3 The resonance condition in EPR

Magnetic fields of about 0.30 T (the value used in most commercial EPR spectrometers) correspond to resonance at

$$\begin{aligned} \nu &= \frac{\overbrace{(2.0023)}^{g_e} \times \overbrace{(9.274 \times 10^{-24} \text{ J T}^{-1})}^{\mu_B} \times \overbrace{(0.30 \text{ T})}^{\mathcal{B}_0}}{6.626 \times 10^{-34} \text{ J s}} \\ &= 8.4 \times 10^9 \text{ s}^{-1} = 8.4 \text{ GHz} \end{aligned}$$

which corresponds to a wavelength of 3.6 cm.

**Self-test 14A.3** Determine the magnetic field for EPR transitions in a spectrometer that uses radiation of wavelength 0.88 cm.

Answer: 1.2 T

**Figure 14A.4** Electron spin levels in a magnetic field. Note that the  $\beta$  state is lower in energy than the  $\alpha$  state (because the magnetogyric ratio of an electron is negative). Resonance is achieved when the frequency of the incident radiation matches the frequency corresponding to the energy separation.

### (b) The EPR spectrometer

It follows from *Brief illustration 14A.3* that most commercial EPR spectrometers operate at wavelengths of approximately 3 cm. Because 3 cm radiation falls in the microwave region of the electromagnetic spectrum, EPR is a microwave technique.

Both Fourier-transform (FT) and continuous wave (CW) EPR spectrometers are available. The FT-EPR instrument is based on the concepts developed in Topic 14C for NMR spectroscopy, except that pulses of microwaves are used to excite electron spins in the sample. The layout of the more common CW-EPR spectrometer is shown in Fig. 14A.5. It consists of a microwave source (a klystron or a Gunn oscillator), a cavity in which the sample is inserted in a glass or quartz container, a microwave detector, and an electromagnet with a field that can be varied in the region of 0.3 T. The EPR spectrum is obtained by monitoring the microwave absorption as the field is changed, and a typical spectrum (of the benzene radical anion,  $C_6H_6^-$ ) is shown in Fig. 14A.6. The peculiar appearance of the spectrum, which is in fact displayed as the first-derivative of the

**Figure 14A.5** The layout of a continuous-wave EPR spectrometer. A typical magnetic field is 0.3 T, which requires 9 GHz (3 cm) microwaves for resonance.

**Figure 14A.6** The EPR spectrum of the benzene radical anion,  $C_6H_6^-$ , in fluid solution.

**Figure 14A.7** When phase-sensitive detection is used, the signal is the first derivative of the absorption intensity. Note that the peak of the absorption corresponds to the point where the derivative passes through zero.

absorption, arises from the detection technique, which is sensitive to the slope of the absorption curve (Fig. 14A.7).

As usual, the intensities of spectral lines in EPR depend on the difference in populations between the ground and excited states. For an electron, the  $\beta$  state lies below the  $\alpha$  state in energy and, by a similar argument to that for nuclei,

$$N_{\beta} - N_{\alpha} \approx \frac{Ng_e\mu_B B_0}{2kT} \text{ Electrons} \quad \text{Population difference} \quad (14A.13)$$

where  $N$  is the total number of spins.

#### Brief illustration 14A.4 Electron spin populations

When 1000 electron spins are exposed to a 1.0 T magnetic field at 20 °C (293 K),

$$N_{\beta} - N_{\alpha} \approx \frac{\overbrace{1000}^N \times \overbrace{2.0023}^{g_e} \times \overbrace{(9.274 \times 10^{-24} \text{ J T}^{-1})}^{\mu_B} \times \overbrace{(1.0 \text{ T})}^{B_0}}{2 \times \underbrace{(1.381 \times 10^{-23} \text{ J K}^{-1})}_k \times \underbrace{(293 \text{ K})}_T} \approx 2.3$$

There is an imbalance of populations of only about 2 electrons in a thousand. However, the imbalance is much larger for electron spins than for nuclear spins (*Brief illustration 14A.2*) because the energy separation between the spin states of electrons is larger than that for nuclear spins even at the lower magnetic field strengths normally employed.

**Self-test 14A.4** It is common to conduct EPR experiments at very low temperatures. At what temperature would the imbalance in spin populations be 5 electrons in 100, with  $B_0 = 0.30$  T?

Answer: 4 K

## Checklist of concepts

- 1. The **nuclear spin quantum number**,  $I$ , of a nucleus is either a non-negative integer or half-integer.
- 2. Nuclei with different values of  $m_I$  have different energies in the presence of a magnetic field.
- 3. **Nuclear magnetic resonance** (NMR) is the observation of resonant absorption of radiofrequency electromagnetic radiation by nuclei in a magnetic field.
- 4. NMR spectrometers consist of a source of radiofrequency radiation and a magnet that provides a strong, uniform field.
- 5. The resonance absorption intensity increases with the strength of the applied magnetic field (as  $\mathcal{B}_0^2$ ).
- 6. Electrons with different values of  $m_s$  have different energies in the presence of a magnetic field.
- 7. **Electron paramagnetic resonance** (EPR) is the observation of resonant absorption of microwave electromagnetic radiation by unpaired electrons in a magnetic field.
- 8. EPR spectrometers consist of a microwave source, a cavity in which the sample is inserted, a microwave detector, and an electromagnet.

## Checklist of equations

Property	Equation	Comment	Equation number
Nuclear magneton	$\mu_N = e\hbar/2m_p$	$\mu_N = 5.051 \times 10^{-27} \text{ J T}^{-1}$	14A.4b

### ► Why do you need to know this material?

To make progress with the analysis of NMR spectra and extract the wealth of information they contain you need to understand how the appearance of a spectrum correlates with molecular structure.

### ► What is the key idea?

The resonance frequency of a magnetic nucleus is affected by its electronic environment and the presence of magnetic nuclei in its vicinity.

### ► What do you need to know already?

You need to be familiar with the general principles of magnetic resonance (Topic 14A) and specifically that resonance occurs when the frequency of the radiofrequency field matches the Larmor frequency.

Nuclear magnetic moments interact with the *local* magnetic field. The local field may differ from the applied field because the latter induces electronic orbital angular momentum (that is, the circulation of electronic currents) which gives rise to a small additional magnetic field  $\delta\mathcal{B}$  at the nuclei. This additional field is proportional to the applied field, and it is conventional to write

$$\delta\mathcal{B} = -\sigma\mathcal{B}_0 \quad \text{Definition} \quad \text{Shielding constant} \quad (14B.1)$$

where the dimensionless quantity  $\sigma$  is called the **shielding constant** of the nucleus ( $\sigma$  is usually positive but may be negative). The ability of the applied field to induce an electronic current in the molecule, and hence affect the strength of the resulting local magnetic field experienced by the nucleus, depends on the details of the electronic structure near the magnetic nucleus of interest, so nuclei in different chemical groups have different shielding constants. The calculation of reliable values of the shielding constant is very difficult, but trends in it are quite well understood and we concentrate on them.

## 14B.1 The chemical shift

Because the total local field  $\mathcal{B}_{\text{loc}}$  is

$$\mathcal{B}_{\text{loc}} = \mathcal{B}_0 + \delta\mathcal{B} = (1 - \sigma)\mathcal{B}_0 \quad (14B.2)$$

the nuclear Larmor frequency (eqn 14A.7 of Topic 14A,  $\nu_{\text{L}} = \gamma_{\text{N}}\mathcal{B}/2\pi$ ) becomes

$$\nu_L = \frac{\gamma_N \mathcal{B}_{\text{loc}}}{2\pi} = \frac{\gamma_N \mathcal{B}_0}{2\pi} (1 - \sigma) \quad (14B.3)$$

This frequency is different for nuclei in different environments. Hence, different nuclei, even of the same element, come into resonance at different frequencies if they are in different molecular environments.

The **chemical shift** of a nucleus is the difference between its resonance frequency and that of a reference standard. The standard for protons is the proton resonance in tetramethylsilane,  $\text{Si}(\text{CH}_3)_4$ , commonly referred to as TMS, which bristles with protons and dissolves without reaction in many solutions. For  $^{13}\text{C}$ , the reference frequency is the  $^{13}\text{C}$  resonance in TMS, and for  $^{31}\text{P}$  it is the  $^{31}\text{P}$  resonance in 85 per cent  $\text{H}_3\text{PO}_4(\text{aq})$ . Other references are used for other nuclei. The separation of the resonance of a particular group of nuclei from the standard increases with the strength of the applied magnetic field because the induced field is proportional to the applied field; the stronger the latter, the greater the shift.

Chemical shifts are reported on the  $\delta$  scale, which is defined as

$$\delta = \frac{\nu - \nu^\circ}{\nu^\circ} \times 10^6 \quad \text{Definition } \delta \text{ Scale} \quad (14B.4)$$

where  $\nu^\circ$  is the resonance frequency of the standard. The advantage of the  $\delta$  scale is that shifts reported on it are independent of the applied field (because both numerator and denominator are proportional to the applied field). The resonance frequencies themselves, however, do depend on the applied field through

$$\nu = \nu^\circ + (\nu^\circ / 10^6) \delta \quad (14B.5)$$

#### Brief illustration 14B.1 The $\delta$ scale

A nucleus with  $\delta = 1.00$  in a spectrometer where  $\nu^\circ = 500$  MHz (a '500 MHz NMR spectrometer'), will have a shift relative to the reference equal to

$$\nu - \nu^\circ = (500 \text{ MHz} / 10^6) \times 1.00 = (500 \text{ Hz}) \times 1.00 = 500 \text{ Hz}$$

because  $1 \text{ MHz} = 10^6 \text{ Hz}$ . In a spectrometer operating at  $\nu^\circ = 100$  MHz, the shift relative to the reference would be only 100 Hz.

*A note on good practice* In much of the literature, chemical shifts are reported in parts per million, ppm, in recognition of the factor of  $10^6$  in the definition; this is unnecessary. If you see ' $\delta = 10$  ppm', interpret it, and use it in eqn 14B.5, as  $\delta = 10$ .

**Self-test 14B.1** What is the shift of the resonance from TMS of a group of nuclei with  $\delta = 3.50$  and an operating frequency of 350 MHz?

Answer: 1.23 kHz

The relation between  $\delta$  and  $\sigma$  is obtained by substituting eqn 14B.3 into eqn 14B.4:

$$\begin{aligned} \delta &= \frac{(1 - \sigma) \mathcal{B}_0 - (1 - \sigma^\circ) \mathcal{B}_0}{(1 - \sigma^\circ) \mathcal{B}_0} \times 10^6 \\ &= \frac{\sigma^\circ - \sigma}{1 - \sigma^\circ} \times 10^6 \approx (\sigma^\circ - \sigma) \times 10^6 \end{aligned} \quad \text{Relation between } \delta \text{ and } \sigma \quad (14B.6)$$

The last line follows from  $\sigma^\circ \ll 1$ . As the shielding constant  $\sigma$ , gets smaller,  $\delta$  increases. Therefore, we speak of nuclei with large chemical shifts as being strongly **deshielded**. Some typical chemical shifts are given in Fig. 14B.1. As can be seen from the illustration, the nuclei of different elements have very different ranges of chemical shifts. The ranges exhibit the variety of electronic environments of the nuclei in molecules: the higher the atomic number of the element, the greater the number of electrons around the nucleus and hence the greater the range of the extent of shielding. By convention, NMR spectra are plotted with  $\delta$  increasing from right to left.

Figure 14B.1 The range of typical chemical shifts for (a)  $^1\text{H}$  resonances and (b)  $^{13}\text{C}$  resonances.

#### Example 14B.1 Interpreting the NMR spectrum of ethanol

Figure 14B.2 shows the NMR spectrum of ethanol. Account for the observed chemical shifts.

**Method** Consider the effect of an electron-withdrawing atom: it deshields strongly those protons to which it is bound, and has a smaller effect on distant protons.

**Answer** The spectrum is consistent with the following assignments:

- The  $\text{CH}_3$  protons form one group of nuclei with  $\delta = 1$ .

**Figure 14B.2** The  $^1\text{H}$ -NMR spectrum of ethanol. The bold letters denote the protons giving rise to the resonance peak, and the step-like curve is the integrated signal.

- The two  $\text{CH}_2$  protons are in a different part of the molecule, experience a different local magnetic field, and resonate at  $\delta=3$ .
- The OH proton is in another environment, and has a chemical shift of  $\delta=4$ .

The increasing value of  $\delta$  (that is, the decrease in shielding) is consistent with the electron-withdrawing power of the O atom: it reduces the electron density of the OH proton most, and that proton is strongly deshielded. It reduces the electron density of the distant methyl protons least, and those nuclei are least deshielded.

The relative intensities of the signals are commonly represented as the height of step-like curves superimposed on the spectrum, as in Fig. 14B.2. In ethanol the group intensities are in the ratio 3:2:1 because there are three  $\text{CH}_3$  protons, two  $\text{CH}_2$  protons, and one OH proton in each molecule.

**Self-test 14B.2** The NMR spectrum of acetaldehyde (ethanal) has lines at  $\delta=2.20$  and  $\delta=9.80$ . Which feature can be assigned to the CHO proton?

Answer:  $\delta=9.80$

## 14B.2 The origin of shielding constants

The calculation of shielding constants is difficult, even for small molecules, for it requires detailed information (using the techniques outlined in Topic 10E) about the distribution of electron density in the ground and excited states and the excitation energies of the molecule. Nevertheless, considerable success has been achieved with small molecules such as  $\text{H}_2\text{O}$  and  $\text{CH}_4$  and even large molecules, such as proteins, are within the scope of some types of calculation. However, it is easier to understand the different contributions to chemical shifts by studying the large body of empirical information now available.

The empirical approach supposes that the observed shielding constant is the sum of three contributions:

$$\sigma = \sigma(\text{local}) + \sigma(\text{neighbour}) + \sigma(\text{solvent}) \quad (14\text{B.7})$$

The **local contribution**,  $\sigma(\text{local})$ , is essentially the contribution of the electrons of the atom that contains the nucleus in question. The **neighbouring group contribution**,  $\sigma(\text{neighbour})$ , is the contribution from the groups of atoms that form the rest of the molecule. The **solvent contribution**,  $\sigma(\text{solvent})$ , is the contribution from the solvent molecules.

### (a) The local contribution

It is convenient to regard the local contribution to the shielding constant as the sum of a **diamagnetic contribution**,  $\sigma_d$ , and a **paramagnetic contribution**,  $\sigma_p$ :

$$\sigma(\text{local}) = \sigma_d + \sigma_p \quad \text{Local contribution to the shielding constant} \quad (14\text{B.8})$$

A diamagnetic contribution to  $\sigma(\text{local})$  opposes the applied magnetic field and shields the nucleus in question. A paramagnetic contribution to  $\sigma(\text{local})$  reinforces the applied magnetic field and deshields the nucleus in question. Therefore,  $\sigma_d > 0$  and  $\sigma_p < 0$ . The total local contribution is positive if the diamagnetic contribution dominates, and is negative if the paramagnetic contribution dominates.

The diamagnetic contribution arises from the ability of the applied field to generate a circulation of charge in the ground-state electron distribution of the atom. The circulation generates a magnetic field that opposes the applied field and hence shields the nucleus. The magnitude of  $\sigma_d$  depends on the electron density close to the nucleus and can be calculated from the **Lamb formula**:<sup>1</sup>

$$\sigma_d = \frac{e^2 \mu_0}{12\pi m_e} \left\langle \frac{1}{r} \right\rangle \quad \text{Lamb formula} \quad (14\text{B.9})$$

where  $\mu_0$  is the vacuum permeability (a fundamental constant, see inside the front cover) and  $r$  is the electron–nucleus distance.

#### Example 14B.2 Using the Lamb formula

Calculate the shielding constant for the proton in a free H atom.

**Method** To calculate  $\sigma_d$  from the Lamb formula, calculate the expectation value of  $1/r$  for a hydrogen 1s orbital. Wavefunctions are given in Table 9A.1.

**Answer** The wavefunction for a hydrogen 1s orbital is

<sup>1</sup> For a derivation, see our *Molecular quantum mechanics* (2011).

$$\psi = \left( \frac{1}{\pi a_0^3} \right)^{1/2} e^{-r/a_0}$$

so, because  $d\tau = r^2 dr \sin\theta d\theta d\phi$ , the expectation value of  $1/r$  is

$$\begin{aligned} \left\langle \frac{1}{r} \right\rangle &= \int \frac{\psi^* \psi}{r} d\tau = \frac{1}{\pi a_0^3} \int_0^{2\pi} d\phi \int_0^\pi \sin\theta d\theta \int_0^\infty r e^{-2r/a_0} dr \\ &= \frac{1}{\pi a_0^3} \times 4\pi \times \frac{a_0^2}{4} = \frac{1}{a_0} \end{aligned}$$

Therefore,

$$\begin{aligned} \sigma_d &= \frac{e^2 \mu_0}{12\pi m_e a_0} = \frac{(1.602 \times 10^{-19} \text{ C})^2 \times \left( 4\pi \times 10^{-7} \frac{\text{kg m}^2 \text{ s}^{-2}}{\text{A}^2} \right)}{12\pi \times (9.109 \times 10^{-31} \text{ kg}) \times (5.292 \times 10^{-11} \text{ m})} \\ &= 1.775 \times 10^{-5} \end{aligned}$$

**Self-test 14B.3** Derive a general expression for  $\sigma_d$  that applies to all hydrogenic atoms.

Answer:  $Ze^2 \mu_0 / 12\pi m_e a_0$

The diamagnetic contribution is the only contribution in closed-shell free atoms. It is also the only contribution to the local shielding for electron distributions that have spherical or cylindrical symmetry. Thus, it is the only contribution to the local shielding from inner cores of atoms, for cores remain nearly spherical even though the atom may be a component of a molecule and its valence electron distribution is highly distorted. The diamagnetic contribution is broadly proportional to the electron density of the atom containing the nucleus of interest. It follows that the shielding is decreased if the electron density on the atom is reduced by the influence of an electronegative atom nearby. That reduction in shielding as the electronegativity of a neighbouring atom increases translates into an increase in the chemical shift  $\delta$  (Fig. 14B.3).

The local paramagnetic contribution,  $\sigma_p$ , arises from the ability of the applied field to force electrons to circulate through the molecule by making use of orbitals that are unoccupied in the ground state. It is zero in free atoms and around the axes of linear molecules (such as ethyne,  $\text{HC}\equiv\text{CH}$ ) where the electrons can circulate freely and a field applied along the internuclear axis is unable to force them into other orbitals. We can expect large paramagnetic contributions from small atoms (because the induced currents are then close to the nucleus) in molecules with low lying excited states (because an applied field can then induce significant currents). In fact, the paramagnetic contribution is the dominant local contribution for atoms other than hydrogen.

### (b) Neighbouring group contributions

The neighbouring group contribution arises from the currents induced in nearby groups of atoms. Consider the influence

**Figure 14B.3** The variation of chemical shielding with electronegativity. The shifts for the methyl protons agree with the trend expected with increasing electronegativity. However, to emphasize that chemical shifts are subtle phenomena, notice that the trend for the methylene protons is opposite to that expected. For these protons another contribution (the magnetic anisotropy of C–H and C–X bonds) is dominant.

of the neighbouring group X on the proton H in a molecule such as H–X. The applied field generates currents in the electron distribution of X and gives rise to an induced magnetic moment proportional to the applied field; the constant of proportionality is the magnetic susceptibility,  $\chi$  (chi), of the group X:  $\mu_{\text{induced}} = \chi \mathcal{B}_0$ . The susceptibility is negative for a diamagnetic group because the induced moment is opposite to the direction of the applied field. The induced moment gives rise to a magnetic field with a component parallel to the applied field and at a distance  $r$  and angle  $\theta$  (1) that has the form (*The chemist's toolkit* 14B.1):

$$\mathcal{B}_{\text{local}} \propto \frac{\mu_{\text{induced}}}{r^3} (1 - 3\cos^2\theta) \quad \text{Local dipolar field} \quad (14B.10a)$$

#### The chemist's toolkit 14B.1 Dipolar fields

Standard electromagnetic theory gives the magnetic field at a point  $r$  from a point magnetic dipole  $\mu$  as

$$\mathcal{B} = \frac{\mu_0}{4\pi r^3} \left( \mu - \frac{3(\mu \cdot r)r}{r^2} \right)$$

where  $\mu_0$  is the vacuum permeability (a fundamental constant with the defined value  $4\pi \times 10^{-7} \text{ T}^2 \text{ J}^{-1} \text{ m}^3$ ). The electric field due to a point electric dipole is given by a similar expression:

$$\mathcal{E} = \frac{1}{4\pi\epsilon_0 r^3} \left( \boldsymbol{\mu} - \frac{3(\boldsymbol{\mu} \cdot \mathbf{r})\mathbf{r}}{r^2} \right)$$

where  $\epsilon_0$  is the vacuum permittivity, which is related to  $\mu_0$  by  $\epsilon_0 = 1/\mu_0 c^2$ . The component of magnetic field in the  $z$ -direction is

$$\mathcal{B}_z = \frac{\mu_0}{4\pi r^3} \left( \mu_z - \frac{3(\boldsymbol{\mu} \cdot \mathbf{r})z}{r^2} \right)$$

with  $z = r \cos \theta$ , the  $z$ -component of the distance vector  $\mathbf{r}$ . If the magnetic dipole is also parallel to the  $z$ -direction, it follows that

$$\mathcal{B}_z = \frac{\mu_0}{4\pi r^3} \left( \mu_z - \frac{3(\mu_z \cos \theta)(r \cos \theta)}{r^2} \right) = \frac{\mu\mu_0}{4\pi r^3} (1 - 3 \cos^2 \theta)$$

We see that the strength of the additional magnetic field experienced by the proton is inversely proportional to the cube of the distance  $r$  between H and X. If the magnetic susceptibility is independent of the orientation of the molecule (is 'isotropic'), the local field averages to zero because  $1 - 3 \cos^2 \theta$  is zero when averaged over a sphere (see Problem 14B.7). To a good approximation, the shielding constant  $\sigma$  (neighbour) depends on the distance  $r$

$$\sigma(\text{neighbour}) \propto (\chi_{\parallel} - \chi_{\perp}) \left( \frac{1 - 3 \cos^2 \theta}{r^3} \right) \quad \text{Neighbouring group contribution} \quad (14B.10b)$$

**Figure 14B.4** A depiction of the field arising from a point magnetic dipole. The three shades of colour represent the strength of field declining with distance (as  $1/r^3$ ), and each surface shows the angle dependence of the  $z$ -component of the field for each distance.

**Figure 14B.5** The variation of the function  $1 - 3 \cos^2 \theta$  with the angle  $\theta$ .

where  $\chi_{\parallel}$  and  $\chi_{\perp}$  are, respectively, the parallel and perpendicular components of the magnetic susceptibility, and  $\theta$  is the angle between the X–H axis and the symmetry axis of the neighbouring group (2). Equation 14B.10b shows that the neighbouring group contribution may be positive or negative according to the relative magnitudes of the two magnetic susceptibilities and the relative orientation of the nucleus with respect to X. If  $54.7^\circ < \theta < 125.3^\circ$ , then  $1 - 3 \cos^2 \theta$  is positive, but it is negative otherwise (Figs. 14B.4 and 14B.5).

#### Brief illustration 14B.2 Ring currents

A special case of a neighbouring group effect is found in aromatic compounds. The strong anisotropy of the magnetic susceptibility of the benzene ring is ascribed to the ability of the field to induce a *ring current*, a circulation of electrons around the ring, when it is applied perpendicular to the molecular plane. Protons in the plane are deshielded (Fig. 14B.6), but any that happen to lie above or below the plane (as members of substituents of the ring) are shielded.

**Figure 14B.6** The shielding and deshielding effects of the ring current induced in the benzene ring by the applied field. Protons attached to the ring are deshielded but a proton attached to a substituent that projects above the ring is shielded.

**Self-test 14B.4** Consider ethyne,  $\text{HC}\equiv\text{CH}$ . Are its protons shielded or deshielded by currents induced by the triple bond?

Answer: Shielded

### (c) The solvent contribution

A solvent can influence the local magnetic field experienced by a nucleus in a variety of ways. Some of these effects arise from specific interactions between the solute and the solvent (such as hydrogen-bond formation and other forms of Lewis acid–base complex formation). The anisotropy of the magnetic susceptibility of the solvent molecules, especially if they are aromatic, can also be the source of a local magnetic field. Moreover, if there are steric interactions that result in a loose but specific interaction between a solute molecule and a solvent molecule, then protons in the solute molecule may experience shielding or deshielding effects according to their location relative to the solvent molecule.

#### Brief illustration 14B.3 The effect of aromatic solvents

An aromatic solvent like benzene can give rise to local currents that shield or deshield a proton in a solute molecule. The arrangement shown in Fig. 14B.7 leads to shielding of a proton on the solute molecule.

**Figure 14B.7** An aromatic solvent (benzene here) can give rise to local currents that shield or deshield a proton in a solute molecule. In this relative orientation of the solvent and solute, the proton on the solute molecule is shielded.

**Self-test 14B.5** Refer to Fig. 14B.7 and suggest an arrangement that leads to deshielding of a proton on the solute molecule.

Answer: Proton on the solute molecule coplanar with the benzene ring

## 14B.3 The fine structure

The splitting of resonances into individual lines by spin–spin coupling shown in Fig. 14B.2 is called the **fine structure** of the

spectrum. It arises because each magnetic nucleus may contribute to the local field experienced by the other nuclei and so modify their resonance frequencies. The strength of the interaction is expressed in terms of the **scalar coupling constant**,  $J$ . The scalar coupling constant is so called because the energy of interaction it describes is proportional to the scalar product of the two interacting spins:  $E \propto \mathbf{I}_1 \cdot \mathbf{I}_2$ . As explained in *Mathematical background 5*, a scalar product depends on the angle between the two vectors, so writing the energy in this way is simply a way of saying that the energy of interaction between two spins depends on their relative orientation. The constant of proportionality in this expression is written  $hJ/\hbar^2$  (so  $E = (hJ/\hbar^2)\mathbf{I}_1 \cdot \mathbf{I}_2$ ): because each spin angular momentum is proportional to  $\hbar$ ,  $E$  is then proportional to  $hJ$  and  $J$  is a frequency (with units hertz, Hz). For nuclei that are constrained to align with the applied field in the  $z$ -direction, the only contribution to  $\mathbf{I}_1 \cdot \mathbf{I}_2$  is  $I_{1z}I_{2z}$ , with eigenvalues  $m_1m_2\hbar^2$ , so in that case the energy due to spin–spin coupling is

$$E_{m_1m_2} = hJm_1m_2 \quad \text{Spin–spin coupling energy} \quad (14B.11)$$

### (a) The appearance of the spectrum

In NMR, letters far apart in the alphabet (typically A and X) are used to indicate nuclei with very different chemical shifts; letters close together (such as A and B) are used for nuclei with similar chemical shifts. We shall consider first an AX system, a molecule that contains two spin- $\frac{1}{2}$  nuclei A and X with very different chemical shifts in the sense that the difference in chemical shift corresponds to a frequency that is large compared to  $J$ .

For a spin- $\frac{1}{2}$  AX system there are four spin states:  $\alpha_A\alpha_X$ ,  $\alpha_A\beta_X$ ,  $\beta_A\alpha_X$ ,  $\beta_A\beta_X$ . The energy depends on the orientation of the spins in the external magnetic field, and if spin–spin coupling is neglected

$$\begin{aligned} E_{m_A m_X} &= -\gamma_N \hbar (1 - \sigma_A) \mathcal{B}_0 m_A - \gamma_N \hbar (1 - \sigma_X) \mathcal{B}_0 m_X \\ &= -h\nu_A m_A - h\nu_X m_X \end{aligned} \quad (14B.12a)$$

where  $\nu_A$  and  $\nu_X$  are the Larmor frequencies of A and X and  $m_A$  and  $m_X$  are their quantum numbers ( $m_A = \pm\frac{1}{2}$ ,  $m_X = \pm\frac{1}{2}$ ). This expression gives the four lines on the left of Fig. 14B.8. When spin–spin coupling is included (by using eqn 14B.11), the energy levels are

$$E_{m_A m_X} = -h\nu_A m_A - h\nu_X m_X + hJm_A m_X \quad (14B.12b)$$

If  $J > 0$ , a lower energy is obtained when  $m_A m_X < 0$ , which is the case if one spin is  $\alpha$  and the other is  $\beta$ . A higher energy is obtained if both spins are  $\alpha$  or both spins are  $\beta$ . The opposite is true if  $J < 0$ . The resulting energy level diagram (for  $J > 0$ ) is shown on the right of Fig. 14B.8. We see that the  $\alpha\alpha$  and  $\beta\beta$

**Figure 14B.8** The energy levels of an AX system. The four levels on the left are those of the two spins in the absence of spin–spin coupling. The four levels on the right show how a positive spin–spin coupling constant affects the energies. The transitions shown are for  $\beta \leftarrow \alpha$  of A or X, the other nucleus (X or A, respectively) remaining unchanged. We have exaggerated the effect for clarity. In practice, the splitting caused by spin–spin coupling is much smaller than that caused by the applied field.

states are both raised by  $\frac{1}{4}hJ$  and that the  $\alpha\beta$  and  $\beta\alpha$  states are both lowered by  $\frac{1}{4}hJ$ .

When a transition of nucleus A occurs, nucleus X remains unchanged. Therefore, the A resonance is a transition for which  $\Delta m_A = +1$  and  $\Delta m_X = 0$ . There are two such transitions, one in which  $\beta_A \leftarrow \alpha_A$  occurs when the X nucleus is  $\alpha$ , and the other in which  $\beta_A \leftarrow \alpha_A$  occurs when the X nucleus is  $\beta$ . They are shown in Fig. 14B.8 and in a slightly different form in Fig. 14B.9. The energies of the transitions are

$$\Delta E = h\nu_A \pm \frac{1}{2}hJ \quad (14B.13a)$$

Therefore, the A resonance consists of a doublet of separation  $J$  centred on the chemical shift of A (Fig. 14B.10). Similar remarks apply to the X resonance, which consists of two

**Figure 14B.9** An alternative depiction of the energy levels and transitions shown in Fig. 14B.8. Once again, we have exaggerated the effect of spin–spin coupling.

**Figure 14B.10** The effect of spin–spin coupling on an AX spectrum. Each resonance is split into two lines separated by  $J$ . The pairs of resonances are centred on the chemical shifts of the protons in the absence of spin–spin coupling.

transitions according to whether the A nucleus is  $\alpha$  or  $\beta$  (as shown in Fig. 14B.9). The transition energies are

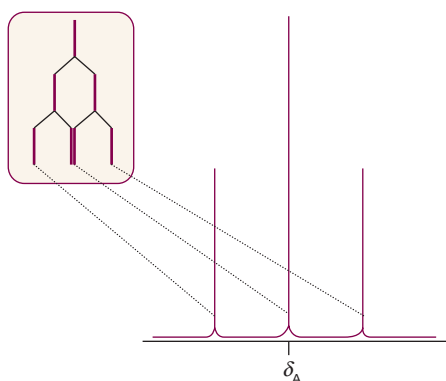

$$\Delta E = h\nu_X \pm \frac{1}{2}hJ \quad (14B.13b)$$

It follows that the X resonance also consists of two lines of the same separation  $J$ , but they are centred on the chemical shift of X (as shown in Fig. 14B.10).

If there is another X nucleus in the molecule with the same chemical shift as the first X (giving an  $AX_2$  species), the X resonance of the  $AX_2$  species is split into a doublet by A, as in the AX case discussed above (Fig. 14B.11). The resonance of A is split into a doublet by one X, and each line of the doublet is split again by the same amount by the second X (Fig. 14B.12). This splitting results in three lines in the intensity ratio 1:2:1 (because the central frequency can be obtained in two ways).

**Figure 14B.11** The X resonance of an  $AX_2$  species is also a doublet, because the two equivalent X nuclei behave like a single nucleus; however, the overall absorption is twice as intense as that of an AX species.

**Figure 14B.12** The origin of the 1:2:1 triplet in the A resonance of an  $AX_2$  species. The resonance of A is split into two by coupling with one X nucleus (as shown in the inset), and then each of those two lines is split into two by coupling to the second X nucleus. Because each X nucleus causes the same splitting, the two central transitions are coincident and give rise to an absorption line of double the intensity of the outer lines.

Three equivalent X nuclei (an  $AX_3$  species) split the resonance of A into four lines of intensity ratio 1:3:3:1 (Fig. 14B.13). The X resonance remains a doublet as a result of the splitting caused by A. In general,  $N$  equivalent spin- $\frac{1}{2}$  nuclei split the resonance of a nearby spin or group of equivalent spins into  $N+1$  lines with an intensity distribution given by Pascal's triangle (3). Successive rows of this triangle are formed by adding together the two adjacent numbers in the line above.

**Figure 14B.13** The origin of the 1:3:3:1 quartet in the A resonance of an  $AX_3$  species. The third X nucleus splits each of the lines shown in Fig. 14B.11 for an  $AX_2$  species into a doublet, and the intensity distribution reflects the number of transitions that have the same energy.

### Example 14B.3 Accounting for the fine structure in a spectrum

Account for the fine structure in the NMR spectrum of the C–H protons of ethanol.

**Method** Consider how each group of equivalent protons (for instance, three methyl protons) split the resonances of the other groups of protons. There is no splitting within groups of equivalent protons. Each splitting pattern can be decided by referring to Pascal's triangle.

**Answer** The three protons of the  $CH_3$  group split the resonance of the  $CH_2$  protons into a 1:3:3:1 quartet with a splitting  $J$ . Likewise, the two protons of the  $CH_2$  group split the resonance of the  $CH_3$  protons into a 1:2:1 triplet with the same splitting  $J$ . The OH resonance is not split because the OH protons migrate rapidly from molecule to molecule (including molecules of impurities in the sample) and their effect averages to zero. In gaseous ethanol, where this migration does not occur, the OH resonance appears as a triplet, showing that the  $CH_2$  protons interact with the OH proton.

**Self-test 14B.6** What fine structure can be expected for the protons in  $^{14}NH_4^+$ ? The spin quantum number of nitrogen-14 is 1.

Answer: 1:1:1 triplet from N

### (b) The magnitudes of coupling constants

The scalar coupling constant of two nuclei separated by  $N$  bonds is denoted  $^N J$ , with subscripts for the types of nuclei involved. Thus,  $^1 J_{CH}$  is the coupling constant for a proton joined directly to a  $^{13}C$  atom, and  $^2 J_{CH}$  is the coupling constant when the same two nuclei are separated by two bonds (as in  $^{13}C-C-H$ ). A typical value of  $^1 J_{CH}$  is in the range 120 to 250 Hz;  $^2 J_{CH}$  is between 10 and 20 Hz. Both  $^3 J$  and  $^4 J$  can give detectable effects in a spectrum, but couplings over larger numbers of bonds can generally be ignored. One of the longest range couplings that has been detected is  $^9 J_{HH} = 0.4$  Hz between the  $CH_3$  and  $CH_2$  protons in  $CH_3C \equiv C-C \equiv C-C \equiv C-CH_2OH$ .

As remarked (in the discussion following eqn 14B.12b), the sign of  $J_{XY}$  indicates whether the energy of two spins is lower when they are parallel ( $J < 0$ ) or when they are antiparallel ( $J > 0$ ). It is found that  $^1 J_{CH}$  is often positive,  $^2 J_{HH}$  is often negative,  $^3 J_{HH}$  is often positive, and so on. An additional point is that  $J$  varies with the angle between the bonds (Fig. 14B.14). Thus, a  $^3 J_{HH}$  coupling constant is often found to depend on the dihedral angle  $\phi$  (4) according to the Karplus equation:

**Figure 14B.14** The variation of the spin–spin coupling constant with angle predicted by the Karplus equation for an HCCH group and an HNCH group.

$${}^3J_{\text{HH}} = A + B\cos\phi + C\cos 2\phi \quad \text{Karplus equation} \quad (14\text{B.14})$$

with  $A$ ,  $B$ , and  $C$  empirical constants with values close to +7 Hz, –1 Hz, and +5 Hz, respectively, for an HCCH fragment. It follows that the measurement of  ${}^3J_{\text{HH}}$  in a series of related compounds can be used to determine their conformations. The coupling constant  ${}^1J_{\text{CH}}$  also depends on the hybridization of the C atom, as the following values indicate:

	sp	sp <sup>2</sup>	sp <sup>3</sup>
${}^1J_{\text{CH}}/\text{Hz}$	250	160	125

#### Brief illustration 14B.4 The Karplus equation

The investigation of H–N–C–H couplings in polypeptides can help reveal their conformation. For  ${}^3J_{\text{HH}}$  coupling in such a group,  $A = +5.1$  Hz,  $B = -1.4$  Hz, and  $C = +3.2$  Hz. For a helical polymer,  $\phi$  is close to  $120^\circ$ , which would give  ${}^3J_{\text{HH}} \approx 4$  Hz. For the sheet-like conformation,  $\phi$  is close to  $180^\circ$ , which would give  ${}^3J_{\text{HH}} \approx 10$  Hz.

**Self-test 14B.7** NMR experiments reveal that for H–C–C–H coupling in polypeptides,  $A = +3.5$  Hz,  $B = -1.6$  Hz, and  $C = +4.3$  Hz. In an investigation of the polypeptide flavodoxin, the  ${}^3J_{\text{HH}}$  coupling constant for such a grouping was determined to be 2.1 Hz. Is this value consistent with a helical or sheet conformation?

Answer: Helical conformation

### (c) The origin of spin–spin coupling

Spin–spin coupling is a very subtle phenomenon and it is better to treat  $J$  as an empirical parameter than to use calculated values. However, we can get some insight into its origins, if not its precise magnitude—or always reliably its sign—by considering the magnetic interactions within molecules.

A nucleus with spin projection  $m_I$  gives rise to a magnetic field with  $z$ -component  $\mathcal{B}_{\text{nuc}}$  at a distance  $R$ , where, to a good approximation,

$$\mathcal{B}_{\text{nuc}} = -\frac{\gamma_N \hbar \mu_0}{4\pi R^3} (1 - 3\cos^2 \theta) m_I \quad (14\text{B.15})$$

The angle  $\theta$  is defined in (1); we saw a version of this expression in eqn 14B.10a.

#### Brief illustration 14B.5 Magnetic fields from nuclei

The  $z$ -component of the magnetic field arising from a proton ( $m_I = \frac{1}{2}$ ) at  $R = 0.30$  nm, with its magnetic moment parallel to the  $z$ -axis ( $\theta = 0$ ) is

$$\begin{aligned} \mathcal{B}_{\text{nuc}} &= -\frac{\overbrace{(2.821 \times 10^{-26} \text{ J T}^{-1})}^{\gamma_N \hbar} \times \overbrace{4\pi \times 10^{-7} \text{ T}^2 \text{ J}^{-1} \text{ m}^3}^{\mu_0}}{4\pi \times \underbrace{(3.0 \times 10^{-10} \text{ m})^3}_R} \times \overbrace{(1 - 3\cos^2 \theta)}^{(-1)} m_I \\ &= 1.0 \times 10^{-4} \text{ T} = 0.10 \text{ mT} \end{aligned}$$

A field of this magnitude can give rise to the splitting of resonance signals in solid samples. In a liquid, the angle  $\theta$  sweeps over all values as the molecule tumbles, and the factor  $1 - 3\cos^2 \theta$  averages to zero. Hence the direct dipolar interaction between spins cannot account for the fine structure of the spectra of rapidly tumbling molecules.

**Self-test 14B.8** In gypsum,  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ , the splitting in the  $\text{H}_2\text{O}$  resonance can be interpreted in terms of a magnetic field of 0.715 mT generated by one proton and experienced by the other. With  $\theta = 0$ , what is the separation of the protons in the  $\text{H}_2\text{O}$  molecule?

Answer: 158 pm

Spin–spin coupling in molecules in solution can be explained in terms of the **polarization mechanism**, in which the interaction is transmitted through the bonds. The simplest case to consider is that of  ${}^1J_{\text{XY}}$ , where X and Y are spin- $\frac{1}{2}$  nuclei joined by an electron-pair bond. The coupling mechanism depends on the fact that the energy depends on the relative orientation of the bonding electrons and the nuclear spins. This electron–nucleus coupling is magnetic in origin, and may be either a dipolar interaction or a **Fermi contact interaction**. A pictorial description of the latter is as follows. First, we regard the magnetic moment of the nucleus as arising from the circulation of a current in a tiny loop with a radius similar to that of the nucleus (Fig. 14B.15). Far from the nucleus the field generated by this loop is indistinguishable from the field generated by a point magnetic dipole. Close to the loop, however, the field differs from that of a point dipole. The magnetic interaction between this non-dipolar field and the electron's magnetic moment is

**Figure 14B.15** The origin of the Fermi contact interaction. From far away, the magnetic field pattern arising from a ring of current (representing the rotating charge of the nucleus, the pale grey sphere) is that of a point dipole. However, if an electron can sample the field close to the region indicated by the sphere, the field distribution differs significantly from that of a point dipole. For example, if the electron can penetrate the sphere, then the spherical average of the field it experiences is not zero.

the contact interaction. The contact interaction—essentially the failure of the point-dipole approximation—depends on the very close approach of an electron to the nucleus and hence can occur only if the electron occupies an s orbital (which is the reason why  $^1J_{\text{CH}}$  depends on the hybridization ratio). We shall suppose that it is energetically favourable for an electron spin and a nuclear spin to be antiparallel (as is the case for a proton and an electron in a hydrogen atom).

If the X nucleus is  $\alpha$ , a  $\beta$  electron of the bonding pair will tend to be found nearby, because that is an energetically favourable arrangement (Fig. 14B.16). The second electron in the bond, which must have  $\alpha$  spin if the other is  $\beta$  (by the Pauli principle; Topic 9B), will be found mainly at the far end of the bond because electrons tend to stay apart to reduce their mutual repulsion. Because it is energetically favourable for the spin of Y to be antiparallel to an electron spin, a Y nucleus with  $\beta$  spin has a lower energy than when it has  $\alpha$  spin. The opposite is true when X is  $\beta$ , for now the  $\alpha$  spin of Y has the lower energy. In other words, the antiparallel arrangement of nuclear spins lies lower in energy than the parallel arrangement as a

**Figure 14B.16** The polarization mechanism for spin-spin coupling ( $^1J_{\text{HH}}$ ). The two arrangements have slightly different energies. In this case,  $J$  is positive, corresponding to a lower energy when the nuclear spins are antiparallel.

**Figure 14B.17** The polarization mechanism for  $^2J_{\text{HH}}$  spin-spin coupling. The spin information is transmitted from one bond to the next by a version of the mechanism that accounts for the lower energy of electrons with parallel spins in different atomic orbitals (Hund's rule of maximum multiplicity). In this case,  $J < 0$ , corresponding to a lower energy when the nuclear spins are parallel.

result of their magnetic coupling with the bond electrons. That is,  $^1J_{\text{CH}}$  is positive.

To account for the value of  $^2J_{\text{XY}}$ , as for  $^2J_{\text{HH}}$  in H—C—H, we need a mechanism that can transmit the spin alignments through the central C atom (which may be  $^{12}\text{C}$ , with no nuclear spin of its own). In this case (Fig. 14B.17), an X nucleus with  $\alpha$  spin polarizes the electrons in its bond, and the  $\alpha$  electron is likely to be found closer to the C nucleus. The more favourable arrangement of two electrons on the same atom is with their spins parallel (Hund's rule, Topic 9B), so the more favourable arrangement is for the  $\alpha$  electron of the neighbouring bond to be close to the C nucleus. Consequently, the  $\beta$  electron of that bond is more likely to be found close to the Y nucleus, and therefore that nucleus will have a lower energy if it is  $\alpha$ . Hence, according to this mechanism, the lower energy will be obtained if the Y spin is parallel to that of X. That is,  $^2J_{\text{HH}}$  is negative.

The coupling of nuclear spin to electron spin by the Fermi contact interaction is most important for proton spins, but it is not necessarily the most important mechanism for other nuclei. These nuclei may also interact by a dipolar mechanism with the electron magnetic moments and with their orbital motion, and there is no simple way of specifying whether  $J$  will be positive or negative.

#### (d) Equivalent nuclei

A group of nuclei are **chemically equivalent** if they are related by a symmetry operation of the molecule and have the same chemical shifts. Chemically equivalent nuclei are nuclei that would be regarded as 'equivalent' according to ordinary chemical criteria. Nuclei are **magnetically equivalent** if, as well as being chemically equivalent, they also have identical spin-spin interactions with any other magnetic nuclei in the molecule.

### Brief illustration 14B.6 Chemical and magnetic equivalence

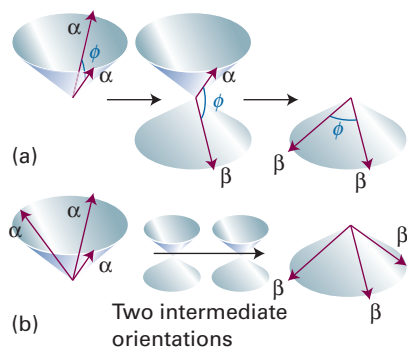

The difference between chemical and magnetic equivalence is illustrated by  $\text{CH}_2\text{F}_2$  and  $\text{H}_2\text{C}=\text{CF}_2$ . In each of these molecules the protons are chemically equivalent: they are related by symmetry and undergo the same chemical reactions. However, although the protons in  $\text{CH}_2\text{F}_2$  are magnetically equivalent, those in  $\text{CH}_2=\text{CF}_2$  are not. One proton in the latter has a *cis* spin-coupling interaction with a given F nucleus whereas the other proton has a *trans* interaction with it. In contrast, in  $\text{CH}_2\text{F}_2$  both protons are connected to a given F nucleus by identical bonds, so there is no distinction between them.

**Self-test 14B.9** Are the  $\text{CH}_3$  protons in ethanol magnetically inequivalent?

Answer: Yes, on account of their different interactions with the  $\text{CH}_2$  protons in the next group

Strictly speaking,  $\text{CH}_3$  protons are magnetically inequivalent. However, they are in practice made magnetically equivalent by the rapid rotation of the  $\text{CH}_3$  group, which averages out any differences. Magnetically inequivalent species can give very complicated spectra (for instance, the proton and  $^{19}\text{F}$  spectra of  $\text{H}_2\text{C}=\text{CF}_2$  each consist of 12 lines), and we shall not consider them further.

An important feature of chemically equivalent magnetic nuclei is that, although they do couple together, the coupling has no effect on the appearance of the spectrum. The qualitative reason for the invisibility of the coupling is that all allowed nuclear spin transitions are *collective* reorientations of groups of equivalent nuclear spins that do not change the relative orientations of the spins within the group (Fig. 14B.18). Then, because the relative orientations of nuclear spins are

**Figure 14B.18** (a) A group of two equivalent nuclei realigns as a group, without change of angle between the spins, when a resonant absorption occurs. Hence it behaves like a single nucleus and the spin–spin coupling between the individual spins of the group is undetectable. (b) Three equivalent nuclei also realign as a group without change of their relative orientations.

not changed in any transition, the magnitude of the coupling between them is undetectable. Hence, an isolated  $\text{CH}_3$  group gives a single, unsplit line because all the allowed transitions of the group of three protons occur without change of their relative orientations.

To express these conclusions more quantitatively, we first need to establish the energy levels of a collection of equivalent nuclei. As shown in the following *Justification* for an  $A_2$  system, they have the values depicted on the right of Fig. 14B.19.

### Justification 14B.1 The energy levels of an $A_2$ system

Consider an  $A_2$  system of two spin- $\frac{1}{2}$  nuclei. First, consider the energy levels in the absence of spin–spin coupling. There are four spin states that (just as for two electrons) can be classified according to their total spin  $I$  (the analogue of  $S$  for two electrons) and their total projection  $M_I$  on the  $z$ -axis. The states are analogous to those for two electrons in singlet and triplet states (Topic 9C):

Spins parallel, $I=1$ :	$M_I=+1$	$\alpha\alpha$
	$M_I=0$	$(1/2^{1/2})\{\alpha\beta+\beta\alpha\}$
	$M_I=-1$	$\beta\beta$
Spins paired, $I=0$ :	$M_I=0$	$(1/2^{1/2})\{\alpha\beta-\beta\alpha\}$

The sign in  $\alpha\beta+\beta\alpha$  signifies an in-phase alignment of spins and  $I=1$ ; the  $-$  sign in  $\alpha\beta-\beta\alpha$  signifies an alignment out of phase by  $\pi$ , and hence  $I=0$ . The effect of a magnetic field on these four states is shown in Fig. 14B.19: the energies of the

**Figure 14B.19** The energy levels of an  $A_2$  system in the absence of spin–spin coupling are shown on the left. When spin–spin coupling is taken into account, the energy levels on the right are obtained. Note that the three states with total nuclear spin  $I=1$  correspond to parallel spins and give rise to the same increase in energy ( $J$  is positive); the one state with  $I=0$  (antiparallel nuclear spins) has a lower energy in the presence of spin–spin coupling. The only allowed transitions are those that preserve the angle between the spins, and so take place between the three states with  $I=1$ . They occur at the same resonance frequency as they would have in the absence of spin–spin coupling.

two states with  $M_I=0$  are unchanged by the field because they are composed of equal proportions of  $\alpha$  and  $\beta$  spins.

The spin–spin coupling energy is proportional to the scalar product of the vectors representing the spins,  $E=(hJ/\hbar^2)\mathbf{I}_1\cdot\mathbf{I}_2$ . The scalar product can be expressed in terms of the total nuclear spin  $I=\mathbf{I}_1+\mathbf{I}_2$  by noting that

$$I^2=(\mathbf{I}_1+\mathbf{I}_2)\cdot(\mathbf{I}_1+\mathbf{I}_2)=I_1^2+I_2^2+2\mathbf{I}_1\cdot\mathbf{I}_2$$

rearranging this expression to

$$\mathbf{I}_1\cdot\mathbf{I}_2=\frac{1}{2}\{I^2-I_1^2-I_2^2\}$$

and replacing the magnitudes by their quantum mechanical values:

$$\mathbf{I}_1\cdot\mathbf{I}_2=\frac{1}{2}\{I(I+1)-I_1(I_1+1)-I_2(I_2+1)\}\hbar^2$$

Then, because  $I_1=I_2=\frac{1}{2}$ , it follows that

$$E=\frac{1}{2}hJ\{I(I+1)-\frac{3}{2}\}$$

For parallel spins,  $I=1$  and  $E=+\frac{1}{4}hJ$ ; for antiparallel spins  $I=0$  and  $E=-\frac{3}{4}hJ$ , as in Fig. 14B.19. We see that three of the states move in energy in one direction and the fourth (the one with antiparallel spins) moves three times as much in the opposite direction.

We now consider the allowed transitions between the states of an  $A_2$  system shown in Fig. 14B.18. The radiofrequency field affects the two equivalent protons equally, so it cannot change the orientation of one proton relative to the other; therefore, the transitions take place within the set of states that correspond to parallel spin (those labelled  $I=1$ ), and no spin-parallel state can change to a spin-antiparallel state (the state with  $I=0$ ). Put another way, the allowed transitions are subject to the selection rule  $\Delta I=0$ . This selection rule is in addition to the rule  $\Delta M_I=\pm 1$  that arises from the conservation of angular momentum and the unit spin of the photon. The allowed transitions are shown in Fig. 14B.19: we see that there are only two transitions, and that they occur at the same resonance frequency that the nuclei would have in the absence of spin–spin coupling. Hence, the spin–spin coupling interaction does not affect the appearance of the spectrum.

### (e) Strongly coupled nuclei

NMR spectra are usually much more complex than the foregoing simple analysis suggests. We have described the extreme case in which the differences in chemical shifts are much greater than the spin–spin coupling constants. In such cases it is simple to identify groups of magnetically equivalent nuclei and to think of the groups of nuclear spins as

reorienting relative to each other. The spectra that result are called **first-order spectra**.

Transitions cannot be allocated to definite groups when the differences in their chemical shifts are comparable to their spin–spin coupling interactions. The complicated spectra that are then obtained are called **strongly coupled spectra** (or ‘second-order spectra’) and are much more difficult to analyse.

#### Brief illustration 14B.7 Strongly coupled spectra

Figure 14B.20 shows NMR spectra of an  $A_2$  system (top) and an AX system (bottom). Both are simple ‘first-order’ spectra. At intermediate relative values of the chemical shift difference and the spin–spin coupling, complex ‘strongly coupled’ spectra are obtained. Note how the inner two lines of the bottom spectrum move together, grow in intensity, and form the single central line of the top spectrum. The two outer lines diminish in intensity and are absent in the top spectrum.

Figure 14B.20 The NMR spectra of an  $A_2$  system (top) and an AX system (bottom) are simple ‘first-order’ spectra.

**Self-test 14B.10** Explain why, in some cases, a second-order spectrum may become simpler (and first-order) at high fields.

Answer: The difference in resonance frequencies increases with field, but spin–spin coupling constants are independent of it

A clue to the type of analysis that is appropriate is given by the notation for the types of spins involved. Thus, an AX spin system (which consists of two nuclei with a large chemical shift difference) has a first-order spectrum. An AB system, on the other hand (with two nuclei of similar chemical shifts), gives a spectrum typical of a strongly coupled system. An AX system may have widely different Larmor frequencies because A and X are nuclei of different elements (such as  $^{13}\text{C}$  and  $^1\text{H}$ ), in which case they form a **heteronuclear spin system**. AX may also denote a **homonuclear spin system** in

which the nuclei are of the same element but in markedly different environments.

## 14B.4 Conformational conversion and exchange processes

The appearance of an NMR spectrum is changed if magnetic nuclei can jump rapidly between different environments. Consider a molecule, such as *N,N*-dimethylformamide, that can jump between conformations; in its case, the methyl shifts depend on whether they are *cis* or *trans* to the carbonyl group (Fig. 14B.21). When the jumping rate is low, the spectrum shows two sets of lines, one each from molecules in each conformation. When the interconversion is fast, the spectrum shows a single line at the mean of the two chemical shifts. At intermediate inversion rates, the line is very broad. This maximum broadening occurs when the lifetime,  $\tau$ , of a conformation gives rise to a linewidth that is comparable to the difference of resonance frequencies,  $\delta\nu$  and both broadened lines blend together into a very broad line. Coalescence of the two lines occurs when

$$\tau = \frac{2^{1/2}}{\pi\delta\nu} \quad \text{Condition for coalescence of two NMR lines} \quad (14B.16)$$

**Figure 14B.21** When a molecule changes from one conformation to another, the positions of its protons are interchanged and the protons jump between magnetically distinct environments.

### Brief illustration 14B.8 The effect of chemical exchange on NMR spectra

The NO group in *N,N*-dimethylnitrosamine,  $(\text{CH}_3)_2\text{N}-\text{NO}$  (5), rotates about the N–N bond and, as a result, the magnetic

environments of the two  $\text{CH}_3$  groups are interchanged. The two  $\text{CH}_3$  resonances are separated by 390 Hz in a 600 MHz spectrometer. According to eqn 14B.16,

$$\tau = \frac{2^{1/2}}{\pi \times (390 \text{ s}^{-1})} = 1.2 \text{ ms}$$

It follows that the signal will collapse to a single line when the interconversion rate exceeds about  $1/\tau = 830 \text{ s}^{-1}$ .

5 *N,N*-Dimethylnitrosamine

**Self-test 14B.11** What would you deduce from the observation of a single line from the same molecule in a 300 MHz spectrometer?

Answer: Conformation lifetime less than 2.3 ms

A similar explanation accounts for the loss of fine structure in solvents able to exchange protons with the sample. For example, hydroxyl protons are able to exchange with water protons. When this **chemical exchange** occurs, a molecule  $\text{ROH}$  with an  $\alpha$ -spin proton (we write this  $\text{ROH}_\alpha$ ) rapidly converts to  $\text{ROH}_\beta$  and then perhaps to  $\text{ROH}_\alpha$  again because the protons provided by the solvent molecules in successive exchanges have random spin orientations. Therefore, instead of seeing a spectrum composed of contributions from both  $\text{ROH}_\alpha$  and  $\text{ROH}_\beta$  molecules (that is, a spectrum showing a doublet structure due to the OH proton) we see a spectrum that shows no splitting caused by coupling of the OH proton (as in Fig. 14B.2 and as discussed in Example 14B.3). The effect is observed when the lifetime of a molecule due to this chemical exchange is so short that the lifetime broadening is greater than the doublet splitting. Because this splitting is often very small (a few hertz), a proton must remain attached to the same molecule for longer than about 0.1 s for the splitting to be observable. In water, the exchange rate is much faster than that, so alcohols show no splitting from the OH protons. In dry dimethylsulfoxide (DMSO), the exchange rate may be slow enough for the splitting to be detected.

## Checklist of concepts

- 1. The **chemical shift** of a nucleus is the difference between its resonance frequency and that of a reference standard.
- 2. The **shielding constant** is the sum of a local contribution, a neighbouring group contribution, and a solvent contribution.
- 3. The **local contribution** is the sum of a diamagnetic contribution and a paramagnetic contribution.
- 4. The **neighbouring group contribution** arises from the currents induced in nearby groups of atoms.
- 5. The **solvent contribution** can arise from specific molecular interactions between the solute and the solvent.
- 6. **Fine structure** is the splitting of resonances into individual lines by spin–spin coupling.
- 7. **Spin–spin coupling** is expressed in terms of the **spin–spin coupling constant  $J$**  and depends on the relative orientation of two nuclear spins.
- 8. The coupling constant decreases as the number of bonds separating two nuclei increases.
- 9. Spin–spin coupling can be explained in terms of the **polarization mechanism** and the **Fermi contact interaction**.
- 10. Chemically and magnetically equivalent nuclei have the same chemical shifts.
- 11. In **strongly coupled spectra**, transitions cannot be allocated to definite groups.
- 12. Coalescence of two NMR lines occurs when a conformational interchange or chemical exchange of nuclei is fast.

## Checklist of equations

Property	Equation	Comment	Equation number
$\delta$ Scale of chemical shifts	$\delta = \{(\nu - \nu^\circ) / \nu^\circ\} \times 10^6$	Definition	14B.4
Relation between chemical shift and shielding constant	$\delta \approx (\sigma^\circ - \sigma) \times 10^6$		14B.6
Local contribution to the shielding constant	$\sigma(\text{local}) = \sigma_d + \sigma_p$		14B.8
Lamb formula	$\sigma_d = (e^2 \mu_0 / 12 \pi m_e) (1/r)$		14B.9
Neighbouring group contribution to the shielding constant	$\sigma(\text{neighbour}) \propto (\chi_{\parallel} - \chi_{\perp}) \{ (1 - 3 \cos^2 \theta) / r^3 \}$	The angle $\theta$ is defined in (1)	14B.10b

### ► Why do you need to know this material?

To understand how nuclear magnetic resonance spectroscopy is used to study large molecules and even diagnose disease, you need to understand how spectral information is obtained by analysing the response of nuclei to the application of strong pulses of radiofrequency radiation.

### ► What is the key idea?

Fourier-transform NMR spectroscopy is the analysis of the radiation emitted by nuclear spins as they return to equilibrium after stimulation by one or more pulses of radiofrequency radiation.

### ► What do you need to know already?

You need to be familiar with the general principles of magnetic resonance (Topic 14A), the features of NMR spectra (Topics 14B), the vector model of angular momentum (Topic 8B), the magnetic properties of

molecules (Topic 18C), and Fourier transforms (Topic 12A and *Mathematical background 7*). The development makes use of the concept of precession at the Larmor frequency (Topic 14A).

The common method of detecting the energy separation between nuclear spin states in NMR spectroscopy is more sophisticated than simply looking for the frequency at which resonance occurs. One of the best analogies that have been suggested to illustrate the preferred way of observing an NMR spectrum is that of detecting the spectrum of vibrations of a bell. We could stimulate the bell with a gentle vibration at a gradually increasing frequency, and note the frequencies at which it resonated with the stimulation. A lot of time would be spent getting zero response when the stimulating frequency was between the bell's vibrational modes. However, if we were simply to hit the bell with a hammer, we would immediately obtain a clang composed of all the frequencies that the bell can produce. The equivalent in NMR is to monitor the radiation nuclear spins emit as they return to equilibrium after the appropriate stimulation. The resulting **Fourier-transform NMR (FT-NMR)** spectroscopy gives greatly increased sensitivity, so opening up much of the periodic table to the technique. Moreover, multiple-pulse FT-NMR gives chemists unparalleled control over the information content and display of spectra.

## 14C.1 The magnetization vector

Consider a sample composed of many identical spin- $\frac{1}{2}$  nuclei. By analogy with the discussion of angular momenta in Topic 8C, a nuclear spin can be represented by a vector of length  $\{I(I+1)\}^{1/2}$  units with a component of length  $m_I$  units along the  $z$ -axis. As the uncertainty principle does not allow us to specify the  $x$ - and  $y$ -components of the angular momentum, all we know is that the vector lies somewhere on a cone around the  $z$ -axis. For  $I = \frac{1}{2}$ , the length of the vector is  $\frac{1}{2}3^{1/2}$  and when  $m_I = +\frac{1}{2}$  it makes an angle of  $\arccos(\frac{1/2}{(\frac{1}{2}3^{1/2})}) = 55^\circ$  to the  $z$ -axis (Fig. 14C.1).

In the absence of a magnetic field, the sample consists of equal numbers of  $\alpha$  and  $\beta$  nuclear spins with their vectors lying at random angles on the cones. These angles are unpredictable, and at this stage we picture the spin vectors as stationary.

**Figure 14C.1** The vector model of angular momentum for a single spin- $\frac{1}{2}$  nucleus. The angle around the  $z$ -axis is indeterminate.

**Figure 14C.2** The magnetization of a sample of spin- $\frac{1}{2}$  nuclei is the resultant of all their magnetic moments. (a) In the absence of an externally applied field, there are equal numbers of  $\alpha$  and  $\beta$  spins at random angles around the  $z$ -axis (the field direction) and the magnetization is zero. (b) In the presence of a field, the spins precess around their cones (that is, there is an energy difference between the  $\alpha$  and  $\beta$  states) and there are slightly more  $\alpha$  spins than  $\beta$  spins. As a result, there is a net magnetization along the  $z$ -axis.

The **magnetization**,  $M$ , of the sample, its net nuclear magnetic moment, is zero (Fig. 14C.2a).

Two changes occur in the magnetization when a magnetic field of magnitude  $\mathcal{B}_0$  is present and aligned in the  $z$ -direction:

- The energies of the two orientations change, the  $\alpha$  spins moving to low energy and the  $\beta$  spins to high energy (provided  $\gamma_N > 0$ ).

At 10 T, the Larmor frequency for protons is 427 MHz, and in the vector model the individual vectors are pictured as precessing at this rate (Topic 14A). This motion is a pictorial representation of the difference in energy of the spin states (it is not an actual representation of reality but is inspired by the actual motion of a classical bar magnet in a magnetic field). As the field is increased, the Larmor frequency increases and the precession becomes faster.

- The populations of the two spin states (the numbers of  $\alpha$  and  $\beta$  spins) at thermal equilibrium change, with slightly more  $\alpha$  spins than  $\beta$  spins (see Topic 14A).

Despite its smallness, this imbalance means that there is a net magnetization that we can represent by a vector  $M$  pointing in

the  $z$ -direction and with a length proportional to the population difference (Fig. 14C.2b).

### (a) The effect of the radiofrequency field

Now consider the effect of a radiofrequency field circularly polarized in the  $xy$ -plane, so that the magnetic component of the electromagnetic field (the only component we need to consider) is rotating around the  $z$ -direction in the same sense as the Larmor precession of the nuclei. The strength of the rotating magnetic field is  $\mathcal{B}_1$ .

To interpret the effects of radiofrequency pulses on the magnetization, it is useful to imagine stepping on to a platform, a so-called **rotating frame**, that rotates around the direction of the applied field. Suppose we choose the frequency of the radiofrequency field to be equal to the Larmor frequency of the spins,  $\nu_L = \gamma_N \mathcal{B}_0 / 2\pi$ ; this choice is equivalent to selecting the resonance condition in the conventional experiment. The rotating magnetic field is in step with the precessing spins, the nuclei experience a steady  $\mathcal{B}_1$  field, and precess about it at a frequency  $\gamma_N \mathcal{B}_1 / 2\pi$  (Fig. 14C.3). Now suppose that the  $\mathcal{B}_1$  field is applied in a pulse of duration  $\Delta\tau = \frac{1}{4} \times 2\pi / \gamma_N \mathcal{B}_1$ , the magnetization tips through an angle of  $\frac{1}{4} \times 2\pi = \pi/2$  ( $90^\circ$ ) away from the vertical  $z$ -direction and we say that we have applied a  **$90^\circ$  pulse**, or a ' $\pi/2$  pulse' (Fig. 14C.4a).

#### Brief illustration 14C.1 Radiofrequency pulses

The duration of a radiofrequency pulse depends on the strength of the  $\mathcal{B}_1$  field. If a  $90^\circ$  pulse requires  $10\ \mu\text{s}$ , then for protons

$$\mathcal{B}_1 = \frac{\pi}{2 \times \underbrace{(2.675 \times 10^{-8} \text{ T}^{-1} \text{ s}^{-1})}_{\gamma_N} \times \underbrace{(1.0 \times 10^{-5} \text{ s})}_{\Delta\tau}} = 5.9 \times 10^{-4} \text{ T}$$

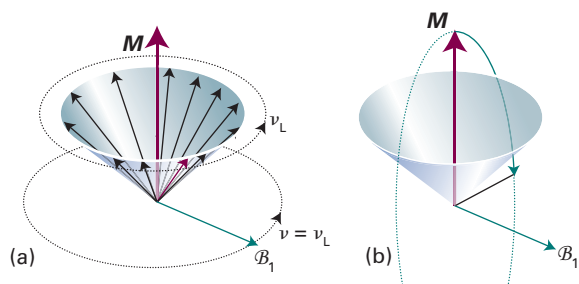

or 0.59 mT.

**Self-test 14C.1** How long would a  $180^\circ$  pulse require for protons?

Answer:  $20\ \mu\text{s}$

Now imagine stepping out of the rotating frame. To a fixed external observer (the role played by a radiofrequency coil), the magnetization vector is now rotating at the Larmor frequency in the  $xy$ -plane (Fig. 14C.4b). The rotating magnetization induces in the coil a signal that oscillates at the Larmor frequency and which can be amplified and processed. In practice, the processing takes place after subtraction of a constant high frequency component (the radiofrequency used for  $\mathcal{B}_1$ ), so that all the signal manipulation takes place at frequencies of a few kilohertz.

As time passes, the individual spins move out of step (partly because they are precessing at slightly different rates, as we

**Figure 14C.3** (a) In a resonance experiment, a circularly polarized radiofrequency magnetic field  $B_1$  is applied in the  $xy$ -plane (the magnetization vector lies along the  $z$ -axis). (b) If we step into a frame rotating at the radiofrequency,  $B_1$  appears to be stationary, as does the magnetization  $M$  if the Larmor frequency is equal to the radiofrequency. When the two frequencies coincide, the magnetization vector of the sample rotates around the direction of the  $B_1$  field.

**Figure 14C.4** (a) If the radiofrequency field is applied for a certain time, the magnetization vector is rotated into the  $xy$ -plane. (b) To an external stationary observer (the coil), the magnetization vector is rotating at the Larmor frequency, and can induce a signal in the coil.

explain later), so the magnetization vector shrinks exponentially with a time constant  $T_2$  and induces an ever weaker signal in the detector coil. The form of the signal that we can expect is therefore the oscillating-decaying **free-induction decay** (FID) shown in Fig. 14C.5. The  $y$ -component of the magnetization varies as

$$M_y(t) = M_0 \cos(2\pi\nu_L t) e^{-t/T_2} \quad \text{Free-induction decay} \quad (14C.1)$$

We have considered the effect of a  $B_1$  pulse applied at exactly the Larmor frequency. However, virtually the same effect is obtained off resonance, provided that the pulse is applied close to  $\nu_L$ . If the difference in frequency is small compared to the inverse of the duration of the 90° pulse, the magnetization will end up in the  $xy$ -plane. Note that we do not need to know the Larmor frequency beforehand: the short pulse is the analogue of the hammer blow on the bell, exciting a range of frequencies. The detected signal shows that a particular resonant frequency is present.

**Figure 14C.5** A simple free-induction decay of a sample of spins with a single resonance frequency.

### (b) Time- and frequency-domain signals

We can think of the magnetization vector of a homonuclear AX spin system with spin-spin coupling constant  $J=0$  as consisting of two parts, one formed by the A spins and the other by the X spins. When the 90° pulse is applied, both magnetization vectors are rotated into the  $xy$ -plane. However, because the A and X nuclei precess at different frequencies, they induce two signals in the detector coils, and the overall FID curve may resemble that in Fig. 14C.6a. The composite FID curve is the analogue of the struck bell emitting a rich tone composed of all the frequencies (in this case, just the two resonance frequencies of the uncoupled A and X nuclei) at which it can vibrate.

The problem we must address is how to recover the resonance frequencies present in a free-induction decay. We know that the FID curve is a sum of decaying oscillating functions, so the problem is to analyse it into its components by carrying out a Fourier transformation. The analysis of the FID curve is achieved by the standard mathematical technique of Fourier transformation, which is explained more fully in *Mathematical background 7* following chapter 18.

**Figure 14C.6** (a) A free-induction decay signal of a sample of AX species and (b) its analysis into its frequency components.

We start by noting that the signal  $S(t)$  in the time domain, the total FID curve, is the sum (more precisely, the integral) over all the contributing frequencies

$$S(t) = \int_{-\infty}^{\infty} I(\nu) e^{-2\pi i \nu t} d\nu \quad (14C.2)$$

Because  $e^{2\pi i \nu t} = \cos(2\pi \nu t) + i \sin(2\pi \nu t)$ , this expression is a sum over harmonically oscillating functions, with each one weighted by the intensity  $I(\nu)$ .

We need  $I(\nu)$ , the spectrum in the frequency domain; it is obtained by evaluating the integral

$$I(\nu) = 2\text{Re} \int_0^{\infty} S(t) e^{2\pi i \nu t} dt \quad (14C.3)$$

where Re means take the real part of the following expression. This integral gives a nonzero value if  $S(t)$  contains a component that matches the oscillating function  $e^{2\pi i \nu t}$ . The integration is carried out at a series of frequencies  $\nu$  on a computer that is built into the spectrometer. When the signal in Fig. 14C.6a is transformed in this way, we get the frequency-domain spectrum shown in Fig. 14C.6b. One line represents the Larmor frequency of the A nuclei and the other that of the X nuclei.

#### Brief illustration 14C.2 Fourier analysis

Fourier analysis is a common feature of most mathematical software packages, but one simple example is the Fourier transform of the function

$$S(t) = S(0) \cos(2\pi \nu_L t) e^{-t/T_2}$$

which describes the behaviour of the FID signal in eqn 14C.1. The result is (Problem 14C.3)

$$I(\nu) = \frac{S(0)T_2}{1 + (\nu_L - \nu)^2 (2\pi T_2)^2}$$

which has the so-called 'Lorentzian' shape, with a maximum intensity at  $I(\nu_L) = S(0)T_2$ .

**Self-test 14C.2** What is the width at half-height  $\Delta\nu_{1/2}$  of the Lorentzian function above?

Answer:  $\Delta\nu_{1/2} = 1/\pi T_2$

The FID curve in Fig. 14C.7 is obtained from a sample of ethanol. The frequency-domain spectrum obtained from it by Fourier transformation is the one discussed in Topic 14B (see Fig. 14B.2). We can now see why the FID curve in Fig. 14C.7 is so complex: it arises from the precession of a magnetization vector that is composed of eight components, each with a characteristic frequency.

**Figure 14C.7** A free-induction decay signal of a sample of ethanol. Its Fourier transform is the frequency-domain spectrum shown in Fig. 14B.2. The total length of the image corresponds to about 1s.

## 14C.2 Spin relaxation

There are two reasons why the component of the magnetization vector in the  $xy$ -plane shrinks. Both reflect the fact that the nuclear spins are not in thermal equilibrium with their surroundings (for then  $M$  lies parallel to  $z$ ). At thermal equilibrium the spins have a Boltzmann distribution, with more  $\alpha$  spins than  $\beta$  spins and lie at random orientations on their precessional cones. The return to equilibrium is the process called **spin relaxation**.

### (a) Longitudinal and transverse relaxation

Consider the effect of a  $180^\circ$  pulse, which may be visualized in the rotating frame as a flip of the net magnetization vector from one direction along the  $z$ -axis (with more  $\alpha$  spins than  $\beta$  spins) to the opposite direction (with more  $\beta$  spins than  $\alpha$  spins). After the pulse, the populations revert to their thermal equilibrium values exponentially. As they do so, the  $z$ -component of magnetization reverts to its equilibrium value  $M_0$  with a time constant called the **longitudinal relaxation time**,  $T_1$  (Fig. 14C.8):

$$M_z(t) - M_0 \propto e^{-t/T_1} \quad \text{Definition Longitudinal relaxation time} \quad (14C.4)$$

Because this relaxation process involves giving up energy to the surroundings (the 'lattice') as  $\beta$  spins revert to  $\alpha$  spins, the time constant  $T_1$  is also called the **spin-lattice relaxation time**. Spin-lattice relaxation is caused by local magnetic fields that fluctuate at a frequency close to the resonance frequency of the  $\beta \rightarrow \alpha$  transition. Such fields can arise from the tumbling motion of molecules in a fluid sample. If molecular tumbling is too slow or too fast compared to the resonance frequency, it will give rise to a fluctuating magnetic field with a frequency that is either too low or too high to stimulate a spin change from  $\beta$  to  $\alpha$ , so  $T_1$  will be long. Only if the molecule tumbles at about the resonance frequency will the fluctuating magnetic

**Figure 14C.8** In longitudinal relaxation the spins relax back towards their thermal equilibrium populations. On the left we see the precessional cones representing spin- $\frac{1}{2}$  angular momenta, and they do not have their thermal equilibrium populations (there are more  $\beta$  spins than  $\alpha$  spins). On the right, which represents the sample a long time after a time  $T_1$  has elapsed, the populations are those characteristic of a Boltzmann distribution. In actuality,  $T_1$  is the time constant for relaxation to the arrangement on the right and  $T_1 \ln 2$  is the half-life of the arrangement on the left.

field be able to induce spin changes effectively, and only then will  $T_1$  be short. The rate of molecular tumbling increases with temperature and with reducing viscosity of the solvent, so we can expect a dependence like that shown in Fig. 14C.9. The quantitative treatment of relaxation times depends on setting up models of molecular motion and using, for instance, the diffusion equation (Topic 19C) adapted for rotational motion.

Now consider the events following a  $90^\circ$  pulse. The magnetization vector in the  $xy$ -plane is large when the spins are bunched together immediately after the pulse. However, this orderly bunching of spins is not at equilibrium and, even if

**Figure 14C.9** The variation of the two relaxation times with the rate at which the molecules move (either by tumbling or migrating through the solution). The horizontal axis can be interpreted as representing temperature or viscosity. Note that at rapid rates of motion, the two relaxation times coincide.

**Figure 14C.10** The transverse relaxation time,  $T_2$ , is the time constant for the phases of the spins to become randomized (another condition for equilibrium) and to change from the orderly arrangement shown on the left to the disorderly arrangement on the right (long after a time  $T_2$  has elapsed). Note that the populations of the states remain the same; only the relative phase of the spins relaxes. In actuality,  $T_2$  is the time constant for relaxation to the arrangement on the right and  $T_2 \ln 2$  is the half-life of the arrangement on the left.

there were no spin–lattice relaxation, we would expect the individual spins to spread out until they were uniformly distributed with all possible angles around the  $z$ -axis (Fig. 14C.10). At that stage, the component of magnetization vector in the plane would be zero. The randomization of the spin directions occurs exponentially with a time constant called the **transverse relaxation time**,  $T_2$ :

$$M_y(t) \propto e^{-t/T_2} \quad \text{Definition} \quad \text{Transverse relaxation time} \quad (14C.5)$$

Because the relaxation involves the relative orientation of the spins around their respective cones,  $T_2$  is also known as the **spin–spin relaxation time**. Any relaxation process that changes the balance between  $\alpha$  and  $\beta$  spins will also contribute to this randomization, so the time constant  $T_2$  is almost always less than or equal to  $T_1$ .

Local magnetic fields also affect spin–spin relaxation. When the fluctuations are slow, each molecule lingers in its local magnetic environment and the spin orientations randomize quickly around their cones. If the molecules move rapidly from one magnetic environment to another, the effects of differences in local magnetic field average to zero: individual spins do not precess at very different rates, they can remain bunched for longer, and spin–spin relaxation does not take place as quickly. In other words, slow molecular motion corresponds to short  $T_2$  and fast motion corresponds to long  $T_2$  (as shown in Fig. 14C.9). Calculations show that, when the motion is fast, the main orientational randomizing effect arises from  $\beta \rightarrow \alpha$  transitions rather than different precession rates on the cones, and then  $T_2 \approx T_1$ .

**Figure 14C.11** A Lorentzian absorption line. The width at half-height is inversely proportional to the parameter  $T_2$  and the longer the transverse relaxation time, the narrower the line.

If the  $y$ -component of magnetization decays with a time constant  $T_2$ , the spectral line is broadened (Fig. 14C.11), and its width at half-height becomes (see *Brief illustration 14C.2*)

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} \quad \text{Width at half-height of an NMR line} \quad (14C.6)$$

Typical values of  $T_2$  in proton NMR are of the order of seconds, so linewidths of around 0.1 Hz can be anticipated, in broad agreement with observation.

So far, we have assumed that the equipment, and in particular the magnet, is perfect, and that the differences in Larmor frequencies arise solely from interactions within the sample. In practice, the magnet is not perfect, and the field is different at different locations in the sample. The inhomogeneity broadens the resonance, and in most cases this **inhomogeneous broadening** dominates the broadening we have discussed so far. It is common to express the extent of inhomogeneous broadening in terms of an **effective transverse relaxation time**,  $T_2^*$ , by using a relation like eqn 14C.6, but writing

$$T_2^* = \frac{1}{\pi \Delta\nu_{1/2}} \quad \text{Definition} \quad \text{Effective transverse relaxation time} \quad (14C.7)$$

where  $\Delta\nu_{1/2}$  is the observed width at half-height of a line with a Lorentzian shape of the form  $I \propto 1/(1 + \nu^2)$ .

#### Brief illustration 14C.3 Inhomogeneous broadening

Consider a line in a spectrum with a width of 10 Hz. It follows from eqn 14C.7 that the effective transverse relaxation time is

$$T_2^* = \frac{1}{\pi \times (10 \text{ s}^{-1})} = 32 \text{ ms}$$

**Self-test 14C.3** Name two processes that could contribute to further broadening of the NMR line.

Answer: Conformational conversion or chemical exchange (Topic 14B)

## (b) The measurement of $T_1$ and $T_2$

The longitudinal relaxation time  $T_1$  can be measured by the **inversion recovery technique**. The first step is to apply a  $180^\circ$  pulse to the sample. A  $180^\circ$  pulse is achieved by applying the  $\mathcal{B}_1$  field for twice as long as for a  $90^\circ$  pulse, so the magnetization vector precesses through  $180^\circ$  and points in the  $z$ -direction (Fig. 14C.12). No signal can be seen at this stage because there is no component of magnetization in the  $xy$ -plane (where the coil can detect it). The  $\beta$  spins begin to relax back into  $\alpha$  spins, and the magnetization vector first shrinks exponentially, falling through zero to its thermal equilibrium value,  $M_0$ . After an interval  $\tau$ , a  $90^\circ$  pulse is applied that rotates the remaining magnetization into the  $xy$ -plane, where it generates an FID signal. The frequency-domain spectrum is then obtained by Fourier transformation.

The intensity of the spectrum obtained in this way depends on the length of the magnetization vector that is rotated into the  $xy$ -plane. The length of that vector changes exponentially as the interval between the two pulses is increased, so the intensity of the spectrum also changes exponentially with increasing  $\tau$ . We can therefore measure  $T_1$  by fitting an exponential curve to the series of spectra obtained with different values of  $\tau$ .

The measurement of  $T_2$  (as distinct from  $T_2^*$ ) depends on being able to eliminate the effects of inhomogeneous broadening. The cunning required is at the root of some of the most important advances that have been made in NMR since its introduction.

A **spin echo** is the magnetic analogue of an audible echo: transverse magnetization is created by a radiofrequency pulse, decays away, is reflected by a second pulse, and grows back to form an echo. The sequence of events is shown in Fig. 14C.13. We can consider the overall magnetization as being made up of a number of different magnetizations, each of which arises from a **spin packet** of nuclei with very similar precession frequencies. The spread in these frequencies arises because the applied field  $\mathcal{B}_0$  is inhomogeneous, so different parts of the sample experience different fields. The precession frequencies also differ if there is more than one chemical shift present. As will be seen,

**Figure 14C.12** (a) The result of applying a  $180^\circ$  pulse to the magnetization in the rotating frame and the effect of a subsequent  $90^\circ$  pulse. (b) The amplitude of the frequency-domain spectrum varies with the interval between the two pulses because spin–lattice relaxation has time to occur.

**Figure 14C.13** The sequence of pulses leading to the observation of a spin echo.

the importance of a spin echo is that it can suppress the effects of both field inhomogeneities and chemical shifts.

First, a  $90^\circ$  pulse is applied to the sample. We follow events by using the rotating frame, in which  $\mathcal{B}_1$  is stationary along the rotating  $x$ -axis and causes the magnetization to rotate into the  $xy$ -plane. The spin packets now begin to fan out because they have different Larmor frequencies, with some above the radio-frequency and some below. The detected signal depends on the resultant of the spin-packet magnetization vectors, and decays with a time-constant  $T_2^*$  because of the combined effects of field inhomogeneity and spin-spin relaxation.

After an evolution period  $\tau$ , a  $180^\circ$  pulse is applied to the sample; this time, about the  $y$ -axis of the rotating frame (the axis of the pulse is changed from  $x$  to  $y$  by a  $90^\circ$  phase shift of the radiofrequency radiation). The pulse rotates the magnetization vectors of the faster spin packets into the positions previously occupied by the slower spin packets, and vice versa. Thus, as the vectors continue to precess, the fast vectors are now behind the slow; the fan begins to close up again, and the resultant signal begins to grow back into an echo. After another interval of length  $\tau$ , all the vectors will once more be aligned along the  $y$ -axis, and the fanning out caused by the field inhomogeneity is said to have been **refocused**: the spin echo has reached its maximum.

The important feature of the technique is that the size of the echo is independent of any local fields that remain constant during the two  $\tau$  intervals. If a spin packet is 'fast' because it happens to be composed of spins in a region of the sample that experiences higher than average fields, then it remains fast throughout both intervals, and what it gains on the first interval it loses on the second interval. Hence, the size of the echo is independent of inhomogeneities in the magnetic field, for these remain constant. The true transverse relaxation arises from fields that vary on a molecular distance scale, and there is no

**Figure 14C.14** The exponential decay of spin echoes can be used to determine the transverse relaxation time.

guarantee that an individual 'fast' spin will remain 'fast' in the refocusing phase: the spins within the packets therefore spread with a time constant  $T_2$ . Hence, the effects of the true relaxation are not refocused, and the size of the echo decays with the time constant  $T_2$  (Fig. 14C.14).

### 14C.3 Spin decoupling

Carbon-13 is a **dilute-spin species** in the sense that it is unlikely that more than one  $^{13}\text{C}$  nucleus will be found in any given small molecule (provided the sample has not been enriched with that isotope; the natural abundance of  $^{13}\text{C}$  is only 1.1 per cent). Even in large molecules, although more than one  $^{13}\text{C}$  nucleus may be present, it is unlikely that they will be close enough to give an observable splitting. Hence, it is not normally necessary to take into account  $^{13}\text{C}$ - $^{13}\text{C}$  spin-spin coupling within a molecule.

Protons are **abundant-spin species** in the sense that a molecule is likely to contain many of them. Protons are abundant-spin species. If we were observing a  $^{13}\text{C}$ -NMR spectrum, we would obtain a very complex spectrum on account of the coupling of the one  $^{13}\text{C}$  nucleus with many of the protons that are present. To avoid this difficulty,  $^{13}\text{C}$ -NMR spectra are normally observed using the technique of **proton decoupling**. Thus, if the  $\text{CH}_3$  protons of ethanol are irradiated with a second, strong, resonant radiofrequency pulse, they undergo rapid spin reorientations and the  $^{13}\text{C}$  nucleus senses an average orientation. As a result, its resonance is a single line and not a 1:3:3:1 quartet. Proton decoupling has the additional advantage of enhancing sensitivity, because the intensity is concentrated into a single transition frequency instead of being spread over several transition frequencies. If care is taken to ensure that the other parameters on which the strength of the signal depends are kept constant, the intensities of proton-decoupled spectra are proportional to the number of  $^{13}\text{C}$  nuclei present. The technique is widely used to characterize synthetic polymers.

## 14C.4 The nuclear Overhauser effect

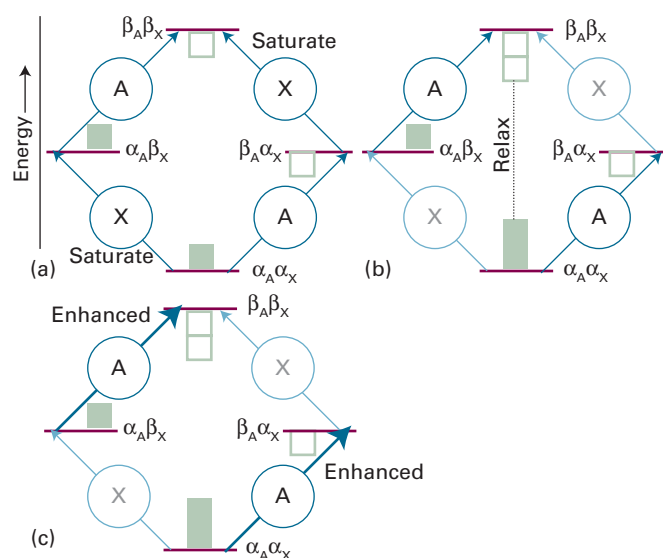

One advantage of protons in NMR is their high magnetogyric ratio, which results in relatively large Boltzmann population differences and also strong coupling to the radiofrequency field, and hence greater resonance intensities than for most other nuclei. In the steady-state **nuclear Overhauser effect** (NOE), spin relaxation processes involving internuclear dipole–dipole interactions are used to transfer this population advantage to another nucleus (such as  $^{13}\text{C}$  or another proton), so that the latter's resonances are modified. In a dipole–dipole interaction between two nuclei, one nucleus influences the behaviour of another nucleus in much the same way that the orientation of a bar magnet is influenced by the presence of another bar magnet nearby.

To understand the effect, consider the populations of the four levels of a homonuclear (for instance, proton) AX system; these levels are shown in Fig. 14B.9. At thermal equilibrium, the population of the  $\alpha_A\alpha_X$  level is the greatest, and that of the  $\beta_A\beta_X$  level is the least; the other two levels have the same energy and an intermediate population. The thermal equilibrium absorption intensities reflect these populations, as shown in Fig. 14C.15. Now consider the combined effect of spin relaxation and keeping the X spins saturated. When we saturate the X transition, the populations of the X levels are equalized ( $N_{\alpha_X} = N_{\beta_X}$ ) and all transitions involving  $\alpha_X \leftrightarrow \beta_X$  spin flips are no longer observed. At this stage there is no change in the populations of the A levels. If that were all there were to happen, all we would see would be the loss of the X resonance and no effect on the A resonance.

Now consider the effect of spin relaxation. Relaxation can occur in a variety of ways if there is a dipolar interaction between the A and X spins. One possibility is for the magnetic field acting between the two spins to cause them *both* to flip simultaneously from  $\beta$  to  $\alpha$ , so the  $\alpha_A\alpha_X$  and  $\beta_A\beta_X$  states regain their thermal equilibrium populations. However, the populations of the  $\alpha_A\beta_X$  and  $\beta_A\alpha_X$  levels remain unchanged at the values characteristic of saturation. As we see from Fig. 14C.16, the population difference between the states joined by

**Figure 14C.15** The energy levels of an AX system and an indication of their relative populations. Each green square above the line represents an excess population and each white square below the line represents a population deficit. The transitions of A and X are marked.

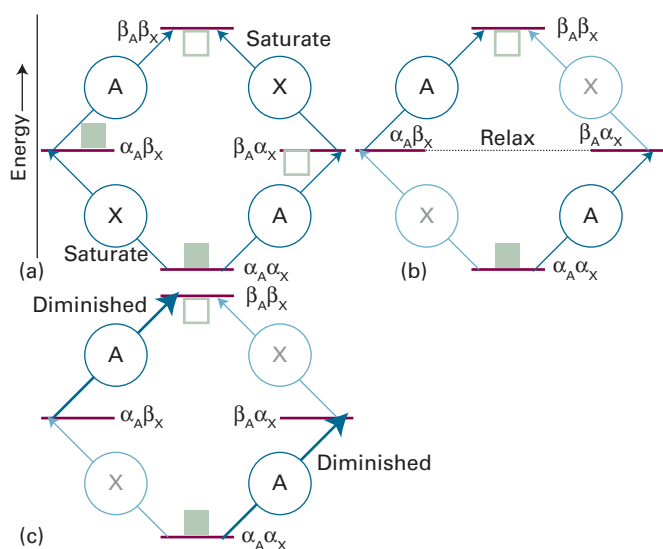

**Figure 14C.16** (a) When the X transition is saturated, the populations of its two states are equalized and the population excess and deficit become as shown (using the same symbols as in Fig. 14C.15). (b) Dipole–dipole relaxation relaxes the populations of the highest and lowest states, and they regain their original populations. (c) The A transitions reflect the difference in populations resulting from the preceding changes, and are enhanced compared with those shown in Fig. 14C.15.

transitions of A is now greater than at equilibrium, so the resonance absorption is enhanced. Another possibility is for the dipolar interaction between the two spins to cause  $\alpha_A$  to flip to  $\beta_A$  and simultaneously  $\beta_X$  to flip to  $\alpha_X$  (or vice versa). This transition equilibrates the populations of  $\alpha_A\beta_X$  and  $\beta_A\alpha_X$  but leaves the  $\alpha_A\alpha_X$  and  $\beta_A\beta_X$  populations unchanged. Now we see from the illustration that the population differences in the states involved in the A transitions are decreased, so the resonance absorption is diminished.

Which effect wins? Does the NOE enhance the A absorption or does it diminish it? As in the discussion of relaxation times in Section 14C.2, the efficiency of the intensity-enhancing  $\beta_A\beta_X \leftrightarrow \beta_A\alpha_X$  relaxation is high if the dipole field oscillates close to the transition frequency, which in this case is about  $2\nu$ ; likewise, the efficiency of the intensity-diminishing  $\alpha_A\beta_X \leftrightarrow \beta_A\alpha_X$  relaxation is high if the dipole field is stationary (as there is no frequency difference between the initial and final states). A large molecule rotates so slowly that there is very little motion at  $2\nu$ , so we expect an intensity decrease (Fig. 14C.17). A small molecule rotating rapidly can be expected to have substantial motion at  $2\nu$ , and a consequent enhancement of the signal. In practice, the enhancement lies somewhere between the two extremes and is reported in terms of the parameter  $\eta$  (eta), where

$$\eta = \frac{I_A - I_A^\circ}{I_A^\circ} \quad \text{NOE enhancement parameter} \quad (14C.8)$$

**Figure 14C.17** (a) When the X transition is saturated, just as in Fig. 14C.16 the populations of its two states are equalized and the population excess and deficit become as shown. (b) Dipole–dipole relaxation relaxes the populations of the two intermediate states, and they regain their original populations. (c) The A transitions reflect the difference in populations resulting from the preceding changes, and are diminished compared with those shown in Fig. 14C.15.

Here  $I_A^0$  and  $I_A$  are the intensities of the NMR signals due to nucleus A before and after application of the long ( $> T_1$ ) radio-frequency pulse that saturates transitions due to the X nucleus. When A and X are nuclei of the same species, such as protons,  $\eta$  lies between  $-1$  (diminution) and  $+\frac{1}{2}$  (enhancement). However,  $\eta$  also depends on the values of the magnetogyric ratios of A and X. In the case of maximal enhancement it is possible to show that

$$\eta = \frac{\gamma_X}{2\gamma_A} \quad (14C.9)$$

where  $\gamma_A$  and  $\gamma_X$  are the magnetogyric ratios of nuclei A and X, respectively.

#### Brief illustration 14C.4 NOE enhancement

From eqn 14C.9 and the data in Table 14A.2, the NOE enhancement parameter for  $^{13}\text{C}$  close to a saturated proton is

$$\eta = \frac{\overbrace{2.675 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}}^{\gamma_{\text{H}}}}{2 \times \underbrace{(6.73 \times 10^7 \text{ T}^{-1} \text{ s}^{-1})}_{\gamma_{^{13}\text{C}}}} = 1.99$$

which shows that an enhancement of about a factor of 2 can be achieved.

**Self-test 14C.4** Interpret the following features of the NMR spectra of a protein: (a) saturation of a proton resonance assigned to the side chain of a methionine residue changes the intensities of proton resonances assigned to the side chains of a tryptophan and a tyrosine residue; (b) saturation of proton resonances assigned to the tryptophan residue did not affect the spectrum of the tyrosine residue.

Answer: The tryptophan and tyrosine residues are close to the methionine residue, but are far from each other

The NOE is also used to determine inter-proton distances. The Overhauser enhancement of a proton A generated by saturating a spin X depends on the fraction of A's spin–lattice relaxation that is caused by its dipolar interaction with X. Because the dipolar field is proportional to  $r^{-3}$ , where  $r$  is the internuclear distance, and the relaxation effect is proportional to the square of the field, and therefore to  $r^{-6}$ , the NOE may be used to determine the geometries of molecules in solution. The determination of the structure of a small protein in solution involves the use of several hundred NOE measurements, effectively casting a net over the protons present. The enormous importance of this procedure is that we can determine the conformation of biological macromolecules in an aqueous environment and do not need to try to make the single crystals that are essential for an X-ray diffraction investigation (Topic 18A).

## 14C.5 Two-dimensional NMR

An NMR spectrum contains a great deal of information and, if many protons are present, is very complex when the fine structures of different groups of lines overlap. The complexity would be reduced if we could use two axes to display the data, with resonances belonging to different groups lying at different locations on the second axis. This separation is essentially what is achieved in **two-dimensional NMR**.

Much modern NMR work makes use of **correlation spectroscopy** (COSY) in which a clever choice of pulses and Fourier transformation techniques makes it possible to determine all spin–spin couplings in a molecule. A typical outcome for an AX system is shown in Fig. 14C.18. The diagram shows contours of equal signal intensity on a plot of intensity against the frequency coordinates  $\nu_1$  and  $\nu_2$ . The **diagonal peaks** are signals centred on  $(\delta_A, \delta_A)$  and  $(\delta_X, \delta_X)$  and lie along the diagonal where  $\nu_1 = \nu_2$ . That is, the spectrum along the diagonal is equivalent to the one-dimensional spectrum obtained with the conventional NMR technique (as in Fig. 14B.2). The **cross peaks** (or *off-diagonal peaks*) are signals centred on  $(\delta_A, \delta_X)$  and  $(\delta_X, \delta_A)$  and owe their existence to the coupling between the A and X nuclei.

Although information from two-dimensional NMR spectroscopy is trivial in an AX system, it can be of enormous help

**Figure 14C.18** An idealization of the COSY spectrum of an AX spin system.

in the interpretation of more complex spectra, leading to a map of the couplings between spins and to the determination of the bonding network in complex molecules. Indeed, the spectrum of a synthetic or biological polymer that would be impossible to interpret in one-dimensional NMR can often be interpreted reasonably rapidly by two-dimensional NMR.

#### Example 14C.1 Interpreting a two-dimensional NMR spectrum

Figure 14C.19 is a portion of the COSY spectrum of the amino acid isoleucine (**1**). Assign the resonances to protons bound to the carbon atoms.

**Method** Cross peaks in this spectrum arise from the coupling of protons that are separated as in H—C—C—H. That is, the fine structure in the spectrum is determined by the values of  $^3J_{\text{HH}}$  coupling constants (Topic 14B). Identify expected couplings from the arrangement of bonds in the molecular structure. Then match spectral and molecular features, taking into consideration the effects of chemical and magnetic equivalence (Topic 14B). For example, expect two cross-peaks to arise from coupling of a proton to two inequivalent protons, even if both protons are bound to the same carbon atom.

**Answer** From the molecular structure, we expect that: (i) the  $C_a$ —H proton is coupled only to the  $C_b$ —H proton, (ii) the  $C_b$ —H protons are coupled to the  $C_a$ —H,  $C_c$ —H, and  $C_d$ —H protons, and (iii) the inequivalent  $C_d$ —H protons are coupled

**Figure 14C.19** Proton COSY spectrum of isoleucine. (The *Example* and corresponding spectrum are adapted from K.E. van Holde et al., *Principles of physical biochemistry*, Prentice Hall, Upper Saddle River (1998).)

to the  $C_b$ —H and  $C_e$ —H protons. We proceed with the assignments by noting that:

- The resonance at  $\delta=1.9$  shares cross-peaks with resonances at  $\delta=3.6$ , 1.4, 1.2, and 0.9.

Only the  $C_b$ —H proton is coupled to protons with four different resonances: the  $C_a$ —H proton, the equivalent  $C_c$ —H protons, and the two inequivalent  $C_d$ —H protons. It follows that the resonance at  $\delta=1.9$  corresponds to the  $C_b$ —H proton.

- The resonance at  $\delta=3.6$  shares a cross-peak with only one other resonance at  $\delta=1.9$ .

We already know that the resonance at  $\delta=1.9$  corresponds to the  $C_b$ —H proton. Only the  $C_a$ —H proton is coupled to the  $C_b$ —H proton and to no other protons. It follows that the resonance at  $\delta=3.6$  corresponds to the  $C_a$ —H proton.

- The proton with resonance at  $\delta=0.8$  is not coupled to the proton with resonance at  $\delta=1.9$ , which we have assigned to the  $C_b$ —H proton.

Only the equivalent  $C_e$ —H protons are not coupled to the  $C_b$ —H proton, which we have already assigned to the resonance at  $\delta=1.9$ . Hence we assign the resonance at  $\delta=0.8$  to the  $C_e$ —H protons.

- The resonances at  $\delta=1.4$  and 1.2 do not share cross-peaks with the resonance at  $\delta=0.9$ .

Yet to be assigned are the resonances corresponding to the  $C_c$ —H and  $C_d$ —H protons. In the light of the expected couplings, the resonances from the inequivalent  $C_d$ —H protons do not share cross-peaks with the resonance from the equivalent  $C_c$ —H protons. It follows that the resonance at  $\delta=0.9$  can be assigned to the equivalent  $C_c$ —H protons and the resonances at  $\delta=1.4$  and 1.2 to the inequivalent  $C_d$ —H protons.

**Self-test 14C.5** The proton chemical shifts for the NH, C<sub>α</sub>H, and C<sub>β</sub>H groups of alanine (H<sub>2</sub>NCH(CH<sub>3</sub>)COOH) are 8.25, 4.35, and 1.39, respectively. Describe the COSY spectrum of alanine between δ=1.00 and 8.50.

Answer: Only the NH and C<sub>α</sub>H protons and the C<sub>α</sub>H and C<sub>β</sub>H protons are expected to show coupling, so the spectrum has only two off-diagonal peaks, one at (8.25, 4.35) and the other at (4.35, 1.39)

We have seen that the nuclear Overhauser effect can provide information about internuclear distances through analysis of enhancement patterns in the NMR spectrum before and after saturation of selected resonances. In **nuclear Overhauser effect spectroscopy** (NOESY) a map of all possible NOE interactions is obtained by using a proper choice of radiofrequency pulses and Fourier transformation techniques. Like a COSY spectrum, a NOESY spectrum consists of a series of diagonal peaks that correspond to the one-dimensional NMR spectrum of the sample. The off-diagonal peaks indicate which nuclei are close enough to each other to give rise to a nuclear Overhauser effect. NOESY data provide internuclear distances of up to about 0.5 nm.

## 14C.6 Solid-state NMR

The principal difficulty with the application of NMR to solids is the low resolution characteristic of solid samples. Nevertheless, there are good reasons for seeking to overcome these difficulties. They include the possibility that a compound of interest is unstable in solution or that it is insoluble, so conventional solution NMR cannot be employed. Moreover, many species, such as polymers and nanomaterials, are intrinsically interesting as solids, and it is important to be able to determine their structures and dynamics when X-ray diffraction techniques fail.

There are three principal contributions to the linewidths of solids. One is the direct magnetic dipolar interaction between nuclear spins. As pointed out in the discussion of spin–spin coupling (Topic 14B), a nuclear magnetic moment gives rise to a local magnetic field which points in different directions at different locations around the nucleus. If we are interested only in the component parallel to the direction of the applied magnetic field (because only this component has a significant effect), then, provided certain subtle effects arising from transformation from the static to the rotating frame are neglected, we can use a classical expression in *The chemist's toolkit* 14B.1 to write the magnitude of the local magnetic field as

$$\mathcal{B}_{\text{loc}} = -\frac{\gamma_N \hbar \mu_0 m_I}{4\pi R^3} (1 - 3\cos^2 \theta) \quad (14C.10)$$

Unlike in solution, in a solid this field is not motionally averaged to zero. Many nuclei may contribute to the total local field

experienced by a nucleus of interest, and different nuclei in a sample may experience a wide range of fields. Typical dipole fields are of the order of 1 mT, which corresponds to splittings and linewidths of the order of 10 kHz.

### Brief illustration 14C.5 Dipolar fields in solids

When the angle  $\theta$  can vary only between 0 and  $\theta_{\text{max}}$ , eqn 14C.10 becomes

$$\mathcal{B}_{\text{loc}} = \frac{\gamma_N \hbar \mu_0 m_I}{4\pi R^3} (\cos^2 \theta_{\text{max}} + \cos \theta_{\text{max}})$$

When  $\theta_{\text{max}} = 30^\circ$  and  $R = 160$  pm, the local field generated by a proton is

$$\begin{aligned} \mathcal{B}_{\text{loc}} &= \frac{\overbrace{(3.546 \dots \times 10^{-32} \text{ T m}^3)}^{\gamma_N \hbar \mu_0} \times \overbrace{\left(\frac{1}{2}\right)}^{m_I} \times \overbrace{1.616}^{\cos^2 \theta_{\text{max}} + \cos \theta_{\text{max}}}}{4\pi \times \underbrace{(1.60 \times 10^{-10} \text{ m})^3}_R} \\ &= 5.57 \times 10^{-4} \text{ T} = 0.557 \text{ mT} \end{aligned}$$

**Self-test 14C.6** Calculate the distance at which the local field from a <sup>13</sup>C nucleus is 0.50 mT, with  $\theta_{\text{max}} = 40^\circ$ .

Answer:  $R = 99$  pm

A second source of linewidth is the anisotropy of the chemical shift. Chemical shifts arise from the ability of the applied field to generate electron currents in molecules. In general, this ability depends on the orientation of the molecule relative to the applied field. In solution, when the molecule is tumbling rapidly, only the average value of the chemical shift is relevant. However, the anisotropy is not averaged to zero for stationary molecules in a solid, and molecules in different orientations have resonances at different frequencies. The chemical shift

**Figure 14C.20** In magic-angle spinning, the sample spins at  $54.74^\circ$  (that is,  $\arccos 1/3^{1/2}$ ) to the applied magnetic field. Rapid motion at this angle averages dipole–dipole interactions and chemical shift anisotropies to zero.

anisotropy also varies with the angle between the applied field and the principal axis of the molecule as  $1 - 3 \cos^2 \theta$ .

The third contribution is the electric quadrupole interaction. Nuclei with  $I > \frac{1}{2}$  have an electric quadrupole moment, a measure of the extent to which the distribution of charge over the nucleus is not uniform (for instance, the positive charge may be concentrated around the equator or at the poles). An electric quadrupole interacts with an electric field gradient, such as may arise from a non-spherical distribution of charge around the nucleus. This interaction also varies as  $1 - 3 \cos^2 \theta$ .

Fortunately, there are techniques available for reducing the linewidths of solid samples. One technique, **magic-angle spinning** (MAS), takes note of the  $1 - 3 \cos^2 \theta$  dependence of the dipole–dipole interaction, the chemical shift anisotropy, and the electric quadrupole interaction. The ‘magic angle’ is the

angle at which  $1 - 3 \cos^2 \theta = 0$ , and corresponds to  $54.74^\circ$ . In the technique, the sample is spun at high speed at the magic angle to the applied field (Fig. 14C.20). All the dipolar interactions and the anisotropies average to the value they would have at the magic angle, but at that angle they are zero. The difficulty with MAS is that the spinning frequency must not be less than the width of the spectrum, which is of the order of kilohertz. However, gas-driven sample spinners that can be rotated at up to 25 kHz are now routinely available, and a considerable body of work has been done.

Pulsed techniques similar to those described in the previous section may also be used to reduce linewidths. Elaborate pulse sequences have also been devised that reduce linewidths by averaging procedures that make use of twisting the magnetization vector through an elaborate series of angles.

## Checklist of concepts

- 1. **Free-induction decay** (FID) is the decay of the magnetization after the application of a radiofrequency pulse.
- 2. Fourier transformation of the FID curve gives the NMR spectrum.
- 3. During **longitudinal** (or **spin–lattice**) **relaxation**,  $\beta$  spins revert to  $\alpha$  spins.
- 4. **Transverse** (or **spin–spin**) **relaxation** is the randomization of spin directions around the  $z$ -axis.
- 5. The **longitudinal relaxation time**  $T_1$  can be measured by the **inversion recovery technique**.
- 6. The **transverse relaxation time**  $T_2$  can be measured by observing **spin echoes**.
- 7. In **proton decoupling** of  $^{13}\text{C}$ -NMR spectra, protons are made to undergo rapid spin reorientations and the  $^{13}\text{C}$  nucleus senses an average orientation.
- 8. The **nuclear Overhauser effect** (NOE) is the modification of the intensity of one resonance by the saturation of another.
- 9. In **two-dimensional** NMR, spectra are displayed in two axes, with resonances belonging to different groups lying at different locations on the second axis.
- 10. **Magic-angle spinning** (MAS) is technique in which the NMR linewidths in a solid sample are reduced by spinning at an angle of  $54.74^\circ$  to the applied magnetic field.

## Checklist of equations

Property	Equation	Comment	Equation number
Free-induction decay	$M_y(t) = M_0 \cos(2\pi\nu_1 t) e^{-t/T_2}$	$T_2$ is the transverse relaxation time	14C.1
Longitudinal relaxation	$M_z(t) - M_0 \propto e^{-t/T_1}$	$T_1$ is the spin–lattice relaxation time	14C.4

### ► Why do you need to know this material?

Many materials and biological systems contain species bearing unpaired electrons. Furthermore, some chemical reactions generate intermediates that contain unpaired electrons. You need to know how to characterize the structures of such species with special spectroscopic techniques.

### ► What is the key idea?

The electron paramagnetic resonance spectrum of a radical arises from the ability of the applied magnetic field to induce local electron currents and the magnetic interaction between the unpaired electron and nuclei with spin.

### ► What do you need to know already?

You need to be familiar with the concepts of electron spin (Topic 9B) and the general principles of magnetic resonance (Topic 14A). The discussion refers to spin-orbit coupling in atoms (Topic 9C) and the Fermi contact interaction in molecules (Topic 14B).

Electron paramagnetic resonance (EPR), which is also known as electron spin resonance (ESR), is used to study radicals formed during chemical reactions or by radiation, radicals that act as probes of biological structure, many d-metal complexes,

and molecules in triplet states (such as those involved in phosphorescence, Topic 13B). The sample may be a gas, a liquid, or a solid, but the free rotation of molecules in the gas phase gives rise to complications.

## 14D.1 The $g$ -value

The resonance frequency for a transition between the  $m_s = -\frac{1}{2}$  and the  $m_s = +\frac{1}{2}$  levels of an electron is

$$h\nu = g_e \mu_B \mathcal{B}_0 \quad \text{Free electron Resonance condition} \quad (14D.1)$$

where  $g_e \approx 2.0023$  (Topic 14A). The magnetic moment of an unpaired electron in a radical also interacts with an external field, but the field it experiences differs from the applied field due to the presence of local magnetic fields arising from electron currents induced in the molecular framework. This difference is taken into account by replacing  $g_e$  by  $g$  and expressing the resonance condition as

$$h\nu = g \mu_B \mathcal{B}_0 \quad \text{EPR resonance condition} \quad (14D.2)$$

where  $g$  is the  $g$ -value of the radical.

### Brief illustration 14D.1 The $g$ -value of a radical

The centre of the EPR spectrum of the methyl radical occurred at 329.40 mT in a spectrometer operating at 9.2330 GHz (radiation belonging to the X band of the microwave region). Its  $g$ -value is therefore

$$g = \frac{\overbrace{(6.626\,08 \times 10^{-34} \text{ J s})}^h \times \overbrace{(9.2330 \times 10^9 \text{ s}^{-1})}^\nu}{\underbrace{(9.2740 \times 10^{-24} \text{ J T}^{-1})}_{\mu_B} \times \underbrace{(0.32940 \text{ T})}_{\mathcal{B}_0}} = 2.0027$$

**Self-test 14D.1** At what magnetic field would the methyl radical come into resonance in a spectrometer operating at 34.000 GHz (radiation belonging to the Q band of the microwave region)?

Answer: 1.213 T

The  $g$ -value is related to the ease with which the applied field can stir up currents through the molecular framework and the strength of the magnetic field the currents generate. Therefore,

**Figure 14D.1** An applied magnetic field can induce circulation of electrons that makes use of excited state orbitals (shown with a white line).

the  $g$ -value gives some information about electronic structure and plays a similar role in EPR to that played by shielding constants in NMR.

Two factors are responsible for the difference of the  $g$ -value from  $g_e$ . Electrons migrate through the molecular framework by making use of excited states (Fig. 14D.1). This circulation gives rise to a local magnetic field that adds to the applied field. The extent to which these currents are induced is inversely proportional to the separation of energy levels,  $\Delta E$ , in the radical or complex. Secondly, the strength of the field experienced by the electron spin as a result of these electronic currents is proportional to the spin-orbit coupling constant,  $\xi$  (Topic 9C). We can conclude that the  $g$ -value differs from  $g_e$  by an amount that is proportional to  $\xi/\Delta E$ . This proportionality is widely observed. Many organic radicals, for which  $\Delta E$  is large and  $\xi$  (for carbon) is small, have  $g$ -values close to 2.0027, not far removed from  $g_e$  itself. Inorganic radicals, which commonly are built from heavier atoms and therefore have larger spin-orbit coupling constants, have  $g$ -values typically in the range 1.9 to 2.1. The  $g$ -values of paramagnetic d-metal complexes often differ considerably from  $g_e$ , varying from 0 to 6, because in them  $\Delta E$  is small on account of the small splitting of d-orbitals brought about by interactions with ligands (Topic 13A).

The  $g$ -value is anisotropic: that is, its magnitude depends on the orientation of the radical with respect to the applied field. The anisotropy arises from the fact that the extent to which an applied field induces currents in the molecule, and therefore the magnitude of the local field, depends on the relative orientation of the molecules and the field. In solution, when the molecule is tumbling rapidly, only the average value of the  $g$ -value is observed. Therefore, anisotropy of the  $g$ -value is observed only for radicals trapped in solids.

## 14D.2 Hyperfine structure

The most important feature of an EPR spectrum is its **hyperfine structure**, the splitting of individual resonance lines into components. In general in spectroscopy, the term ‘hyperfine

structure’ means the structure of a spectrum that can be traced to interactions of the electrons with nuclei other than as a result of the latter’s point electric charge. The source of the hyperfine structure in EPR is the magnetic interaction between the electron spin and the magnetic dipole moments of the nuclei present in the radical which give rise to local magnetic fields.

### (a) The effects of nuclear spin

Consider the effect on the EPR spectrum of a single H nucleus located somewhere in a radical. The proton spin is a source of magnetic field and, depending on the orientation of the nuclear spin, the field it generates adds to or subtracts from the applied field. The total local field is therefore

$$\mathcal{B}_{\text{loc}} = \mathcal{B}_0 + am_I \quad m_I = \pm \frac{1}{2} \quad (14D.3)$$

where  $a$  is the **hyperfine coupling constant**. Half the radicals in a sample have  $m_I = +\frac{1}{2}$ , so half resonate when the applied field satisfies the condition

$$h\nu = g\mu_B(\mathcal{B}_0 + \frac{1}{2}a), \quad \text{or} \quad \mathcal{B}_0 = \frac{h\nu}{g\mu_B} - \frac{1}{2}a \quad (14D.4a)$$

The other half (which have  $m_I = -\frac{1}{2}$ ) resonate when

$$h\nu = g\mu_B(\mathcal{B}_0 - \frac{1}{2}a), \quad \text{or} \quad \mathcal{B}_0 = \frac{h\nu}{g\mu_B} + \frac{1}{2}a \quad (14D.4b)$$

Therefore, instead of a single line, the spectrum shows two lines of half the original intensity separated by  $a$  and centred on the field determined by  $g$  (Fig. 14D.2).

**Figure 14D.2** The hyperfine interaction between an electron and a spin- $\frac{1}{2}$  nucleus results in four energy levels in place of the original two. As a result, the spectrum consists of two lines (of equal intensity) instead of one. The intensity distribution can be summarized by a simple stick diagram. The diagonal lines show the energies of the states as the applied field is increased, and resonance occurs when the separation of states matches the fixed energy of the microwave photon.

If the radical contains an  $^{14}\text{N}$  atom ( $I=1$ ), its EPR spectrum consists of three lines of equal intensity, because the  $^{14}\text{N}$  nucleus has three possible spin orientations, and each spin orientation is possessed by one-third of all the radicals in the sample. In general, a spin- $I$  nucleus splits the spectrum into  $2I+1$  hyperfine lines of equal intensity.

When there are several magnetic nuclei present in the radical, each one contributes to the hyperfine structure. In the case of equivalent protons (for example, the two  $\text{CH}_2$  protons in the radical  $\text{CH}_3\text{CH}_2$ ) some of the hyperfine lines are coincident. If the radical contains  $N$  equivalent protons, then there are  $N+1$  hyperfine lines with an intensity distribution given by Pascal's triangle (Topic 14B, reproduced here as 1). The spectrum of the benzene radical anion in Fig. 14D.3, which has seven lines with intensity ratio 1:6:15:20:15:6:1, is consistent with a radical containing six equivalent protons. More generally, if the radical contains  $N$  equivalent nuclei with spin quantum number  $I$ , then there are  $2NI+1$  hyperfine lines with an intensity distribution based on a modified version of Pascal's triangle as shown in the following *Example*.

		1				
	1	1				
	1	2	1

**Figure 14D.3** The EPR spectrum of the benzene radical anion,  $\text{C}_6\text{H}_6^-$ , in fluid solution, with  $a$  the hyperfine splitting of the spectrum. The centre of the spectrum is determined by the  $g$ -value of the radical.

#### Example 14D.1 Predicting the hyperfine structure of an EPR spectrum

A radical contains one  $^{14}\text{N}$  nucleus ( $I=1$ ) with hyperfine constant 1.61 mT and two equivalent protons ( $I=\frac{1}{2}$ ) with hyperfine constant 0.35 mT. Predict the form of the EPR spectrum.

**Method** Consider the hyperfine structure that arises from each type of nucleus or group of equivalent nuclei in succession. So, split a line with one nucleus, then each of those lines

is split by a second nucleus (or group of nuclei), and so on. It is best to start with the nucleus with the largest hyperfine splitting; however, any choice could be made, and the order in which nuclei are considered does not affect the conclusion.

**Answer** The  $^{14}\text{N}$  nucleus gives three hyperfine lines of equal intensity separated by 1.61 mT. Each line is split into doublets of spacing 0.35 mT by the first proton, and each line of these doublets is split into doublets with the same 0.35 mT splitting (Fig. 14D.4). The central lines of each split doublet coincide, so the proton splitting gives 1:2:1 triplets of internal splitting 0.35 mT. Therefore, the spectrum consists of three equivalent 1:2:1 triplets.

**Figure 14D.4** The analysis of the hyperfine structure of radicals containing one  $^{14}\text{N}$  nucleus ( $I=1$ ) and two equivalent protons.

**Self-test 14D.2** Predict the form of the EPR spectrum of a radical containing three equivalent  $^{14}\text{N}$  nuclei.

Answer: See Fig. 14D.5.

**Figure 14D.5** The analysis of the hyperfine structure of radicals containing three equivalent  $^{14}\text{N}$  nuclei.

#### (b) The McConnell equation

The hyperfine structure of an EPR spectrum is a kind of fingerprint that helps to identify the radicals present in a sample. Moreover, because the magnitude of the splitting depends on the distribution of the unpaired electron in the vicinity of the magnetic nuclei, the spectrum can be used to map the

molecular orbital occupied by the unpaired electron. For example, because the hyperfine splitting in  $C_6H_6^-$  is 0.375 mT, and one proton is close to a C atom that has one-sixth the unpaired electron spin density (because the electron is spread uniformly around the ring), the hyperfine splitting caused by a proton in the electron spin entirely confined to a single adjacent C atom should be  $6 \times 0.375 \text{ mT} = 2.25 \text{ mT}$ . If in another aromatic radical we find a hyperfine splitting constant  $a$ , then the **spin density**,  $\rho$ , the probability that an unpaired electron is on the atom, can be calculated from the **McConnell equation**:

$$a = Q\rho \quad \text{McConnell equation} \quad (14D.5)$$

with  $Q = 2.25 \text{ mT}$ . In this equation,  $\rho$  is the spin density on a C atom and  $a$  is the hyperfine splitting observed for the H atom to which it is attached. This expression simply represents the fact that the hyperfine coupling to the H atom is likely to be proportional to the spin density on the C atom to which it is attached.

#### Brief illustration 14D.2 The McConnell equation

The hyperfine structure of the EPR spectrum of  $C_{10}H_8^-$ , the naphthalene radical anion, can be interpreted as arising from two groups of four equivalent protons. Those at the 1, 4, 5, and 8 positions in the ring have  $a = 0.490 \text{ mT}$  and those in the 2, 3, 6, and 7 positions have  $a = 0.183 \text{ mT}$ . The densities obtained by using the McConnell equation are, respectively (2),

$$\rho = \frac{0.490 \text{ mT}}{2.25 \text{ mT}} = 0.218 \quad \text{and} \quad \rho = \frac{0.183 \text{ mT}}{2.25 \text{ mT}} = 0.0813$$

**Self-test 14D.3** The spin density in  $C_{14}H_{10}^-$ , the anthracene radical anion, is shown in (3). Predict the form of its EPR spectrum.

Answer: A 1:2:1 triplet of splitting 0.43 mT split into a 1:4:6:4:1 quintet of splitting 0.22 mT, split into a 1:4:6:4:1 quintet of splitting 0.11 mT,  $3 \times 5 \times 5 = 75$  lines in all

### (c) The origin of the hyperfine interaction

The hyperfine interaction is an interaction between the magnetic moments of the unpaired electron and the nuclei. There are two contributions to the interaction.

An electron in a p orbital centred on a nucleus does not approach the nucleus very closely, so it experiences a field that appears to arise from a point magnetic dipole. The resulting interaction is called the **dipole–dipole interaction**. The contribution of a magnetic nucleus to the local field experienced by the unpaired electron is given by an expression like that in eqn 14B.10a (a dependence proportional to  $(1 - 3 \cos^2 \theta)/r^3$ ). A characteristic of this type of interaction is that it is anisotropic and averages to zero when the radical is free to tumble. Therefore, hyperfine structure due to the dipole–dipole interaction is observed only for radicals trapped in solids.

An s electron is spherically distributed around a nucleus and so has zero average dipole–dipole interaction with the nucleus even in a solid sample. However, because it has a nonzero probability of being at the nucleus, it is incorrect to treat the interaction as one between two point dipoles. As explained in Topic 14B, an s electron has a Fermi contact interaction with the nucleus, a magnetic interaction that occurs when the point dipole approximation fails. The contact interaction is isotropic (that is, independent of the radical's orientation), and consequently is shown even by rapidly tumbling molecules in fluids (provided the spin density has some s character).

The dipole–dipole interactions of p electrons and the Fermi contact interaction of s electrons can be quite large. For example, a 2p electron in a nitrogen atom experiences an average field of about 3.4 mT from the  $^{14}\text{N}$  nucleus. A 1s electron in a hydrogen atom experiences a field of about 50 mT as a result of its Fermi contact interaction with the central proton. More values are listed in Table 14D.1. The magnitudes of the contact interactions in radicals can be interpreted in terms of the s orbital character of the molecular orbital occupied by the unpaired electron, and the dipole–dipole interaction can be interpreted in terms of the p character. The analysis of hyperfine structure therefore gives information about the composition of the orbital, and especially the hybridization of the atomic orbitals.

Table 14D.1\* Hyperfine coupling constants for atoms,  $a/\text{mT}$

Nuclide	Isotropic coupling	Anisotropic coupling
$^1\text{H}$	50.8 (1s)	
$^2\text{H}$	7.8 (1s)	
$^{14}\text{N}$	55.2 (2s)	4.8 (2p)
$^{19}\text{F}$	1720 (2s)	108.4 (2p)

\*More values are given in the Resource section.

#### Brief illustration 14D.3 The composition of a molecular orbital from analysis of the hyperfine structure

From Table 14D.1, the hyperfine interaction between a 2s electron and the nucleus of a nitrogen atom is 55.2 mT. The EPR spectrum of  $\text{NO}_2$  shows an isotropic hyperfine interaction of

5.7 mT. The  $s$  character of the molecular orbital occupied by the unpaired electron is the ratio  $5.7/55.2=0.10$ . For a continuation of this story, see Problem 14D.6.

**Self-test 14D.4** In  $\text{NO}_2$  the anisotropic part of the hyperfine coupling is 1.3 mT. What is the  $p$  character of the molecular orbital occupied by the unpaired electron?

Answer: 0.38

We still have the source of the hyperfine structure of the  $\text{C}_6\text{H}_6^-$  anion and other aromatic radical anions to explain. The sample is fluid, and as the radicals are tumbling the hyperfine structure cannot be due to the dipole–dipole interaction. Moreover, the protons lie in the nodal plane of the  $\pi$  orbital occupied by the unpaired electron, so the structure cannot be due to a Fermi contact interaction. The explanation lies in a **polarization mechanism** similar to the one responsible for spin–spin coupling in NMR. There is a magnetic interaction between a proton and the  $\alpha$  electrons ( $m_s = \pm\frac{1}{2}$ ) which results in one of the electrons tending to be found with a greater probability nearby

**Figure 14D.6** The polarization mechanism for the hyperfine interaction in  $\pi$ -electron radicals. The arrangement in (a) is lower in energy than that in (b), so there is an effective coupling between the unpaired electron and the proton.

(Fig. 14D.6). The electron with opposite spin is therefore more likely to be close to the C atom at the other end of the bond. The unpaired electron on the C atom has a lower energy if it is parallel to that electron (Hund's rule favours parallel electrons on atoms), so the unpaired electron can detect the spin of the proton indirectly. Calculation using this model leads to a hyperfine interaction in agreement with the observed value of 2.25 mT.

## Checklist of concepts

1. The EPR resonance condition is written in terms of the  **$g$ -value** of the radical.
2. The value of  $g$  depends on the ability of the applied field to induce local electron currents in the radical.
3. The **hyperfine structure** of an EPR spectrum is its splitting of individual resonance lines into components by the magnetic interaction between the electron and nuclei with spin.
4. If a radical contains  $N$  equivalent nuclei with spin quantum number  $I$ , then there are  $2NI + 1$  hyperfine lines with an intensity distribution given by a modified version of Pascal's triangle.
5. Hyperfine structure can be explained by **dipole–dipole interactions**, **Fermi contact interactions**, and the **polarization mechanism**.
6. The **spin density** is the probability that an unpaired electron is on the atom.

## Checklist of equations

Property	Equation	Comment	Equation number
EPR resonance condition	$h\nu = g\mu_B\mathcal{B}_0$	No hyperfine interaction	14D.2
	$h\nu = g\mu_B(\mathcal{B}_0 \pm \frac{1}{2}a)$	Hyperfine interaction between an electron and a proton	14D.4
McConnell equation	$a = Q\rho$	$Q = 2.25$ mT	14D.5

# CHAPTER 14 Magnetic resonance

## TOPIC 14A General principles

### Discussion questions

**14A.1** To determine the structures of macromolecules by NMR spectroscopy, chemists use spectrometers that operate at the highest available fields and frequencies. Justify this choice.

**14A.2** Compare the effects of magnetic fields on the energies of nuclei and the energies of electrons.

**14A.3** What is the Larmor frequency? What is its role in magnetic resonance?

### Exercises

**14A.1(a)** Given that  $g$  is a dimensionless number, what are the units of  $\gamma_N$  expressed in tesla and hertz?

**14A.1(b)** Given that  $g$  is a dimensionless number, what are the units of  $\gamma_N$  expressed in SI base units?

**14A.2(a)** For a proton, what are the magnitude of the spin angular momentum and its allowed components along the  $z$ -axis? What are the possible orientations of the angular momentum in terms of the angle it makes with the  $z$ -axis?

**14A.2(b)** For a  $^{14}\text{N}$  nucleus, what are the magnitude of the spin angular momentum and its allowed components along the  $z$ -axis? What are the possible orientations of the angular momentum in terms of the angle it makes with the  $z$ -axis?

**14A.3(a)** What is the resonance frequency of a proton in a magnetic field of 13.5 T?

**14A.3(b)** What is the resonance frequency of a  $^{19}\text{F}$  nucleus in a magnetic field of 17.1 T?

**14A.4(a)**  $^{33}\text{S}$  has a nuclear spin of  $\frac{3}{2}$  and a nuclear  $g$ -factor of 0.4289. Calculate the energies of the nuclear spin states in a magnetic field of 6.800 T.

**14A.4(b)**  $^{14}\text{N}$  has a nuclear spin of 1 and a nuclear  $g$ -factor of 0.404. Calculate the energies of the nuclear spin states in a magnetic field of 10.50 T.

**14A.5(a)** Calculate the frequency separation of the nuclear spin levels of a  $^{13}\text{C}$  nucleus in a magnetic field of 15.4 T given that the magnetogyric ratio is  $6.73 \times 10^{-7} \text{ T}^{-1} \text{ s}^{-1}$ .

**14A.5(b)** Calculate the frequency separation of the nuclear spin levels of a  $^{14}\text{N}$  nucleus in a magnetic field of 14.4 T given that the magnetogyric ratio is  $1.93 \times 10^{-7} \text{ T}^{-1} \text{ s}^{-1}$ .

**14A.6(a)** In which of the following systems is the energy level separation larger? (i) A proton in a 600 MHz NMR spectrometer, (ii) a deuteron in the same spectrometer.

**14A.6(b)** In which of the following systems is the energy level separation larger? (i) A  $^{14}\text{N}$  nucleus in (for protons) a 600 MHz NMR spectrometer, (ii) an electron in a radical in a field of 0.300 T.

**14A.7(a)** Calculate the relative population differences ( $\delta N/N$ , where  $\delta N$  denotes a small difference  $N_\alpha - N_\beta$ ) for protons in fields of (i) 0.30 T, (ii) 1.5 T, and (iii) 10 T at 25 °C.

**14A.7(b)** Calculate the relative population differences ( $\delta N/N$ , where  $\delta N$  denotes a small difference  $N_\alpha - N_\beta$ ) for  $^{13}\text{C}$  nuclei in fields of (i) 0.50 T, (ii) 2.5 T, and (iii) 15.5 T at 25 °C.

**14A.8(a)** The first generally available NMR spectrometers operated at a frequency of 60 MHz; today it is not uncommon to use a spectrometer that operates at 800 MHz. What are the relative population differences of  $^{13}\text{C}$  spin states in these two spectrometers at 25 °C?

**14A.8(b)** What are the relative population differences of  $^{19}\text{F}$  spin states in spectrometers operating at 60 MHz and 450 MHz at 25 °C?

**14A.9(a)** What magnetic field would be required in order to use an EPR X-band spectrometer (9 GHz) to observe  $^1\text{H}$ -NMR and a 300 MHz spectrometer to observe EPR?

**14A.9(b)** Some commercial EPR spectrometers use 8 mm microwave radiation (the 'Q band'). What magnetic field is needed to satisfy the resonance condition?

### Problems

**14A.1** A scientist investigates the possibility of neutron spin resonance, and has available a commercial NMR spectrometer operating at 300 MHz. What field is required for resonance? What is the relative population difference at room temperature? Which is the lower energy spin state of the neutron?

**14A.2\*** The relative sensitivity of NMR lines for equal numbers of different nuclei at constant temperature for a given frequency is  $R_\nu \propto (I+1)\mu^3$  whereas for a given field it is  $R_B \propto \{(I+1)I^2\}\mu^3$ . (a) From the data in Table 14A.2, calculate these sensitivities for the deuteron,  $^{13}\text{C}$ ,  $^{14}\text{N}$ ,  $^{19}\text{F}$ , and  $^{31}\text{P}$  relative to the proton. (b) Develop the equation for  $R_B$  from the equation for  $R_\nu$ .

**14A.3** With special techniques, known collectively as magnetic resonance imaging (MRI), it is possible to obtain NMR spectra of entire organisms. A key to MRI is the application of a magnetic field that varies linearly across the specimen. Consider a flask of water held in a field that varies in the

$z$ -direction according to  $\mathcal{B}_0 + \mathcal{G}_z z$ , where  $\mathcal{G}_z$  is the field gradient along the  $z$ -direction. Then the water protons will be resonant at the frequencies

$$\nu_L(z) = \frac{\gamma_N}{2\pi} (\mathcal{B}_0 + \mathcal{G}_z z)$$

(Similar equations may be written for gradients along the  $x$ - and  $y$ -directions.) Application of a 90° radiofrequency pulse with  $\nu = \nu_L(z)$  will result in a signal with an intensity that is proportional to the numbers of protons at the position  $z$ . Now suppose a uniform disk-shaped organ is in a linear field gradient, and that the MRI signal is proportional to the number of protons in a slice of width  $\delta z$  at each horizontal distance  $z$  from the centre of the disk. Sketch the shape of the absorption intensity for the MRI image of the disk before any computer manipulation has been carried out.

\* These problems were supplied by Charles Trapp and Carmen Giunta.

## TOPIC 14B Features of NMR spectra

### Discussion questions

**14B.1** Describe the significance of the chemical shift in relation to the terms 'high-field' and 'low-field'.

**14B.2** Discuss in detail the origins of the local, neighbouring group, and solvent contributions to the shielding constant.

**14B.3** Explain why groups of equivalent protons do not exhibit the spin-spin coupling that exists between them.

**14B.4** Explain the difference between magnetically equivalent and chemically equivalent nuclei, and give two examples of each.

**14B.5** Discuss how the Fermi contact interaction and the polarization mechanism contribute to spin-spin couplings in NMR.

### Exercises

**14B.1(a)** What are the relative values of the chemical shifts observed for nuclei in the spectrometers mentioned in Exercise 14A.9a in terms of (i)  $\delta$  values, (ii) frequencies?

**14B.1(b)** What are the relative values of the chemical shifts observed for nuclei in the spectrometers mentioned in Exercise 14A.9b in terms of (i)  $\delta$  values, (ii) frequencies?

**14B.2(a)** The chemical shift of the  $\text{CH}_3$  protons in acetaldehyde (ethanal) is  $\delta = 2.20$  and that of the CHO proton is 9.80. What is the difference in local magnetic field between the two regions of the molecule when the applied field is (i) 1.5 T, (ii) 15 T?

**14B.2(b)** The chemical shift of the  $\text{CH}_3$  protons in diethyl ether is  $\delta = 1.16$  and that of the  $\text{CH}_2$  protons is 3.36. What is the difference in local magnetic field between the two regions of the molecule when the applied field is (i) 1.9 T, (ii) 16.5 T?

**14B.3(a)** Sketch the appearance of the  $^1\text{H}$ -NMR spectrum of acetaldehyde (ethanal) using  $J = 2.90$  Hz and the data in Exercise 14B.2(a) in a spectrometer operating at (i) 250 MHz, (ii) 800 MHz.

**14B.3(b)** Sketch the appearance of the  $^1\text{H}$ -NMR spectrum of diethyl ether using  $J = 6.97$  Hz and the data in Exercise 14B.2(b) in a spectrometer operating at (i) 400 MHz, (ii) 650 MHz.

**14B.4(a)** Sketch the form of the  $^{19}\text{F}$ -NMR spectra of a natural sample of  $^{10}\text{BF}_4^-$  and  $^{11}\text{BF}_4^-$ .

**14B.4(b)** Sketch the form of the  $^{31}\text{P}$ -NMR spectra of a sample of  $^{31}\text{PF}_6^-$ .

**14B.5(a)** From the data in Table 14A.2, predict the frequency needed for  $^{19}\text{F}$ -NMR in an NMR spectrometer designed to observe proton

resonance at 800 MHz. Sketch the proton and  $^{19}\text{F}$  resonances in the NMR spectrum of  $\text{FH}_2^+$ .

**14B.5(b)** From the data in Table 14A.2, predict the frequency needed for  $^{31}\text{P}$ -NMR in an NMR spectrometer designed to observe proton resonance at 500 MHz. Sketch the proton and  $^{31}\text{P}$  resonances in the NMR spectrum of  $\text{PH}_4^+$ .

**14B.6(a)** Construct a version of Pascal's triangle to show the fine structure that might arise from spin-spin coupling to a group of four spin- $\frac{3}{2}$  nuclei.

**14B.6(b)** Construct a version of Pascal's triangle to show the fine structure that might arise from spin-spin coupling to a group of three spin- $\frac{5}{2}$  nuclei.

**14B.7(a)** Sketch the form of an  $\text{A}_3\text{M}_2\text{X}_4$  spectrum, where A, M, and X are protons with distinctly different chemical shifts and  $J_{\text{AM}} > J_{\text{AX}} > J_{\text{MX}}$ .

**14B.7(b)** Sketch the form of an  $\text{A}_2\text{M}_2\text{X}_5$  spectrum, where A, M, and X are protons with distinctly different chemical shifts and  $J_{\text{AM}} > J_{\text{AX}} > J_{\text{MX}}$ .

**14B.8(a)** Which of the following molecules have sets of nuclei that are chemically but not magnetically equivalent? (i)  $\text{CH}_3\text{CH}_3$ , (ii)  $\text{CH}_2 = \text{CH}_2$ .

**14B.8(b)** Which of the following molecules have sets of nuclei that are chemically but not magnetically equivalent? (i)  $\text{CH}_2 = \text{C} = \text{CF}_2$ , (ii) *cis*- and *trans*- $[\text{Mo}(\text{CO})_4(\text{PH}_3)_2]$ .

**14B.9(a)** A proton jumps between two sites with  $\delta = 2.7$  and  $\delta = 4.8$ . At what rate of interconversion will the two signals collapse to a single line in a spectrometer operating at 550 MHz?

**14B.9(b)** A proton jumps between two sites with  $\delta = 4.2$  and  $\delta = 5.5$ . At what rate of interconversion will the two signals collapse to a single line in a spectrometer operating at 350 MHz?

### Problems

**14B.1** You are designing an MRI spectrometer (see Problem 14A.3). What field gradient (in microtesla per metre,  $\mu\text{T m}^{-1}$ ) is required to produce a separation of 100 Hz between two protons separated by the long diameter of a human kidney (taken as 8 cm) given that they are in environments with  $\delta = 3.4$ ? The radiofrequency field of the spectrometer is at 400 MHz and the applied field is 9.4 T.

**14B.2** Refer to Fig. 14B.14 and use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book to draw a family of curves showing the variation of  $^3J_{\text{HH}}$  with  $\phi$  for which  $A = +7.0$  Hz,  $B = -1.0$  Hz, and  $C$  varies slightly from a typical value of +5.0 Hz. What is the effect of changing the value of the parameter  $C$  on the shape of the curve? In a similar fashion, explore the effect of the values of  $A$  and  $B$  on the shape of the curve.

**14B.3\*** Various versions of the Karplus equation (eqn 14B.14) have been used to correlate data on vicinal proton coupling constants in systems of the type  $\text{R}_1\text{R}_2\text{CHCHR}_3\text{R}_4$ . The original version, (M. Karplus, *J. Am. Chem. Soc.* **85**, 2870 (1963)), is  $^3J_{\text{HH}} = A \cos^2 \phi_{\text{HH}} + B$ . When  $\text{R}_3 = \text{R}_4 = \text{H}$ ,  $^3J_{\text{HH}} = 7.3$  Hz; when  $\text{R}_3 = \text{CH}_3$  and  $\text{R}_4 = \text{H}$ ,  $^3J_{\text{HH}} = 8.0$  Hz; when  $\text{R}_3 = \text{R}_4 = \text{CH}_3$ ,  $^3J_{\text{HH}} = 11.2$  Hz. Assume

that only staggered conformations are important and determine which version of the Karplus equation fits the data better.

**14B.4\*** It might be unexpected that the Karplus equation, which was first derived for  $^3J_{\text{HH}}$  coupling constants, should also apply to vicinal coupling between the nuclei of metals such as tin. T.N. Mitchell and B. Kowall (*Magn. Reson. Chem.* **33**, 325 (1995)) have studied the relation between  $^3J_{\text{HH}}$  and  $^3J_{\text{SnSn}}$  in compounds of the type  $\text{Me}_3\text{SnCH}_2\text{CHR}_3\text{SnMe}_3$  and find that  $^3J_{\text{SnSn}} = 78.86 \ ^3J_{\text{HH}} + 27.84$  Hz. (a) Does this result support a Karplus type equation for tin? Explain your reasoning. (b) Obtain the Karplus equation for  $^3J_{\text{SnSn}}$  and plot it as a function of the dihedral angle. (c) Draw the preferred conformation.

**14B.5** Show that the coupling constant as expressed by the Karplus equation passes through a minimum when  $\cos \phi = B/4C$ .

**14B.6** In a liquid, the dipolar magnetic field averages to zero: show this result by evaluating the average of the field given in eqn 14B.15. *Hint*: the surface area element is  $\sin \theta \, d\theta \, d\phi$  in polar coordinates.

## TOPIC 14C Pulse techniques in NMR

### Discussion questions

**14C.1** Discuss in detail the effects of a  $90^\circ$  pulse and of a  $180^\circ$  pulse on a system of spin- $\frac{1}{2}$  nuclei in a static magnetic field.

**14C.2** Suggest a reason why the relaxation times of  $^{13}\text{C}$  nuclei are typically much longer than those of  $^1\text{H}$  nuclei.

**14C.3** Suggest a reason why the spin-lattice relaxation time of a small molecule (like benzene) in a mobile, deuterated hydrocarbon solvent increases whereas that of a large molecule (like a polymer) decreases.

### Exercises

**14C.1(a)** The duration of a  $90^\circ$  or  $180^\circ$  pulse depends on the strength of the  $\mathcal{B}_1$  field. If a  $180^\circ$  pulse requires  $12.5\ \mu\text{s}$ , what is the strength of the  $\mathcal{B}_1$  field? How long would the corresponding  $90^\circ$  pulse require?

**14C.1(b)** The duration of a  $90^\circ$  or  $180^\circ$  pulse depends on the strength of the  $\mathcal{B}_1$  field. If a  $90^\circ$  pulse requires  $5\ \mu\text{s}$ , what is the strength of the  $\mathcal{B}_1$  field? How long would the corresponding  $180^\circ$  pulse require?

**14C.2(a)** What is the effective transverse relaxation time when the width of a resonance line is  $1.5\ \text{Hz}$ ?

**14C.2(b)** What is the effective transverse relaxation time when the width of a resonance line is  $12\ \text{Hz}$ ?

**14C.3(a)** Predict the maximum enhancement (as the value of  $\eta$ ) that could be obtained in a NOE observation in which  $^{31}\text{P}$  is coupled to protons.

**14C.3(b)** Predict the maximum enhancement (as the value of  $\eta$ ) that could be obtained in a NOE observation in which  $^{19}\text{F}$  is coupled to protons.

**14C.4(a)** Figure 14.1 shows the proton COSY spectrum of 1-nitropropane. Account for the appearance of off-diagonal peaks in the spectrum.

**14C.4(b)** The proton chemical shifts for the  $\text{NH}$ ,  $\text{C}_\alpha\text{H}$ , and  $\text{C}_\beta\text{H}$  groups of alanine are  $8.25\ \text{ppm}$ ,  $4.35\ \text{ppm}$ , and  $1.39\ \text{ppm}$ , respectively. Sketch the COSY spectrum of alanine between  $1.00$  and  $8.50\ \text{ppm}$ .

### Problems

**14C.1\*** Suppose that the FID in Fig. 14C.5 was recorded in a  $400\ \text{MHz}$  spectrometer, and that the interval between maxima in the oscillations in the FID is  $0.12\ \text{s}$ . What is the Larmor frequency of the nuclei and the spin-spin relaxation time?

**14C.2** Use mathematical software to construct the FID curve for a set of three nuclei with resonances at  $\delta = 3.2, 4.1,$  and  $5.0$  in a spectrometer operating at  $800\ \text{MHz}$ . Suppose that  $T_1 = 1.0\ \text{s}$ . Go on to plot FID curves that show how they vary as the magnetic field of the spectrometer is changed.

**14C.3** To gain some appreciation for the numerical work done by computers interfaced to NMR spectrometers, perform the following calculations. (a) The total FID  $F(t)$  of a signal containing many frequencies, each corresponding to a different nucleus, is given by

$$F(t) = \sum_j S_{0j} \cos(2\pi\nu_{1j}t) e^{-t/T_{2j}}$$

where, for each nucleus  $j$ ,  $S_{0j}$  is the maximum intensity of the signal,  $\nu_{1j}$  is the Larmor frequency, and  $T_{2j}$  is the spin-spin relaxation time. Plot the FID for the case

$$\begin{array}{lll} S_{01} = 1.0 & \nu_{11} = 50\ \text{MHz} & T_{21} = 0.50\ \mu\text{s} \\ S_{02} = 3.0 & \nu_{12} = 10\ \text{MHz} & T_{22} = 1.0\ \mu\text{s} \end{array}$$

**14C.4** Discuss the origin of the nuclear Overhauser effect and how it can be used to measure distances between protons in a biopolymer.

**14C.5** Discuss the origins of diagonal and cross peaks in the COSY spectrum of an AX system.

**Figure 14.1** The COSY spectrum of 1-nitropropane ( $\text{NO}_2\text{CH}_2\text{CH}_2\text{CH}_3$ ). The circles show enhanced views of the spectral features. (Spectrum provided by Prof. G. Morris.)

(b) Explore how the shape of the FID curve changes with changes in the Larmor frequency and the spin-spin relaxation time. (c) Use mathematical software to calculate and plot the Fourier transforms of the FID curves you calculated in parts (a) and (b). How do spectral linewidths vary with the value of  $T_2$ ? *Hint:* This operation can be performed with the ‘fast Fourier transform’ routine available in most mathematical software packages. Please consult the package’s user manual for details.

**14C.4** (a) In many instances it is possible to approximate the NMR lineshape by using a *Lorentzian function* of the form

$$I_{\text{Lorentzian}}(\omega) = \frac{S_0 T_2}{1 + T_2^2 (\omega - \omega_0)^2}$$

where  $I(\omega)$  is the intensity as a function of the angular frequency  $\omega = 2\pi\nu$ ,  $\omega_0$  is the resonance frequency,  $S_0$  is a constant, and  $T_2$  is the spin-spin relaxation time. Confirm that for this lineshape the width at half-height is  $1/\pi T_2$ .

(b) Under certain circumstances, NMR lines are Gaussian functions of the frequency, given by

$$I_{\text{Gaussian}}(\omega) = S_0 T_2 e^{-T_2^2 (\omega - \omega_0)^2}$$

Confirm that for the Gaussian lineshape the width at half-height is equal to  $2(\ln 2)^{1/2}/T_2$ . (c) Compare and contrast the shapes of Lorentzian and Gaussian lines by plotting two lines with the same values of  $S_0$ ,  $T_2$ , and  $\omega_0$ .

**14C.5** The shape of a spectral line,  $I(\omega)$ , is related to the free induction decay signal  $G(t)$  by

$$I(\omega) = a \operatorname{Re} \int_0^{\infty} G(t) e^{i\omega t} dt$$

where  $a$  is a constant and ‘Re’ means take the real part of what follows. Calculate the lineshape corresponding to an oscillating, decaying function  $G(t) = \cos \omega t e^{-t/\tau}$ .

**14C.6** In the language of Problem 14C.5, show that if  $G(t) = (a \cos \omega t + b \sin \omega t) e^{-t/\tau}$ , then the spectrum consists of two lines with intensities proportional to  $a$  and  $b$  and located at  $\omega = \omega_1$  and  $\omega_2$ , respectively.

**14C.7** The  $z$ -component of the magnetic field at a distance  $R$  from a magnetic moment parallel to the  $z$ -axis is given by eqn 14C.10. In a solid, a proton at a distance  $R$  from another can experience such a field and the measurement of the splitting it causes in the spectrum can be used to calculate  $R$ . In gypsum, for instance, the splitting in the  $\text{H}_2\text{O}$  resonance can be interpreted in terms of

a magnetic field of 0.715 mT generated by one proton and experienced by the other. What is the separation of the protons in the  $\text{H}_2\text{O}$  molecule?

**14C.8** Interpret the following features of the NMR spectra of hen lysozyme: (a) saturation of a proton resonance assigned to the side chain of methionine-105 changes the intensities of proton resonances assigned to the side chains of tryptophan-28 and tyrosine-23; (b) saturation of proton resonances assigned to tryptophan-28 did not affect the spectrum of tyrosine-23.

**14C.9** In a liquid crystal a molecule might not rotate freely in all directions and the dipolar interaction might not average to zero. Suppose a molecule is trapped so that, although the vector separating two protons may rotate freely around the  $z$ -axis, the colatitude may vary only between 0 and  $\theta'$ . Use mathematical software to average the dipolar field over this restricted range of orientation and confirm that the average vanishes when  $\theta'$  is equal to  $\pi$  (corresponding to free rotation over a sphere). What is the average value of the local dipolar field for the  $\text{H}_2\text{O}$  molecule in Problem 14C.7 if it is dissolved in a liquid crystal that enables it to rotate up to  $\theta' = 30^\circ$ ?

## TOPIC 14D Electron paramagnetic resonance

### Discussion questions

**14D.1** Describe how the Fermi contact interaction and the polarization mechanism contribute to hyperfine interactions in EPR.

**14D.2** Explain how the EPR spectrum of an organic radical can be used to identify and map the molecular orbital occupied by the unpaired electron.

### Exercises

**14D.1(a)** The centre of the EPR spectrum of atomic hydrogen lies at 329.12 mT in a spectrometer operating at 9.2231 GHz. What is the  $g$  value of the electron in the atom?

**14D.1(b)** The centre of the EPR spectrum of atomic deuterium lies at 330.02 mT in a spectrometer operating at 9.2482 GHz. What is the  $g$  value of the electron in the atom?

**14D.2(a)** A radical containing two equivalent protons shows a three-line spectrum with an intensity distribution 1:2:1. The lines occur at 330.2 mT, 332.5 mT, and 334.8 mT. What is the hyperfine coupling constant for each proton? What is the  $g$  value of the radical given that the spectrometer is operating at 9.319 GHz?

**14D.2(b)** A radical containing three equivalent protons shows a four-line spectrum with an intensity distribution 1:3:3:1. The lines occur at 331.4 mT, 333.6 mT, 335.8 mT, and 338.0 mT. What is the hyperfine coupling constant for each proton? What is the  $g$  value of the radical given that the spectrometer is operating at 9.332 GHz?

**14D.3(a)** A radical containing two inequivalent protons with hyperfine constants 2.0 mT and 2.6 mT gives a spectrum centred on 332.5 mT. At what fields do the hyperfine lines occur and what are their relative intensities?

**14D.3(b)** A radical containing three inequivalent protons with hyperfine constants 2.11 mT, 2.87 mT, and 2.89 mT gives a spectrum centred on

332.8 mT. At what fields do the hyperfine lines occur and what are their relative intensities?

**14D.4(a)** Predict the intensity distribution in the hyperfine lines of the EPR spectra of (i)  $\cdot\text{CH}_3$ , (ii)  $\cdot\text{CD}_3$ .

**14D.4(b)** Predict the intensity distribution in the hyperfine lines of the EPR spectra of (i)  $\cdot\text{CH}_2\text{CH}_3$ , (ii)  $\cdot\text{CD}_2\text{CD}_3$ .

**14D.5(a)** The benzene radical anion has  $g = 2.0025$ . At what field should you search for resonance in a spectrometer operating at (i) 9.313 GHz, (ii) 33.80 GHz?

**14D.5(b)** The naphthalene radical anion has  $g = 2.0024$ . At what field should you search for resonance in a spectrometer operating at (i) 9.501 GHz, (ii) 34.77 GHz?

**14D.6(a)** The EPR spectrum of a radical with a single magnetic nucleus is split into four lines of equal intensity. What is the nuclear spin of the nucleus?

**14D.6(b)** The EPR spectrum of a radical with two equivalent nuclei of a particular kind is split into five lines of intensity ratio 1:2:3:2:1. What is the spin of the nuclei?

**14D.7(a)** Sketch the form of the hyperfine structures of radicals  $\text{XH}_2$  and  $\text{XD}_2$ , where the nucleus X has  $I = \frac{5}{2}$ .

**14D.7(b)** Sketch the form of the hyperfine structures of radicals  $\text{XH}_3$  and  $\text{XD}_3$ , where the nucleus X has  $I = \frac{3}{2}$ .

### Problems

**14D.1** It is possible to produce very high magnetic fields over small volumes by special techniques. What would be the resonance frequency of an electron spin in an organic radical in a field of 1.0 kT? How does this frequency compare to typical molecular rotational, vibrational, and electronic energy-level separations?

**14D.2** The angular  $\text{NO}_2$  molecule has a single unpaired electron and can be trapped in a solid matrix or prepared inside a nitrite crystal by radiation damage of  $\text{NO}_2^-$  ions. When the applied field is parallel to the OO direction the centre of the spectrum lies at 333.64 mT in a spectrometer operating

at 9.302 GHz. When the field lies along the bisector of the ONO angle, the resonance lies at 331.94 mT. What are the  $g$  values in the two orientations?

**14D.3** The hyperfine coupling constant in  $\cdot\text{CH}_3$  is 2.3 mT. Use the information in Table 14D.1 to predict the splitting between the hyperfine lines of the spectrum of  $\cdot\text{CD}_3$ . What are the overall widths of the hyperfine spectra in each case?

**14D.4** The  $p$ -dinitrobenzene radical anion can be prepared by reduction of  $p$ -dinitrobenzene. The radical anion has two equivalent N nuclei ( $I=1$ ) and four equivalent protons. Predict the form of the EPR spectrum using  $a(\text{N})=0.148$  mT and  $a(\text{H})=0.112$  mT.

**14D.5** The hyperfine coupling constants observed in the radical anions **1**, **2**, and **3** are shown (in millitesla, mT). Use the value for the benzene radical anion to map the probability of finding the unpaired electron in the  $\pi$  orbital on each C atom.

**14D.6** When an electron occupies a 2s orbital on an N atom it has a hyperfine interaction of 55.2 mT with the nucleus. The spectrum of  $\text{NO}_2$  shows an isotropic hyperfine interaction of 5.7 mT. For what proportion of its time is the unpaired electron of  $\text{NO}_2$  occupying a 2s orbital? The hyperfine coupling constant for an electron in a 2p orbital of an N atom is 3.4 mT. In  $\text{NO}_2$  the anisotropic part of the hyperfine coupling is 1.3 mT. What proportion of its time does the unpaired electron spend in the 2p orbital of the N atom in  $\text{NO}_2$ ? What is the total probability that the electron will be found on (a) the N atoms, (b) the O atoms? What is the hybridization ratio of the N atom? Does the hybridization support the view that  $\text{NO}_2$  is angular?

**14D.7** Sketch the EPR spectra of the di-*tert*-butyl nitroxide radical (**4**) at 292 K in the limits of very low concentration (at which electron exchange is negligible), moderate concentration (at which electron exchange effects begin to be observed), and high concentration (at which electron exchange effects predominate).

**4** di-*tert*-Butyl nitroxide

## Integrated activities

**14.1** Consider the following series of molecules: benzene, methylbenzene, trifluoromethylbenzene, benzonitrile, and nitrobenzene in which the substituents *para* to the C atom of interest are H,  $\text{CH}_3$ ,  $\text{CF}_3$ , CN, and  $\text{NO}_2$ , respectively. (a) Use the computational method of your choice to calculate the net charge at the C atom *para* to these substituents in this series of organic molecules. (b) It is found empirically that the  $^{13}\text{C}$  chemical shift of the *para* C atom increases in the order: methylbenzene, benzene, trifluoromethylbenzene, benzonitrile, nitrobenzene. Is there a correlation between the behaviour of the  $^{13}\text{C}$  chemical shift and the computed net charge on the  $^{13}\text{C}$  atom? (c) The  $^{13}\text{C}$  chemical shifts of the *para* C atoms in each of the molecules that you examined computationally are as follows:

Substituent	$\text{CH}_3$	H	$\text{CF}_3$	CN	$\text{NO}_2$
$\delta$	128.4	128.5	128.9	129.1	129.4

Is there a linear correlation between net charge and  $^{13}\text{C}$  chemical shift of the *para* C atom in this series of molecules? (d) If you did find a correlation in part (c), explain the physical origins of the correlation.

**14.2** The computational techniques described in Topic 10E have shown that the amino acid tyrosine participates in a number of biological electron transfer reactions, including the processes of water oxidation to  $\text{O}_2$  in plant photosynthesis and of  $\text{O}_2$  reduction to water in oxidative phosphorylation. During the course of these electron transfer reactions, a tyrosine radical forms with spin density delocalized over the side chain of the amino acid. (a) The phenoxy radical shown in **5** is a suitable model of the tyrosine radical. Using molecular modelling software and the computational method of your choice (semi-empirical or *ab initio* methods), calculate the spin densities at the O atom and at all of the C atoms in **5**. (b) Predict the form of the EPR spectrum of **5**.

**5** Phenoxy radical

**14.3** Two groups of protons have  $\delta=4.0$  and  $\delta=5.2$  and are interconverted by a conformational change of a fluxional molecule. In a 60 MHz spectrometer the spectrum collapsed into a single line at 280 K but at 300 MHz the collapse did not occur until the temperature had been raised to 300 K. What is the activation energy of the interconversion?

**14.4** NMR spectroscopy may be used to determine the equilibrium constant for dissociation of a complex between a small molecule, such as an enzyme inhibitor I, and a protein, such as an enzyme E:

In the limit of slow chemical exchange, the NMR spectrum of a proton in I would consist of two resonances: one at  $\nu_1$  for free I and another at  $\nu_{\text{EI}}$  for bound I. When chemical exchange is fast, the NMR spectrum of the same proton in I consists of a single peak with a resonance frequency  $\nu$  given by  $\nu = f_1\nu_1 + f_{\text{EI}}\nu_{\text{EI}}$ , where  $f_1 = [\text{I}]/([\text{I}] + [\text{EI}])$  and  $f_{\text{EI}} = [\text{EI}]/([\text{I}] + [\text{EI}])$  are, respectively, the fractions of free I and bound I. For the purposes of analysing the data, it is also useful to define the frequency differences  $\delta\nu = \nu - \nu_1$  and  $\Delta\nu = \nu_{\text{EI}} - \nu_1$ . Show that when the initial concentration of I,  $[\text{I}]_0$ , is much greater than the initial concentration of E,  $[\text{E}]_0$ , a plot of  $[\text{I}]_0$  against  $\delta\nu^{-1}$  is a straight line with slope  $[\text{E}]_0\Delta\nu$  and  $y$ -intercept  $-K_1$ .

# CHAPTER 15

## Statistical thermodynamics

Statistical thermodynamics provides the link between the microscopic properties of matter and its bulk properties. It provides a means of calculating thermodynamic properties from structural and spectroscopic data and gives insight into the molecular origins of chemical properties.

### 15A The Boltzmann distribution

The ‘Boltzmann distribution’, which is used to predict the populations of states in systems at thermal equilibrium, is among the most important equations in chemistry for it summarizes the populations of states; it also provides insight into the nature of ‘temperature’. The structure of the Topic separates its key implications from its rather heavy derivation.

### 15B Partition functions

The Boltzmann distribution introduces the concept of a ‘partition function’, which is the central mathematical concept of the rest of the chapter. We see how to interpret the partition function and how to calculate it in a number of simple cases.

### 15C Molecular energies

A partition function is the thermodynamic version of a wavefunction, and contains all the thermodynamic information about a system. As a first step in extracting that information, we see how to use partition functions to calculate the mean values of the basic modes of motion of a collection of independent molecules.

### 15D The canonical ensemble

Molecules do interact with one another, and statistical thermodynamics would be incomplete without being able to take these

interactions into account. This Topic shows how that is done in principle by introducing the ‘canonical ensemble’, and hints at how this concept can be used.

### 15E The internal energy and the entropy

The main work of the chapter is to show how molecular partition functions are used to calculate (and give insight into) the two basic thermodynamic functions, the internal energy and the entropy. The latter is based on another central equation introduced by Boltzmann, his definition of ‘statistical entropy’.

### 15F Derived functions

With expressions relating internal energy and entropy to partition functions, we are ready to develop expressions for the derived thermodynamic functions, such as the Helmholtz and Gibbs energies. Then, with the Gibbs energy available, we can make the final step into the calculations of chemically significant expressions by showing how equilibrium constants can be calculated from structural and spectroscopic data.

### What is the impact of this material?

There are numerous applications of statistical arguments in biochemistry. We have selected one of the most directly related to partition functions: *Impact* I15.1 describes the helix–coil equilibrium in a polypeptide and the role of cooperative behaviour.

To read more about the impact of this material, scan the QR code, or go to [bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-15-1.html](https://bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-15-1.html)

# 15A The Boltzmann distribution

### ► Why do you need to know this material?

The Boltzmann distribution is the key to understanding a great deal of chemistry. All thermodynamic properties can be interpreted in its terms, as can the temperature dependence of equilibrium constants and the rates of chemical reactions. It also illuminates the meaning of ‘temperature’. There is, perhaps, no more important unifying concept in chemistry.

### ► What is the key idea?

The most probable distribution of molecules over the available energy levels subject to certain restraints depends on a single parameter, the temperature.

### ► What do you need to know already?

You need to be aware that molecules can exist only in certain discrete energy levels (*Foundations B* and *Topic 7A*) and that in some cases more than one state has the same energy. The principal mathematical tools used in this Topic are simple probability theory and Lagrange multipliers; the latter is explained in *The chemist’s toolkit 15A.1*.

The problem we address in this Topic is the calculation of the populations of states for any type of molecule in any mode of motion at any temperature. The only restriction is that the

molecules should be independent, in the sense that the total energy of the system is a sum of their individual energies. We are discounting (at this stage) the possibility that in a real system a contribution to the total energy may arise from interactions between molecules. We also adopt the **principle of equal *a priori* probabilities**, the assumption that all possibilities for the distribution of energy are equally probable. ‘*A priori*’ in this context loosely means ‘as far as one knows’. We have no reason to presume otherwise than that for a collection of molecules at thermal equilibrium, a vibrational state of a certain energy, for instance, is as likely to be populated as a rotational state of the same energy.

One very important conclusion that will emerge from the following analysis is that the overwhelmingly most probable populations of the available states depend on a single parameter, the ‘temperature’. That is, the work we do here provides a molecular justification for the concept of temperature and some insight into this crucially important quantity.

## 15A.1 Configurations and weights

Any individual molecule may exist in states with energies  $\epsilon_0, \epsilon_1, \dots$ . For reasons that will become clear, we shall always take the lowest available state as the zero of energy (that is, we set  $\epsilon_0=0$ ), and measure all other energies relative to that state. To obtain the actual energy of the system we may have to add a constant to the energy calculated on this basis. For example, if we are considering the vibrational contribution to the energy, then we must add the total zero-point energy of any oscillators in the system.

### (a) Instantaneous configurations

At any instant there will be  $N_0$  molecules in the state 0 with energy  $\epsilon_0$ ,  $N_1$  in the state 1 with  $\epsilon_1$ , and so on, with  $N_0+N_1+\dots=N$ , the total number of molecules in the system. Initially we suppose that all the states have exactly the same energy. The specification of the set of populations  $N_0, N_1, \dots$  in the form  $\{N_0, N_1, \dots\}$  is a statement of the instantaneous **configuration** of the system. The instantaneous configuration fluctuates with time because the populations change, perhaps as a result of collisions. At this stage the energies of all the configurations are identical so there is no restriction on how many of the  $N$  molecules are in each state.

We can picture a large number of different instantaneous configurations. One, for example, might be  $\{N,0,0,\dots\}$ , corresponding to every molecule being in state 0. Another might be  $\{N-2,2,0,0,\dots\}$ , in which two molecules are in state 1. The latter configuration is intrinsically more likely to be found than the former because it can be achieved in more ways:  $\{N,0,0,\dots\}$  can be achieved in only one way, but  $\{N-2,2,0,\dots\}$  can be achieved in  $\frac{1}{2}N(N-1)$  different ways (Fig. 15A.1; see the following *Justification*). If, as a result of collisions, the system were to fluctuate between the configurations  $\{N,0,0,\dots\}$  and  $\{N-2,2,0,\dots\}$ , it would almost always be found in the second, more likely configuration, especially if  $N$  were large. In other words, a system free to switch between the two configurations would show properties characteristic almost exclusively of the second configuration. A general configuration  $\{N_0, N_1, \dots\}$  can be achieved in  $\mathcal{W}$  different ways, where  $\mathcal{W}$  is called the **weight** of the configuration. The weight of the configuration  $\{N_0, N_1, \dots\}$  is given by the expression

$$\mathcal{W} = \frac{N!}{N_0! N_1! N_2! \dots} \quad \text{Weight of a configuration} \quad (15A.1)$$

with  $x! = x(x-1)\dots 1$  and by definition  $0! = 1$ . Equation 15A.1 is a generalization of the formula  $\mathcal{W} = \frac{1}{2}N(N-1)$ , and reduces to it for the configuration  $\{N-2, 2, 0, \dots\}$ .

**Figure 15A.1** Whereas a configuration  $\{5,0,0,\dots\}$  can be achieved in only one way, a configuration  $\{3,2,0,\dots\}$  can be achieved in the ten different ways shown here, where the tinted blocks represent different molecules.

#### Brief illustration 15A.1 The weight of a configuration

To calculate the number of ways of distributing 20 identical objects with the arrangement 1, 0, 3, 5, 10, 1, we note that the configuration is  $\{1,0,3,5,10,1\}$  with  $N=20$ ; therefore the weight is

$$\mathcal{W} = \frac{20!}{1!0!3!5!10!1!} = 9.31 \times 10^8$$

**Self-test 15A.1** Calculate the weight of the configuration in which 20 objects are distributed in the arrangement 0, 1, 5, 0, 8, 0, 3, 2, 0, 1.

Answer:  $4.19 \times 10^{10}$

#### Justification 15A.1 The weight of a configuration

First, consider the weight of the configuration  $\{N-2,2,0,0,\dots\}$ , which is prepared from the configuration  $\{N,0,0,0,\dots\}$  by the migration of two molecules from state 0 into state 2. One candidate for migration to state 1 can be selected in  $N$  ways. There are  $N-1$  candidates for the second choice, so the total number of choices is  $N(N-1)$ . However, we should not distinguish the choice (Jack, Jill) from the choice (Jill, Jack) because they lead to the same configurations. Therefore, only half the choices lead to distinguishable configurations, and the total number of distinguishable choices is  $\frac{1}{2}N(N-1)$ .

Now we generalize this remark. Consider the number of ways of distributing  $N$  balls into bins. The first ball can be selected in  $N$  different ways, the next ball in  $N-1$  different ways for the balls remaining, and so on. Therefore, there are  $N(N-1)\dots 1 = N!$  ways of selecting the balls for distribution over the bins. However, if there are  $N_0$  balls in the bin labelled  $\varepsilon_0$ , there would be  $N_0!$  different ways in which the same balls could have been chosen (Fig. 15A.2). Similarly, there are  $N_1!$  ways in which the  $N_1$  balls in the bin labelled  $\varepsilon_1$  can be chosen, and so on. Therefore, the total number of distinguishable ways

**Figure 15A.2** The 18 molecules shown here can be distributed into four receptacles (distinguished by the three vertical lines) in  $18!$  different ways. However,  $3!$  of the selections that put three molecules in the first receptacle are equivalent,  $6!$  that put six molecules into the second receptacle are equivalent, and so on. Hence the number of distinguishable arrangements is  $18!/3!6!5!4!$ , or about 515 million.

of distributing the balls so that there are  $N_0$  in bin  $\varepsilon_0$ ,  $N_1$  in bin  $\varepsilon_1$ , etc. regardless of the order in which the balls were chosen is  $N!/N_0!N_1!\dots$ , which is the content of eqn 15A.1.

It will turn out to be more convenient to deal with the natural logarithm of the weight,  $\ln \mathcal{W}$ , rather than with the weight itself. We shall therefore need the expression

$$\begin{aligned} \ln \mathcal{W} &= \ln \frac{N!}{N_0! N_1! N_2! \dots} \stackrel{\ln(\frac{x}{y}) = \ln x - \ln y}{\hat{=}} \ln N! - \ln N_0! - \ln N_1! - \ln N_2! - \dots \\ &\stackrel{\ln xy = \ln x + \ln y}{\hat{=}} \ln N! - \ln N_0! - \ln N_1! - \ln N_2! - \dots = \ln N! - \sum_i \ln N_i! \end{aligned}$$

One reason for introducing  $\ln \mathcal{W}$  is that it is easier to make approximations. In particular, we can simplify the factorials by using *Stirling's approximation*

$$\ln x! \approx \left(x + \frac{1}{2}\right) \ln x - x + \frac{1}{2} \ln 2\pi \quad x \gg 1 \quad \text{Stirling's approximation} \quad (15A.2a)$$

This approximation is in error by less than 1 per cent when  $x$  is greater than about 10. We deal with far larger values of  $x$ , and the simplified version

$$\ln x! \approx x \ln x - x \quad x \gg 1 \quad \text{Stirling's approximation} \quad (15A.2b)$$

is adequate. Then the approximate expression for the weight is

$$\begin{aligned} \ln \mathcal{W} &= \{N \ln N - N\} - \sum_i \{N_i \ln N_i - N_i\} \\ &= N \ln N - N - \sum_i N_i \ln N_i + N \quad [\text{because } \sum_i N_i = N] \\ &= N \ln N - \sum_i N_i \ln N_i \end{aligned} \quad (15A.3)$$

## (b) The most probable distribution

We have seen that the configuration  $\{N-2, 2, 0, \dots\}$  dominates  $\{N, 0, 0, \dots\}$ , and it should be easy to believe that there may be other configurations that have a much greater weight than both. We shall see, in fact, that there is a configuration with so great a weight that it overwhelms all the rest in importance to such an extent that the system will almost always be found in it. The properties of the system will therefore be characteristic of that particular dominating configuration. This dominating configuration can be found by looking for the values of  $N_i$  that lead to a maximum value of  $\mathcal{W}$ . Because  $\mathcal{W}$  is a function of all the  $N_i$ , we can do this search by varying the  $N_i$  and looking for the values that correspond to  $d\mathcal{W}=0$  (just as in the search for the maximum of any function), or equivalently a maximum value of  $\ln \mathcal{W}$ . However, there are two difficulties with this procedure.

At this point we allow the states to have different energies. The first difficulty that results from this change is the need to take into account the fact that the only permitted configurations are those corresponding to the specified, constant, total energy of the system. This requirement rules out many configurations;  $\{N, 0, 0, \dots\}$  and  $\{N-2, 2, 0, \dots\}$ , for instance, have different energies (unless  $\epsilon_0$  and  $\epsilon_1$  happen to have the same energy), so both cannot occur in the same isolated system. It follows that in looking for the configuration with the greatest weight, we must ensure that the configuration also satisfies the condition

$$\sum_i N_i \epsilon_i = E \quad \text{Constant energy} \quad \text{Energy constraint} \quad (15A.4)$$

where  $E$  is the total energy of the system.

The second constraint is that, because the total number of molecules present is also fixed (at  $N$ ), we cannot arbitrarily vary all the populations simultaneously. Thus, increasing the population of one state by 1 demands that the population of another state must be reduced by 1. Therefore, the search for the maximum value of  $\mathcal{W}$  is also subject to the condition

$$\sum_i N_i = N \quad \text{Constant total number of molecules} \quad \text{Number constraint} \quad (15A.5)$$

We show in the next section that the populations in the configuration of greatest weight, subject to the two constraints in eqns 15A.4 and 15A.5, depend on the energy of the state according to the **Boltzmann distribution**:

$$\frac{N_i}{N} = \frac{e^{-\beta \epsilon_i}}{\sum_i e^{-\beta \epsilon_i}} \quad \text{Boltzmann distribution} \quad (15A.6a)$$

The denominator on eqn 15A.6a is denoted  $q$  and called the **partition function**:

$$q = \sum_i e^{-\beta \epsilon_i} \quad \text{Definition} \quad \text{Partition function} \quad (15A.6b)$$

At this stage the partition function is no more than a convenient abbreviation for the sum; but in Topic 15B we see that it is central to the statistical interpretation of thermodynamic properties.

Equation 15A.6a is the justification of the remark that a single parameter, here denoted  $\beta$ , determines the most probable populations of the states of the system. We confirm in Topic 15D and anticipate throughout this Topic that

$$\beta = \frac{1}{kT} \quad (15A.7)$$

where  $T$  is the thermodynamic temperature and  $k$  is Boltzmann's constant. In other words:

The temperature is the unique parameter that governs the most probable populations of states of a system at thermal equilibrium.

### Brief illustration 15A.2 The Boltzmann distribution

Suppose that two conformations of a molecule differ in energy by  $5.0 \text{ kJ mol}^{-1}$  (corresponding to  $8.3 \text{ zJ}$  for a single molecule;  $1 \text{ zJ} = 10^{-21} \text{ J}$ ), so conformation A lies at energy 0 and conformation B lies at  $\epsilon = 8 \text{ zJ}$ . At  $20^\circ \text{C}$  ( $293 \text{ K}$ ) the denominator in eqn 15A.6a is

$$\sum_i e^{-\beta \epsilon_i} = 1 + e^{-\epsilon/kT} = 1 + e^{-(8.3 \times 10^{-21} \text{ J}) / (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (293 \text{ K})} = 1.13$$

The proportion of molecules in conformation B at this temperature is therefore

$$\frac{N_B}{N} = \frac{e^{-(8.3 \times 10^{-21} \text{ J}) / (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (293 \text{ K})}}{1.13} = 0.11$$

or 11 per cent of the molecules.

**Self-Test 15A.2** Suppose that there is a third conformation a further  $0.50 \text{ kJ mol}^{-1}$  above B. What proportion of molecules will now be in conformation B?

Answer: 0.10, 10 per cent

### (c) The relative population of states

If we are interested only in the relative populations of states, the sum in the denominator of the Boltzmann distribution need not be evaluated, because it cancels when the ratio is taken:

$$\frac{N_i}{N_j} = \frac{e^{-\beta \varepsilon_i}}{e^{-\beta \varepsilon_j}} = e^{-\beta(\varepsilon_i - \varepsilon_j)} \quad \text{Thermal equilibrium} \quad \text{Boltzmann population ratio} \quad (15A.8a)$$

That  $\beta \propto 1/T$  is plausible is demonstrated by noting from eqn 15A.8a that for a given energy separation the ratio of populations  $N_i/N_0$  decreases as  $\beta$  increases, which is what is expected as the temperature decreases. At  $T=0$  ( $\beta=\infty$ ) all the population is in the ground state and the ratio is zero. Equation 15A.8a is enormously important for understanding a wide range of chemical phenomena and is the form in which the Boltzmann distribution is commonly employed (for instance, in the discussion of the intensities of spectral transitions, Topics 12A and 14A). It tells us that the relative population of two states falls off exponentially with their difference in energy.

A very important point to note is that the Boltzmann distribution gives the relative populations of *states*, not energy *levels*. Several states might correspond to the same energy, and each state has a population given by eqn 15A.6. If we want to consider the relative populations of energy levels rather than states, then we need to take into account this degeneracy. Thus, if the level of energy  $\varepsilon_i$  is  $g_i$ -fold degenerate (in the sense that there are  $g_i$  states with that energy), and the level of energy  $\varepsilon_j$  is  $g_j$ -fold degenerate, then the relative total populations of the levels are given by

$$\frac{N_i}{N_j} = \frac{g_i e^{-\beta \varepsilon_i}}{g_j e^{-\beta \varepsilon_j}} = \frac{g_i}{g_j} e^{-\beta(\varepsilon_i - \varepsilon_j)} \quad \text{Thermal equilibrium, degeneracies} \quad \text{Boltzmann population ratio} \quad (15A.8b)$$

#### Example 15A.1 Calculating the relative populations of rotational states

Calculate the relative populations of the  $J=1$  and  $J=0$  rotational states of HCl at  $25^\circ\text{C}$ .

**Method** Although the ground state is non-degenerate, the level with  $J=1$  is triply degenerate ( $M_J=0, \pm 1$ ); see Topic 12B. From Topic 12B, the energy of state with quantum number  $J$  is  $\varepsilon_J = hc\tilde{B}J(J+1)$ . Use  $\tilde{B} = 10.591 \text{ cm}^{-1}$ . A useful relation is  $kT/hc = 207.22 \text{ cm}^{-1}$  at  $298.15 \text{ K}$ .

**Answer** The energy separation of states with  $J=1$  and  $J=0$  is

$$\varepsilon_1 - \varepsilon_0 = 2hc\tilde{B}$$

The ratio of the population of a state with  $J=1$  and any *one* of its three states  $M_J$  to the population of the single state with  $J=0$  is therefore

$$\frac{N_{J,M_J}}{N_0} = e^{-2hc\tilde{B}\beta}$$

The relative populations of the *levels*, taking into account the three-fold degeneracy of the upper state, is

$$\frac{N_J}{N_0} = 3e^{-2hc\tilde{B}\beta}$$

Insertion of  $hc\tilde{B}\beta = hc\tilde{B}/kT = (10.591 \text{ cm}^{-1}) / (207.22 \text{ cm}^{-1}) = 0.0511\dots$  then gives

$$\frac{N_J}{N_0} = 3e^{-2 \times 0.0511\dots} = 2.708$$

We see that because the  $J=1$  level is triply degenerate, it has a higher population than the level with  $J=0$ , despite being of higher energy. As the example illustrates, it is very important to take note of whether you are asked for the relative populations of individual states or of a (possibly degenerate) energy level.

**Self-test 15A.3** What is the ratio of the populations of the levels with  $J=2$  and  $J=1$  at the same temperature?

Answer: 1.359

## 15A.2 The derivation of the Boltzmann distribution

We have remarked that  $\ln \mathcal{W}$  is easier to handle than  $\mathcal{W}$ . Therefore, to find the form of the Boltzmann distribution, we look for the condition for  $\ln \mathcal{W}$  being a maximum rather than dealing directly with  $\mathcal{W}$ . Because  $\ln \mathcal{W}$  depends on all the  $N_i$ , when a configuration changes and the  $N_i$  change to  $N_i + dN_i$ , the function  $\ln \mathcal{W}$  changes to  $\ln \mathcal{W} + d \ln \mathcal{W}$ , where

$$d \ln \mathcal{W} = \sum_i \left( \frac{\partial \ln \mathcal{W}}{\partial N_i} \right) dN_i$$

All this expression states is that a change in  $\ln \mathcal{W}$  is the sum of contributions arising from changes in each value of  $N_i$ .

**(a) The role of constraints**

At a maximum,  $d \ln \mathcal{W} = 0$ . However, when the  $N_i$  change, they do so subject to the two constraints

$$\sum_i \varepsilon_i dN_i = 0 \quad \sum_i dN_i = 0 \quad \text{Constraints} \quad (15A.9)$$

The first constraint recognizes that the total energy must not change, and the second recognizes that the total number of molecules must not change. These two constraints prevent us from solving  $d \ln \mathcal{W} = 0$  simply by setting all  $(\partial \ln \mathcal{W} / \partial N_i) = 0$  because the  $dN_i$  are not all independent.

The way to take constraints into account was devised by the French mathematician Lagrange, and is called the **method of undetermined multipliers** (*The chemist's toolkit* 15A.1). All we need of that method is as follows:

- Each constraint is multiplied by a constant and then added to the main variation equation.
- The variables are then treated as though they were all independent.
- The constants are evaluated at the end of the calculation.

### The chemist's toolkit 15A.1 The method of undetermined multipliers

Suppose we need to find the maximum (or minimum) value of some function  $f$  that depends on several variables  $x_1, x_2, \dots, x_n$ . When the variables undergo a small change from  $x_i$  to  $x_i + \delta x_i$ , the function changes from  $f$  to  $f + \delta f$ , where

$$\delta f = \sum_{i=1}^n \left( \frac{\partial f}{\partial x_i} \right) \delta x_i$$

At a minimum or maximum,  $\delta f = 0$ , so then

$$\sum_{i=1}^n \left( \frac{\partial f}{\partial x_i} \right) \delta x_i = 0$$

If the  $x_i$  were all independent, all the  $\delta x_i$  would be arbitrary, and this equation could be solved by setting each  $(\partial f / \partial x_i) = 0$  individually. When the  $x_i$  are not all independent, the  $\delta x_i$  are not all independent, and the simple solution is no longer valid. We proceed as follows.

Let the constraint connecting the variables be an equation of the form  $g = 0$ . The constraint  $g = 0$  is always valid, so  $g$  remains unchanged when the  $x_i$  are varied:

$$\delta g = \sum_{i=1}^n \left( \frac{\partial g}{\partial x_i} \right) \delta x_i = 0$$

Because  $\delta g$  is zero, we can multiply it by a parameter,  $\lambda$ , and add it to the preceding equation:

$$\sum_{i=1}^n \left\{ \left( \frac{\partial f}{\partial x_i} \right) + \lambda \left( \frac{\partial g}{\partial x_i} \right) \right\} \delta x_i = 0$$

This equation can be solved for one of the  $\delta x_i$ ,  $\delta x_n$  for instance, in terms of all the other  $\delta x_i$ . All those other  $\delta x_i$  ( $i = 1, 2, \dots, n-1$ ) are independent, because there is only one constraint on the system. But  $\lambda$  is arbitrary; therefore we can choose it so that

$$\left( \frac{\partial f}{\partial x_n} \right) + \lambda \left( \frac{\partial g}{\partial x_n} \right) = 0 \quad (\text{A})$$

Then

$$\sum_{i=1}^{n-1} \left\{ \left( \frac{\partial f}{\partial x_i} \right) + \lambda \left( \frac{\partial g}{\partial x_i} \right) \right\} \delta x_i = 0$$

Now the  $n-1$  variations  $\delta x_i$  are independent, so the solution of this equation is

$$\left( \frac{\partial f}{\partial x_i} \right) + \lambda \left( \frac{\partial g}{\partial x_i} \right) = 0 \quad i = 1, 2, \dots, n-1$$

However, eqn A has exactly the same form as this equation, so the maximum or minimum of  $f$  can be found by solving

$$\left( \frac{\partial f}{\partial x_i} \right) + \lambda \left( \frac{\partial g}{\partial x_i} \right) = 0 \quad i = 1, 2, \dots, n$$

If there is more than one constraint,  $g_1 = 0, g_2 = 0, \dots$ , and this final result generalizes to

$$\left( \frac{\partial f}{\partial x_i} \right) + \lambda_1 \left( \frac{\partial g_1}{\partial x_i} \right) + \lambda_2 \left( \frac{\partial g_2}{\partial x_i} \right) + \dots = 0, \quad i = 1, 2, \dots, n$$

with a corresponding multiplier,  $\lambda_1, \lambda_2, \dots$  for each constraint.

Thus, as there are two constraints we introduce the two constants  $\alpha$  and  $-\beta$  and write

$$\begin{aligned} & \sum_i \left( \frac{\partial \ln \mathcal{W}}{\partial N_i} \right) dN_i + \alpha \sum_i dN_i - \beta \sum_i \varepsilon_i dN_i \\ &= \sum_i \left\{ \left( \frac{\partial \ln \mathcal{W}}{\partial N_i} \right) + \alpha - \beta \varepsilon_i \right\} dN_i = 0 \end{aligned}$$

All the  $dN_i$  are now treated as independent. Hence the only way of satisfying  $d \ln \mathcal{W} = 0$  is to require that for each  $i$ ,

$$\left( \frac{\partial \ln \mathcal{W}}{\partial N_i} \right) + \alpha - \beta \varepsilon_i = 0 \quad (15A.10)$$

when the  $N_i$  have their most probable values. We show in the following *Justification* that

$$\frac{\partial \ln \mathcal{W}}{\partial N_i} = -\ln \frac{N_i}{N} \quad (15A.11)$$

It follows from eqn 15A.10 that

$$-\ln \frac{N_i}{N} + \alpha - \beta \varepsilon_i = 0$$

and therefore that

$$\frac{N_i}{N} = e^{\alpha - \beta \varepsilon_i} \quad (15A.12)$$

which is very close to being the Boltzmann distribution.

### Justification 15.A.2 The derivative of the weight

Equation 15A.3 for  $\mathcal{W}$  is

$$\ln \mathcal{W} = N \ln N - \sum_i N_i \ln N_i$$

There is a small housekeeping step to take before differentiating  $\ln \mathcal{W}$  with respect to  $N_i$ ; this equation is identical to

$$\ln \mathcal{W} = N \ln N - \sum_j N_j \ln N_j$$

because all we have done is to change the ‘name’ of the states from  $i$  to  $j$ . This step makes sure that we do not confuse the  $i$  in the differentiation variable ( $N_i$ ) with the  $i$  in the summation. Now differentiation of this expression gives

$$\frac{\partial \ln \mathcal{W}}{\partial N_i} = \frac{\partial(N \ln N)}{\partial N_i} - \sum_j \frac{\partial(N_j \ln N_j)}{\partial N_i}$$

The derivative of the (blue) first term on the right is obtained as follows:

$$\begin{aligned} \frac{\partial(N \ln N)}{\partial N_i} &= \overbrace{\left( \frac{\partial N}{\partial N_i} \right)}^1 \ln N + N \overbrace{\left( \frac{\partial \ln N}{\partial N_i} \right)}^{(1/N) \partial N / \partial N_i} \\ &= \ln N + \frac{1}{\partial N / \partial N_i} = \ln N + 1 \end{aligned}$$

The (blue)  $\ln N$  in the first term on the right in the second line arises because  $N = N_1 + N_2 + \dots$  and so the derivative of  $N$  with respect to any of the  $N_i$  is 1: that is,  $\partial N / \partial N_i = 1$ . The second term on the right in the second line arises because  $\partial(\ln N) / \partial N_i = (1/N) \partial N / \partial N_i$ . The final 1 is then obtained in the same way as in the preceding remark, by using  $\partial N / \partial N_i = 1$ .

For the derivative of the second term we first note that

$$\frac{\partial \ln N_j}{\partial N_i} = \frac{1}{N_j} \left( \frac{\partial N_j}{\partial N_i} \right)$$

If  $i \neq j$ ,  $N_j$  is independent of  $N_i$ , so  $\partial N_j / \partial N_i = 0$ . However, if  $i = j$ ,  $\partial N_i / \partial N_i = 1$ . Therefore,

$$\frac{\partial N_j}{\partial N_i} = \delta_{ij}$$

with  $\delta_{ij}$  the Kronecker delta ( $\delta_{ij} = 1$  if  $i = j$ ,  $\delta_{ij} = 0$  otherwise). Then

$$\begin{aligned} \sum_j \frac{\partial \ln N_j}{\partial N_i} \ln N_j &= \sum_j \left\{ \overbrace{\left( \frac{\partial N_j}{\partial N_i} \right)}^{\delta_{ij}} \ln N_j + N_j \overbrace{\left( \frac{\partial \ln N_j}{\partial N_i} \right)}^{(1/N_j) \partial N_j / \partial N_i} \right\} \\ &= \sum_j \left\{ \delta_{ij} \ln N_j + \overbrace{\left( \frac{\partial N_j}{\partial N_i} \right)}^{\delta_{ij}} \right\} = \sum_j \delta_{ij} (\ln N_j + 1) \\ &= \ln N_i + 1 \end{aligned}$$

On bringing the two terms together we can write

$$\frac{\partial \ln \mathcal{W}}{\partial N_i} = \ln N + 1 - (\ln N_i + 1) = -\ln \frac{N_i}{N}$$

as in eqn 15A.11.

## (b) The values of the constants

At this stage we note that

$$N = \sum_i N_i = \sum_i N e^{\alpha - \beta \varepsilon_i} = N e^{\alpha} \sum_i e^{-\beta \varepsilon_i}$$

Because the  $N$  cancels on each side of this equality, it follows that

$$e^{\alpha} = \frac{1}{\sum_i e^{-\beta \varepsilon_i}} \quad (15A.13)$$

and therefore

$$\frac{N_i}{N} = e^{\alpha - \beta \varepsilon_i} = e^{\alpha} e^{-\beta \varepsilon_i} = \frac{e^{-\beta \varepsilon_i}}{\sum_i e^{-\beta \varepsilon_i}} \quad \text{Boltzmann distribution} \quad (15A.14)$$

which is eqn 15A.6a.

The development of statistical concepts of thermodynamics begins with the Boltzmann distribution, with quantum theory (Chapter 7) providing insight into and ways of calculating the energies  $\varepsilon_i$  in eqn 15A.14.

## Checklist of concepts

- 1. The **principle of equal *a priori* probabilities** assumes that all possibilities for the distribution of energy are equally probable.
- 2. The **instantaneous configuration** of a system of  $N$  molecules is the specification of the set of populations  $N_0, N_1, \dots$  of the energy levels  $\epsilon_0, \epsilon_1, \dots$
- 3. The **Boltzmann distribution** gives the numbers of molecules in each state of a system at any temperature.
- 4. The **relative populations** of energy levels, as opposed to states, must take into account the degeneracies of the energy levels.

over the available energy levels (Topic 15A). In that Topic we introduce the concept of partition function, which is developed here. You need to be aware of the expressions for the rotational and vibrational levels of molecules (Topics 12B and 12D) and the energy levels of a particle in a box (Topic 8A).

The partition function  $q = \sum_i e^{-\beta \epsilon_i}$  is introduced in Topic 15A simply as a symbol to denote the sum over states that occurs in the denominator of the Boltzmann distribution (eqn 15A.6a,  $p_i = e^{-\beta \epsilon_i} / q$ , with  $p_i = N_i / N$ ), but it is far more important than that might suggest. For instance, it contains all the information needed to calculate the bulk properties of a system of independent particles. In this respect  $q$  plays a role for bulk matter very similar to that played by the wavefunction in quantum mechanics for individual molecules:  $q$  is a kind of thermal wavefunction. This Topic shows how the partition function is calculated in a variety of important cases in preparation for seeing how thermodynamic information is extracted (in Topics 15C and 15E).

### ► Why do you need to know this material?

Statistical thermodynamics provides the link between molecular properties that have been calculated or derived from spectroscopy and thermodynamic properties, including equilibrium concepts. The connection is the partition function. Therefore, this material is an essential foundation for understanding physical and chemical properties of bulk matter in terms of the properties of the constituent molecules.

### ► What is the key idea?

The partition function is calculated by drawing on calculated or spectroscopically derived structural information about molecules.

### ► What do you need to know already?

You need to know that the Boltzmann distribution expresses the most probable distribution of molecules

## 15B.1 The significance of the partition function

The molecular partition function is

$$q = \sum_{\text{states } i} e^{-\beta \epsilon_i} \quad \text{Definition} \quad \text{Molecular partition function} \quad (15B.1a)$$

where  $\beta = 1/kT$ . As emphasized in Topic 15A, the sum is over *states*, not *energy levels*. If  $g_i$  states have the same energy  $\epsilon_i$  (so the level is  $g_i$ -fold degenerate), we write

$$q = \sum_{\text{levels } i} g_i e^{-\beta \epsilon_i} \quad \text{Alternative definition} \quad \text{Molecular partition function} \quad (15B.1b)$$

where the sum is now over energy levels (sets of states with the same energy), not individual states. Also as emphasized in Topic 15A, we always take the lowest available state as the zero of energy and set  $\epsilon_0 = 0$ .

**Brief illustration 15B.1** A partition function

Suppose a molecule is confined to the following non-degenerate energy levels:  $0, \epsilon, 2\epsilon, \dots$  (Fig. 15B.1; later we shall see that this array of levels is used when considering molecular vibration). Then the molecular partition function is

$$q = 1 + e^{-\beta\epsilon} + e^{-2\beta\epsilon} + \dots = 1 + e^{-\beta\epsilon} + (e^{-\beta\epsilon})^2 + \dots$$

**Figure 15B.1** The equally-spaced infinite array of energy levels used in the calculation of the partition function. A harmonic oscillator has the same spectrum of levels.

The sum of the geometrical series  $1 + x + x^2 + \dots$  is  $1/(1-x)$ , so in this case

$$q = \frac{1}{1 - e^{-\beta\epsilon}}$$

This function is plotted in Fig. 15B.2.

**Figure 15B.2** The partition function for the system shown in Fig. 15B.1 (a harmonic oscillator) as a function of temperature.

**Self-test 15B.1** Suppose the molecule can exist in only two states, with energies  $0$  and  $\epsilon$ . Derive and plot the expression for the partition function.

Answer:  $q = 1 + e^{-\beta\epsilon}$ , Fig. 15 B.3

**Figure 15B.3** The partition function for a two-level system as a function of temperature. The two graphs differ in the scale of the temperature axis to show the approach to 1 as  $T \rightarrow 0$  and the slow approach to 2 as  $T \rightarrow \infty$ .

We have derived the following important expression for the partition function for a uniform ladder of states of spacing  $\epsilon$ :

$$q = \frac{1}{1 - e^{-\beta\epsilon}} \quad \text{Uniform ladder} \quad \text{Partition function} \quad (15B.2a)$$

We can use this expression to interpret the physical significance of a partition function. To do so, we first note that the Boltzmann distribution for this arrangement of energy levels gives the fraction,  $p_i = N_i/N$ , of molecules in the state with energy  $\epsilon_i$  as

$$p_i = \frac{e^{-\beta\epsilon_i}}{q} = (1 - e^{-\beta\epsilon}) e^{-\beta\epsilon_i} \quad \text{Uniform ladder} \quad \text{Population} \quad (15B.2b)$$

Figure 15B.4 shows how  $p_i$  varies with temperature. At very low temperatures (large  $\beta$ ), where  $q$  is close to 1, only the lowest state is significantly populated. As the temperature is raised, the population breaks out of the lowest state, and the upper states become progressively more highly populated. At the same time, the partition function rises from 1 towards 2, so we see that its value gives an indication of the range of states populated at any given temperature. The name ‘partition function’ reflects the sense in which  $q$  measures how the total number of molecules is distributed—partitioned—over the available states.

The corresponding expressions for a two-level system derived in *Self-test 15B.1* are

$$q = 1 + e^{-\beta\epsilon} \quad \text{Two-level system} \quad \text{Partition function} \quad (15B.3a)$$

$$p_i = \frac{e^{-\beta\epsilon_i}}{q} = \frac{e^{-\beta\epsilon_i}}{1 + e^{-\beta\epsilon}} \quad \text{Two-level system} \quad \text{Population} \quad (15B.3b)$$

**Figure 15B.4** The populations of the energy levels of the system shown in Fig.15B.1 at different temperatures, and the corresponding values of the partition function as calculated from eqn 15B.2b. Note that  $\beta=1/kT$ .

In this case, because  $\epsilon_0=0$  and  $\epsilon_1=\epsilon$ ,

$$p_0 = \frac{1}{1+e^{-\beta\epsilon}} \quad p_1 = \frac{e^{-\beta\epsilon}}{1+e^{-\beta\epsilon}} \quad (15B.4)$$

These functions are plotted in Fig. 15B.5. Notice how the populations are  $p_0=1$  and  $p_1=0$  and the partition function is  $q=1$  (one state occupied) at  $T=0$ . However, the populations tend towards equality ( $p_0=p_1=\frac{1}{2}$ ) and  $q=2$  (two states occupied) as  $T \rightarrow \infty$ .

*A note on good practice* A common error is to suppose that when  $T=\infty$  all the molecules in the system will be found in the upper energy state; however, we see from eqn 15B.4 that as  $T \rightarrow \infty$ , the populations of states become equal. The same conclusion is true of multi-level systems too: as  $T \rightarrow \infty$ , all states become equally populated.

**Figure 15B.5** The fraction of populations of the two states of a two-level system as a function of temperature (eqn 15B.4). Note that as the temperature approaches infinity, the populations of the two states become equal (and the fractions both approach 0.5).

We can now generalize the conclusion that the partition function indicates the number of thermally accessible states. When  $T$  is close to zero, the parameter  $\beta=1/kT$  is close to infinity. Then every term except one in the sum defining  $q$  is zero because each one has the form  $e^{-x}$  with  $x \rightarrow \infty$ . The exception is the term with  $\epsilon_0 \equiv 0$  (or the  $g_0$  states at zero energy if they are  $g_0$ -fold degenerate), because then  $\epsilon_0/kT \equiv 0$  whatever the temperature, including zero. As there is only one surviving term when  $T=0$ , and its value is  $g_0$ , it follows that

$$\lim_{T \rightarrow 0} q = g_0$$

That is, at  $T=0$ , the partition function is equal to the degeneracy of the ground state (commonly, but not necessarily, 1).

Now consider the case when  $T$  is so high that for each term in the sum  $\epsilon_j/kT \approx 0$ . Because  $e^{-x}=1$  when  $x=0$ , each term in the sum now contributes 1. It follows that the sum is equal to the number of molecular states, which in general is infinite:

$$\lim_{T \rightarrow \infty} q = \infty$$

In some idealized cases, the molecule may have only a finite number of states; then the upper limit of  $q$  is equal to the number of states, as we saw for the two-level system.

In summary, we see that:

The molecular partition function gives an indication of the number of states that are thermally accessible to a molecule at the temperature of the system.

At  $T=0$ , only the ground level is accessible and  $q=g_0$ . At very high temperatures, virtually all states are accessible, and  $q$  is correspondingly large.

## 15B.2 Contributions to the partition function

The energy of a molecule is the sum of contributions from its different modes of motion:

$$\epsilon_i = \epsilon_i^T + \epsilon_i^R + \epsilon_i^V + \epsilon_i^E \quad (15B.5)$$

where T denotes translation, R rotation, V vibration, and E the electronic contribution. The electronic contribution is not actually a 'mode of motion', but it is convenient to include it here. The separation of terms in eqn 15B.5 is only approximate (except for translation) because the modes are not completely independent, but in most cases it is satisfactory. The separation of the electronic and vibrational motions is justified provided only the ground electronic state is occupied (for otherwise the vibrational characteristics depend on the electronic state) and, for the electronic ground state, that the Born–Oppenheimer

approximation is valid (Topic 10A). The separation of the vibrational and rotational modes is justified to the extent that the rotational constant (Topic 12B) is independent of the vibrational state.

Given that the energy is a sum of independent contributions, the partition function factorizes into a product of contributions:

$$\begin{aligned} q &= \sum_i e^{-\beta \epsilon_i} = \sum_{i \text{ (all states)}} e^{-\beta \epsilon_i^T - \beta \epsilon_i^R - \beta \epsilon_i^V - \beta \epsilon_i^E} \\ &= \sum_{i \text{ (translational)}} \sum_{i \text{ (rotational)}} \sum_{i \text{ (vibrational)}} \sum_{i \text{ (electronic)}} e^{-\beta \epsilon_i^T - \beta \epsilon_i^R - \beta \epsilon_i^V - \beta \epsilon_i^E} \\ &= \left( \sum_{i \text{ (translational)}} e^{-\beta \epsilon_i^T} \right) \left( \sum_{i \text{ (rotational)}} e^{-\beta \epsilon_i^R} \right) \left( \sum_{i \text{ (vibrational)}} e^{-\beta \epsilon_i^V} \right) \\ &\quad \times \left( \sum_{i \text{ (electronic)}} e^{-\beta \epsilon_i^E} \right) \end{aligned}$$

That is,

$$q = q^T q^R q^V q^E \quad \text{Factorization of the partition function} \quad (15B.6)$$

This factorization means that we can investigate each contribution separately. In general, exact analytical expressions for partition functions cannot be obtained. However, approximate expressions can often be found and prove to be very important for understanding chemical phenomena; they are derived in the following sections and collected at the end of the Topic.

### (a) The translational contribution

The translational partition function for a particle of mass  $m$  free to move in a one-dimensional container of length  $X$  can be evaluated by making use of the fact that the separation of energy levels is very small and that large numbers of states are accessible at normal temperatures. As shown in the following *Justification*, in this case

$$\begin{aligned} q &= \frac{X}{\Lambda} \\ q_X^T &= \left( \frac{2\pi m}{h^2 \beta} \right)^{1/2} X \end{aligned} \quad \begin{array}{l} \text{One-dimensional} \\ \text{container} \end{array} \quad \begin{array}{l} \text{Translational} \\ \text{partition} \\ \text{function} \end{array} \quad (15B.7a)$$

It will prove convenient to anticipate once again that  $\beta = 1/kT$  and to write this expression as  $q_X^T = X/\Lambda$ , with

$$\Lambda = \frac{h}{(2\pi m k T)^{1/2}} \quad \text{Definition} \quad \text{Thermal wavelength} \quad (15B.7b)$$

The quantity  $\Lambda$  (uppercase lambda) has the dimensions of length and is called the **thermal wavelength** (sometimes the ‘thermal de Broglie wavelength’) of the molecule. The thermal wavelength decreases with increasing mass and temperature.

This expression shows that the partition function for translational motion increases with the length of the box and the mass of the particle, for in each case the separation of the energy levels becomes smaller and more levels become thermally accessible. For a given mass and length of the box, the partition function also increases with increasing temperature (decreasing  $\beta$ ), because more states become accessible.

#### Justification 15B.1 The partition function for a particle in a one-dimensional box

The energy levels of a molecule of mass  $m$  in a container of length  $X$  are given by eqn 8A.6b ( $E_n = n^2 h^2 / 8mL^2$ ) with  $L = X$ :

$$E_n = \frac{n^2 h^2}{8mX^2}$$

The lowest level ( $n=1$ ) has energy  $h^2/8mX^2$ , so the energies relative to that level are

$$\epsilon_n = (n^2 - 1)\epsilon \quad \epsilon = h^2/8mX^2$$

The sum to evaluate is therefore

$$q_X^T = \sum_{n=1}^{\infty} e^{-(n^2-1)\beta\epsilon}$$

The translational energy levels are very close together in a container the size of a typical laboratory vessel; therefore, the sum can be approximated by an integral:

$$q_X^T = \int_1^{\infty} e^{-(n^2-1)\beta\epsilon} dn \approx \int_0^{\infty} e^{-n^2\beta\epsilon} dn$$

The extension of the lower limit to  $n=0$  and the replacement of  $n^2 - 1$  by  $n^2$  introduces negligible error but turns the integral into standard form. We make the substitution  $x^2 = n^2\beta\epsilon$ , implying  $dn = dx/(\beta\epsilon)^{1/2}$ , and therefore that

$$q_X^T = \left( \frac{1}{\beta\epsilon} \right)^{1/2} \int_0^{\infty} e^{-x^2} dx = \left( \frac{1}{\beta\epsilon} \right)^{1/2} \frac{\pi^{1/2}}{2} = \left( \frac{2\pi m}{h^2 \beta} \right)^{1/2} X$$

This relation has the form of eqn 15B.7a,  $q = X/\Lambda$ , provided  $\Lambda$  is identified as

$$\Lambda = \left( \frac{h^2 \beta}{2\pi m} \right)^{1/2} \stackrel{\beta=1/kT}{=} \frac{h}{(2\pi m k T)^{1/2}}$$

as in eqn 15B.7b.

The total energy of a molecule free to move in three dimensions is the sum of its translational energies in all three directions:

$$\epsilon_{m_1 n_1 n_2 n_3} = \epsilon_{n_1}^{(X)} + \epsilon_{n_2}^{(Y)} + \epsilon_{n_3}^{(Z)} \quad (15B.8)$$

where  $n_1$ ,  $n_2$ , and  $n_3$  are the quantum numbers for motion in the  $x$ -,  $y$ -, and  $z$ -directions, respectively. Therefore, because  $e^{a+b+c} = e^a e^b e^c$ , the partition function factorizes as follows:

$$q^T = \sum_{\text{all } n} e^{-\beta \epsilon_{n_1}^{(x)} - \beta \epsilon_{n_2}^{(y)} - \beta \epsilon_{n_3}^{(z)}} = \sum_{\text{all } n} e^{-\beta \epsilon_{n_1}^{(x)}} e^{-\beta \epsilon_{n_2}^{(y)}} e^{-\beta \epsilon_{n_3}^{(z)}}$$

$$= \left( \sum_{n_1} e^{-\beta \epsilon_{n_1}^{(x)}} \right) \left( \sum_{n_2} e^{-\beta \epsilon_{n_2}^{(y)}} \right) \left( \sum_{n_3} e^{-\beta \epsilon_{n_3}^{(z)}} \right)$$

That is,

$$q^T = q_x^T q_y^T q_z^T \quad (15B.9)$$

Equation 15B.7a gives the partition function for translational motion in the  $x$ -direction. The only change for the other two directions is to replace the length  $X$  by the lengths  $Y$  or  $Z$ . Hence the partition function for motion in three dimensions is

$$q^T = \left( \frac{2\pi m}{h^2 \beta} \right)^{3/2} XYZ = \frac{(2\pi m k T)^{3/2}}{h^3} XYZ \quad (15B.10a)$$

The product of lengths  $XYZ$  is the volume,  $V$ , of the container, so we can write

$$q^T = \frac{V}{\Lambda^3} \quad \begin{array}{l} \text{Three-dimensional} \\ \text{container} \end{array} \quad \begin{array}{l} \text{Translational} \\ \text{partition} \\ \text{function} \end{array} \quad (15B.10b)$$

with  $\Lambda$  as defined in eqn 15B.7b. As in the one-dimensional case, the partition function increases with the mass of the particle (as  $m^{3/2}$ ) and the volume of the container (as  $V$ ); for a given mass and volume, the partition function increases with temperature (as  $T^{3/2}$ ). As in one dimension,  $q^T \rightarrow \infty$  as  $T \rightarrow \infty$  because an infinite number of states becomes accessible as the temperature is raised. Even at room temperature,  $q^T \approx 2 \times 10^{28}$  for an  $O_2$  molecule in a vessel of volume  $100 \text{ cm}^3$ .

### Brief illustration 15B.2 The translational partition function

To calculate the translational partition function of an  $H_2$  molecule confined to a  $100 \text{ cm}^3$  vessel at  $25^\circ\text{C}$  we use  $m = 2.016 m_u$ ; then, from  $\Lambda = h/(2\pi m k T)^{1/2}$ ,

$$\Lambda = \frac{6.626 \times 10^{-34} \text{ J s}}{\left\{ 2\pi \times (2.016 \times 1.6605 \times 10^{-27} \text{ kg}) \times \left( 1.381 \times 10^{-23} \text{ J K}^{-1} \right) \times (298 \text{ K}) \right\}^{1/2}}$$

$\begin{array}{c} 1J = \\ 1\text{kg m}^2 \text{ s}^{-2} \end{array}$

$\begin{array}{c} 1J = \\ 1\text{kg m}^2 \text{ s}^{-2} \end{array}$

$$= 7.12 \times 10^{-11} \text{ m}$$

Therefore,

$$q^T = \frac{1.00 \times 10^{-4} \text{ m}^3}{(7.12 \times 10^{-11} \text{ m})^3} = 2.77 \times 10^{26}$$

About  $10^{26}$  quantum states are thermally accessible, even at room temperature and for this light molecule. Many states are occupied if the thermal wavelength (which in this case is  $71.2 \text{ pm}$ ) is small compared with the linear dimensions of the container.

**Self-test 15B.2** Calculate the translational partition function for a  $D_2$  molecule under the same conditions.

Answer:  $q^T = 7.8 \times 10^{26}$ ,  $2^{3/2}$  times larger

The validity of the approximations that led to eqn 15B.10 can be expressed in terms of the average separation,  $d$ , of the particles in the container. Because  $q$  is the total number of accessible states, the average number of translational states per molecule is  $q^T/N$ . For this quantity to be large, we require  $V/NA^3 \gg 1$ . However,  $V/N$  is the volume occupied by a single particle, and therefore the average separation of the particles is  $d = (V/N)^{1/3}$ . The condition for there being many states available per molecule is therefore  $d^3/\Lambda^3 \gg 1$ , and therefore  $d \gg \Lambda$ . That is, for eqn 15B.10 to be valid, *the average separation of the particles must be much greater than their thermal wavelength*. For  $H_2$  molecules at 1 bar and  $298 \text{ K}$ , the average separation is  $3 \text{ nm}$ , which is significantly larger than their thermal wavelength ( $71.2 \text{ pm}$ ).

The validity of eqn 15B.10 can be expressed in a different way by noting that the approximations that led to it are valid if many states are occupied, which requires  $V/\Lambda^3$  to be large. That will be so if  $\Lambda$  is small compared with the linear dimensions of the container. For  $H_2$  at  $25^\circ\text{C}$ ,  $\Lambda = 71 \text{ pm}$ , which is far smaller than any conventional container is likely to be (but comparable to pores in zeolites or cavities in clathrates). For  $O_2$ , a heavier molecule,  $\Lambda = 18 \text{ pm}$ .

## (b) The rotational contribution

The energy levels of a linear rotor are  $\epsilon_J = hc\tilde{B}J(J+1)$ , with  $J = 0, 1, 2, \dots$  (Topic 12B). The state of lowest energy has zero energy, so no adjustment need be made to the energies given by this expression. Each level consists of  $2J+1$  degenerate states. Therefore, the partition function of a non-symmetrical (AB) linear rotor is

$$q^R = \sum_J \frac{g_J}{(2J+1)} e^{-\beta \epsilon_J} \quad (15B.11)$$

The direct method of calculating  $q^R$  is to substitute the experimental values of the rotational energy levels into this expression and to sum the series numerically.

**Example 15B.1** Evaluating the rotational partition function explicitly

Evaluate the rotational partition function of  $^1\text{H}^{35}\text{Cl}$  at  $25^\circ\text{C}$ , given that  $\tilde{B}=10.591\text{cm}^{-1}$ .

**Method** We need to evaluate eqn 15B.11 term by term. We use  $kT/hc=207.224\text{cm}^{-1}$  at  $298.15\text{K}$ . The sum is readily evaluated by using mathematical software.

**Answer** To show how successive terms contribute, we draw up the following table by using  $hc\tilde{B}/kT=0.05111$  (Fig. 15B.6):

$J$	0	1	2	3	4	...	10
$(2J+1)e^{-0.05111J(J+1)}$	1	2.71	3.68	3.79	3.24	...	0.08

**Figure 15B.6** The contributions to the rotational partition function of an HCl molecule at  $25^\circ\text{C}$ . The vertical axis is the value of  $(2J+1)e^{-\beta hc\tilde{B}J(J+1)}$ . Successive terms (which are proportional to the populations of the levels) pass through a maximum because the population of individual states decreases exponentially, but the degeneracy of the levels increases with  $J$ .

The sum required by eqn 15B.11 (the sum of the numbers in the second row of the table) is 19.9, hence  $q^R=19.9$  at this temperature. Taking  $J$  up to 50 gives  $q^R=19.902$ . Notice that about ten  $J$ -levels are significantly populated but the number of populated states is larger on account of the  $(2J+1)$ -fold degeneracy of each level.

**Self-test 15B.3** Evaluate the rotational partition function for  $^1\text{H}^{35}\text{Cl}$  at  $0^\circ\text{C}$ .

Answer: 18.26

At room temperature,  $kT/hc \approx 200\text{cm}^{-1}$ . The rotational constants of many molecules are close to  $1\text{cm}^{-1}$  (Table 12D.1) and often smaller (though the very light  $\text{H}_2$  molecule, for which  $\tilde{B}=60.9\text{cm}^{-1}$ , is one exception). It follows that many rotational levels are populated at normal temperatures. When this is the case, we show in the following two *Justifications* that the partition function may be approximated by

$$q^R = \frac{kT}{hc\tilde{B}} \quad \text{Linear rotor} \quad \text{Rotational partition function} \quad (15B.12a)$$

$$q^R = \left(\frac{kT}{hc}\right)^{3/2} \left(\frac{\pi}{\tilde{A}\tilde{B}\tilde{C}}\right)^{1/2} \quad \text{Nonlinear rotor} \quad \text{Rotational partition function} \quad (15B.12b)$$

where  $\tilde{A}$ ,  $\tilde{B}$ , and  $\tilde{C}$  are the rotational constants of the molecule expressed as wavenumbers. However, before using these expressions, read on (to eqns 15B.13 and 15B.14).

**Justification 15B.2** The rotational contribution for linear molecules

When many rotational states are occupied and  $kT$  is much larger than the separation between neighbouring states, the sum in the partition function can be approximated by an integral, much as we did for translational motion:

$$q^R = \int_0^\infty (2J+1)e^{-\beta hc\tilde{B}J(J+1)} dJ$$

This integral can be evaluated without much effort by making the substitution  $x = \beta hc\tilde{B}J(J+1)$ , so that  $dx/dJ = \beta hc\tilde{B}(2J+1)$  and therefore  $(2J+1)dJ = dx/\beta hc\tilde{B}$ . Then

$$q^R = \frac{1}{\beta hc\tilde{B}} \int_0^\infty e^{-x} dx = \frac{1}{\beta hc\tilde{B}} \quad \text{Integral E.1}$$

which (because  $\beta = 1/kT$ ) is eqn 15B.12a.

**Brief illustration 15B.3** The rotational contribution

For  $^1\text{H}^{35}\text{Cl}$  at  $298.15\text{K}$  we use  $kT/hc = 207.224\text{cm}^{-1}$  and  $\tilde{B} = 10.591\text{cm}^{-1}$ . Then

$$q^R = \frac{kT}{hc\tilde{B}} = \frac{207.224\text{cm}^{-1}}{10.591\text{cm}^{-1}} = 19.59$$

The value is in good agreement with the exact value (19.02) and with much less work.

**Self-test 15B.4** Evaluate the rotational contribution to the partition function for  $^1\text{H}^{35}\text{Cl}$  at  $0^\circ\text{C}$ .

Answer: 17.93

**Justification 15B.3** The rotational contribution for nonlinear molecules

The energies of a symmetric rotor (Topic 12B) are

$$E_{J,K,M_J} = hc\tilde{B}J(J+1) + hc(\tilde{A} - \tilde{B})K^2$$

with  $J=0, 1, 2, \dots, K=J, J-1, \dots, -J$ , and  $M_J=J, J-1, \dots, -J$ . Instead of considering these ranges, the same values can be

**Figure 15B.7** (a) The sum over  $J=0, 1, 2, \dots$  and  $K=J, J-1, \dots, -J$  (depicted by the circles) can be covered (b) by allowing  $K$  to range from  $-\infty$  to  $\infty$ , with  $J$  confined to  $|K|, |K|+1, \dots, \infty$  for each value of  $K$ .

covered by allowing  $K$  to range from  $-\infty$  to  $\infty$ , with  $J$  confined to  $|K|, |K|+1, \dots, \infty$  for each value of  $K$  (Fig. 15B.7). Because the energy is independent of  $M_J$ , and there are  $2J+1$  values of  $M_J$  for each value of  $J$ , each value of  $J$  is  $(2J+1)$ -fold degenerate. It follows that the partition function

$$q = \sum_{J=0}^{\infty} \sum_{K=-J}^J \sum_{M_J=-J}^J e^{-\beta E_{J,K,M_J}}$$

can be written equivalently as

$$\begin{aligned} q &= \sum_{J=0}^{\infty} \sum_{K=-J}^J (2J+1) e^{-\beta E_{J,K,M_J}} = \sum_{K=-\infty}^{\infty} \sum_{J=|K|}^{\infty} (2J+1) e^{-\beta E_{J,K,M_J}} \\ &= \sum_{K=-\infty}^{\infty} e^{-hc\beta(\tilde{A}-\tilde{B})K^2} \sum_{J=|K|}^{\infty} (2J+1) e^{-hc\beta\tilde{B}J(J+1)} \end{aligned}$$

As in *Justification 15B.2* we assume that the temperature is so high that numerous states are occupied and that the sums may be approximated by integrals. Then

$$q = \int_{-\infty}^{\infty} e^{-hc\beta(\tilde{A}-\tilde{B})K^2} \int_{|K|}^{\infty} (2J+1) e^{-hc\beta\tilde{B}J(J+1)} dJ dK$$

As before, the integral over  $J$  can be recognized as the integral of the derivative of a function, which is the function itself, so, as you should verify,

$$\int_{|K|}^{\infty} (2J+1) e^{-hc\beta\tilde{B}J(J+1)} dJ = \frac{1}{hc\beta\tilde{B}} e^{-hc\beta\tilde{B}K^2}$$

We have also supposed that  $|K| \gg 1$  for most contributions and replaced  $|K|(|K|+1)$  by  $K^2$ . Now we can write

$$\begin{aligned} q &= \frac{1}{hc\beta\tilde{B}} \int_{-\infty}^{\infty} e^{-hc\beta(\tilde{A}-\tilde{B})K^2} e^{-hc\beta\tilde{B}K^2} dK = \frac{1}{hc\beta\tilde{B}} \int_{-\infty}^{\infty} e^{-hc\beta\tilde{A}K^2} dK \\ &= \frac{1}{hc\beta\tilde{B}} \left( \frac{\pi}{hc\beta\tilde{A}} \right)^{1/2} \end{aligned}$$

We conclude that

$$q = \frac{1}{(hc\beta)^{3/2}} \left( \frac{\pi}{\tilde{A}\tilde{B}^2} \right)^{1/2} = \left( \frac{kT}{hc} \right)^{3/2} \left( \frac{\pi}{\tilde{A}\tilde{B}^2} \right)^{1/2}$$

For an asymmetric rotor, one of the  $\tilde{B}$  is replaced by  $\tilde{C}$ , to give eqn 15B.12b.

A useful way of expressing the temperature above which the rotational approximation is valid is to introduce the **characteristic rotational temperature**,  $\theta^R = hc\tilde{B}/k$ . Then 'high temperature' means  $T \gg \theta^R$  and under these conditions the rotational partition function of a linear molecule is simply  $T/\theta^R$ . Some typical values of  $\theta^R$  are given in Table 15B.1. The value for  $^1\text{H}_2$  (87.6 K) is abnormally high and we must be careful with the approximation for this molecule.

The general conclusion at this stage is that molecules with large moments of inertia (and hence small rotational constants and low characteristic rotational temperatures) have large rotational partition functions. The large value of  $q^R$  reflects the closeness in energy (compared with  $kT$ ) of the rotational levels in large, heavy molecules, and the large number of rotational states that are accessible at normal temperatures.

We must take care, however, not to include too many rotational states in the sum. For a homonuclear diatomic molecule or a symmetrical linear molecule (such as  $\text{CO}_2$  or  $\text{HC}\equiv\text{CH}$ ), a rotation through  $180^\circ$  results in an indistinguishable state of the molecule. Hence, the number of thermally accessible states is only half the number that can be occupied by a heteronuclear diatomic molecule, where rotation through  $180^\circ$  does result in a distinguishable state. Therefore, for a symmetrical linear molecule,

$$q^R = \frac{kT}{2hc\tilde{B}} = \frac{T}{2\theta^R} \quad \text{Symmetrical linear rotor} \quad \text{Rotational partition function} \quad (15B.13a)$$

The equations for symmetrical and non-symmetrical molecules can be combined into a single expression by introducing the **symmetry number**,  $\sigma$ , which is the number of indistinguishable orientations of the molecule. Then

$$q^R = \frac{T}{\sigma\theta^R} \quad \text{Linear rotor} \quad \text{Rotational partition function} \quad (15B.13b)$$

**Table 15B.1\*** Rotational temperatures of diatomic molecules

	$\theta^R/\text{K}$
$^1\text{H}_2$	87.6
$^1\text{H}^{35}\text{Cl}$	15.2
$^{14}\text{N}_2$	2.88
$^{35}\text{Cl}_2$	0.351

\* More values are given in the *Resource section*, Table 12D.1.

For a heteronuclear diatomic molecule  $\sigma=1$ ; for a homonuclear diatomic molecule or a symmetrical linear molecule,  $\sigma=2$ .

#### Justification 15B.4 The origin of the symmetry number

The quantum mechanical origin of the symmetry number is the Pauli principle, which forbids the occupation of certain states. It is shown in Topic 12C, for example, that  $\text{H}_2$  may occupy rotational states with even  $J$  only if its nuclear spins are paired (*para*-hydrogen), and odd  $J$  states only if its nuclear spins are parallel (*ortho*-hydrogen). There are three states of *ortho*- $\text{H}_2$  to each value of  $J$  (because there are three parallel spin states of the two nuclei).

To set up the rotational partition function we note that 'ordinary' molecular hydrogen is a mixture of one part *para*- $\text{H}_2$  (with only its even- $J$  rotational states occupied) and three parts *ortho*- $\text{H}_2$  (with only its odd- $J$  rotational states occupied). Therefore, the average partition function per molecule is

$$q^{\text{R}} = \frac{1}{4} \sum_{\text{even } J} (2J+1)e^{-\beta hc \tilde{B} J(J+1)} + \frac{3}{4} \sum_{\text{odd } J} (2J+1)e^{-\beta hc \tilde{B} J(J+1)}$$

The odd- $J$  states are more heavily weighted than the even- $J$  states (Fig. 15B.8). From the illustration we see that we would obtain approximately the same answer for the partition function (the sum of all the populations) if each  $J$  term contributed half its normal value to the sum. That is, the last equation can be approximated as

$$q^{\text{R}} = \frac{1}{2} \sum_J (2J+1)e^{-\beta hc \tilde{B} J(J+1)}$$

and this approximation is very good when many terms contribute (at high temperatures,  $T \gg 87.6$  K).

**Figure 15B.8** The values of the individual terms  $(2J+1)e^{-\beta hc \tilde{B} J(J+1)}$  contributing to the mean partition function of a 3:1 mixture of *ortho*- and *para*- $\text{H}_2$ . The partition function is the sum of all these terms. At high temperatures, the sum is approximately equal to the sum of the terms over all values of  $J$ , each with a weight of  $\frac{1}{2}$ . This is the sum of the contributions indicated by the curve.

**Figure 15B.9** The relative populations of the rotational energy levels of  $\text{CO}_2$ . Only states with even  $J$  values are occupied. The full line shows the smoothed, averaged population of levels.

The same type of argument may be used for linear symmetrical molecules in which identical bosons are interchanged by rotation (such as  $\text{CO}_2$ ). As pointed out in Topic 12C, if the nuclear spin of the bosons is 0, then only even- $J$  states are admissible. Because only half the rotational states are occupied, the rotational partition function is only half the value of the sum obtained by allowing all values of  $J$  to contribute (Fig. 15B.9).

The same care must be exercised for other types of symmetrical molecule, and for a nonlinear molecule we write

$$q^{\text{R}} = \frac{1}{\sigma} \left( \frac{kT}{hc} \right)^{3/2} \left( \frac{\pi}{\tilde{A}\tilde{B}\tilde{C}} \right)^{1/2} \quad \text{Nonlinear rotor} \quad \text{Rotational partition function} \quad (15B.14)$$

Some typical values of the symmetry numbers are given in Table 15B.2. For the way that group theory is used to identify the value of the symmetry number, see Problem 15B.9.

**Table 15B.2\*** Symmetry numbers of molecules

	$\sigma$
$^1\text{H}_2$	2
$^1\text{H}^2\text{H}$	1
$\text{NH}_3$	3
$\text{C}_6\text{H}_6$	12

\* More values are given in the *Resource section*, Table 12D.1.

#### Brief illustration 15B.4 The symmetry number

The value  $\sigma(\text{H}_2\text{O})=2$  reflects the fact that a  $180^\circ$  rotation about the bisector of the  $\text{H}-\text{O}-\text{H}$  angle interchanges two indistinguishable atoms. In  $\text{NH}_3$ , there are three indistinguishable orientations around the axis, as shown in 1. For

$\text{CH}_4$ , any of three  $120^\circ$  rotations about any of its four C–H bonds leaves the molecule in an indistinguishable state (2), so the symmetry number is  $3 \times 4 = 12$ . For benzene, any of six orientations around the axis perpendicular to the plane of the molecule leaves it apparently unchanged (Fig. 15B.10), as does a rotation of  $180^\circ$  around any of six axes in the plane of the molecule (three of which pass along each C–H bond and the remaining three pass through each C–C bond in the plane of the molecule).

**Figure 15B.10** The 12 equivalent orientations of a benzene molecule that can be reached by pure rotations, and give rise to a symmetry number of 12. The six pale colours are the underside of the hexagon after that face has been rotated into view.

**Self-test 15B.5** What is the symmetry number for a naphthalene molecule?

Answer: 3

### (c) The vibrational contribution

The vibrational partition function of a molecule is calculated by substituting the measured vibrational energy levels into the exponentials appearing in the definition of  $q^V$ , and summing them numerically. However, provided it is permissible to assume that the vibrations are harmonic, there is a much simpler way. In that case, the vibrational energy levels form a uniform ladder of separation  $hc\tilde{\nu}$  (Topics 8B and 12D), which is exactly the problem treated in *Brief illustration 15B.1* and summarized in eqn 15B.2a. Therefore we can use that result with  $\varepsilon = hc\tilde{\nu}$  and conclude immediately that

**Figure 15B.11** The vibrational partition function of a molecule in the harmonic approximation. Note that the partition function is linearly proportional to the temperature when the temperature is high ( $T \gg \theta^V$ ).

$$q^V = \frac{1}{1 - e^{-\beta hc\tilde{\nu}}} \quad \text{Harmonic approximation} \quad \text{Vibrational partition function} \quad (15B.15)$$

This function is plotted in Fig. 15B.11 (which is essentially the same as Fig. 15B.1). Similarly, the population of each state is given by eqn 15B.2b.

#### Brief illustration 15B.5 The vibrational partition function

To calculate the partition function of  $\text{I}_2$  molecules at 298.15 K we note from Table 12D.1 that their vibrational wavenumber is  $214.6 \text{ cm}^{-1}$ . Then, because at 298.15 K,  $kT/hc = 207.224 \text{ cm}^{-1}$ , we have

$$\beta\varepsilon = \frac{hc\tilde{\nu}}{kT} = \frac{214.6 \text{ cm}^{-1}}{207.224 \text{ cm}^{-1}} = 1.035\dots$$

Then it follows from eqn 15B.15 that

$$q^V = \frac{1}{1 - e^{-1.035\dots}} = 1.55$$

We can infer that only the ground and first excited states are significantly populated.

**Self-test 15B.6** Evaluate the populations of the first three vibrational states.

Answer:  $p_0 = 0.645$ ,  $p_1 = 0.229$ ,  $p_2 = 0.081$

In a polyatomic molecule, each normal mode (Topic 12E) has its own partition function (provided the anharmonicities are so small that the modes are independent). The overall vibrational partition function is the product of the individual partition functions, and we can write  $q^V = q^V(1)q^V(2)\dots$ , where  $q^V(K)$  is the partition function for the  $K$ th normal mode and is calculated by direct summation of the observed spectroscopic levels.

**Example 15B.2** Calculating a vibrational partition function

The wavenumbers of the three normal modes of H<sub>2</sub>O are 3656.7 cm<sup>-1</sup>, 1594.8 cm<sup>-1</sup>, and 3755.8 cm<sup>-1</sup>. Evaluate the vibrational partition function at 1500 K.

**Method** Use eqn 15B.15 for each mode, and then form the product of the three contributions. At 1500 K,  $kT/hc = 1042.6$  cm<sup>-1</sup>.

**Answer** We draw up the following table displaying the contributions of each mode:

Mode:	1	2	3
$\tilde{\nu}/\text{cm}^{-1}$	3656.7	1594.8	3755.8
$hc\tilde{\nu}/kT$	3.507	1.530	3.602
$q^V$	1.031	1.276	1.028

The overall vibrational partition function is therefore

$$q^V = 1.031 \times 1.276 \times 1.028 = 1.352$$

The three normal modes of H<sub>2</sub>O are at such high wavenumbers that even at 1500 K most of the molecules are in their vibrational ground state. However, there may be so many normal modes in a large molecule that their overall contribution may be significant even though each mode is not appreciably excited. For example, a nonlinear molecule containing 10 atoms has  $3N - 6 = 24$  normal modes (Topic 12E). If we assume a value of about 1.1 for the vibrational partition function of one normal mode, the overall vibrational partition function is about  $q^V \approx (1.1)^{24} = 9.8$ , which indicates significant vibrational excitation relative to a smaller molecule, such as H<sub>2</sub>O.

**Self-test 15B.7** Repeat the calculation for CO<sub>2</sub>, where the vibrational wavenumbers are 1388 cm<sup>-1</sup>, 667.4 cm<sup>-1</sup>, and 2349 cm<sup>-1</sup>, the second being the doubly-degenerate bending mode.

Answer: 6.79

In many molecules the vibrational wavenumbers are so great that  $\beta hc\tilde{\nu} > 1$ . For example, the lowest vibrational wavenumber of CH<sub>4</sub> is 1306 cm<sup>-1</sup>, so  $\beta hc\tilde{\nu} = 6.3$  at room temperature. Most C–H stretches normally lie in the range 2850 to 2960 cm<sup>-1</sup>, so for them  $\beta hc\tilde{\nu} \approx 14$ . In these cases,  $e^{-\beta hc\tilde{\nu}}$  in the denominator of  $q^V$  is very close to zero (for example,  $e^{-6.3} = 0.002$ ), and the vibrational partition function for a single mode is very close to 1 ( $q^V = 1.002$  when  $\beta hc\tilde{\nu} = 6.3$ ), implying that only the zero-point level is significantly occupied.

Now consider the case of bonds with such low vibrational frequencies that  $\beta hc\tilde{\nu} \ll 1$ . When this condition is satisfied,

**Table 15B.3\*** Vibrational temperatures of diatomic molecules

	$\theta^V/\text{K}$
<sup>1</sup> H <sub>2</sub>	6332
<sup>1</sup> H <sup>35</sup> Cl	4304
<sup>14</sup> N <sub>2</sub>	3393
<sup>35</sup> Cl <sub>2</sub>	805

\* More values are given in the Resource section, Table 12D.1.

the partition function may be approximated by expanding the exponential ( $e^x = 1 + x + \dots$ ):

$$q^V = \frac{1}{1 - e^{-\beta hc\tilde{\nu}}} = \frac{1}{1 - (1 - \beta hc\tilde{\nu} + \dots)}$$

That is, for weak bonds at high temperatures,

$$q^V \approx \frac{kT}{hc\tilde{\nu}} \quad \text{High-temperature approximation} \quad \text{Vibrational partition function} \quad (15B.16)$$

The temperatures for which eqn 15B.16 is valid can be expressed in terms of the **characteristic vibrational temperature**,  $\theta^V = hc\tilde{\nu}/k$  (Table 15B.3). The value for H<sub>2</sub> (6332 K) is abnormally high because the atoms are so light and the vibrational frequency is correspondingly high. In terms of the vibrational temperature, ‘high temperature’ means  $T \gg \theta^V$ , and when this condition is satisfied,  $q^V = T/\theta^V$  (the analogue of the rotational expression).

**(d) The electronic contribution**

Electronic energy separations from the ground state are usually very large, so for most cases  $q^E = 1$  because only the ground state is occupied. An important exception arises in the case of atoms and molecules having electronically degenerate ground states, in which case  $q^E = g^E$ , where  $g^E$  is the degeneracy of the electronic ground state. Alkali metal atoms, for example, have doubly degenerate ground states (corresponding to the two orientations of their electron spin), so  $q^E = 2$ .

**Brief illustration 15B.6** The electronic partition function

Some atoms and molecules have low lying electronically excited states. An example is NO, which has a configuration of the form  $\dots\pi^1$  (Topic 10C). The energy of the two degenerate states in which the orbital and spin momenta are parallel (giving the  ${}^2\Pi_{3/2}$  term, Fig. 15B.12) is slightly greater than that of the two degenerate states in which they are antiparallel (giving the  ${}^2\Pi_{1/2}$  term).

**Figure 15B.12** The doubly-degenerate ground electronic level of NO (with the spin and orbital angular momentum around the axis in opposite directions) and the doubly-degenerate first excited level (with the spin and orbital momenta parallel). The upper level is thermally accessible at room temperature.

The separation, which arises from spin-orbit coupling, is only  $121 \text{ cm}^{-1}$ . If we denote the energies of the two levels as  $E_{1/2}=0$  and  $E_{3/2}=\epsilon$ , the partition function is

$$q^E = \sum_{\text{levels } i} g_i e^{-\beta \epsilon_i} = 2 + 2e^{-\beta \epsilon}$$

This function is plotted in Fig. 15B.13. At  $T=0$ ,  $q^E=2$ , because only the doubly degenerate ground state is accessible. At high

**Figure 15B.13** The variation with temperature of the electronic partition function of an NO molecule. Note that the curve resembles that for a two-level system (Fig.15B.3), but rises from 2 (the degeneracy of the lower level) and approaches 4 (the total number of states) at high temperatures.

temperatures,  $q^E$  approaches 4 because all four states are accessible. At  $25^\circ\text{C}$ ,  $q^E=3.1$ .

**Self-test 15B.8** A certain atom has a fourfold degenerate ground state and a sixfold degenerate excited state at  $400 \text{ cm}^{-1}$  above the ground state. Calculate its electronic partition function at  $25^\circ\text{C}$ .

Answer: 4.87

## Checklist of concepts

- 1. The **molecular partition function** is an indication of the number of thermally accessible states at the temperature of interest.
- 2. If the **energy of a molecule** is given by the sum of contributions, then the molecular partition function is a product of contributions from the different modes.
- 3. The **symmetry number** takes into account the number of indistinguishable orientations of a symmetrical molecule.
- 4. The **vibrational partition function** of a molecule may be approximated by that of an harmonic oscillator.
- 5. Because electronic energy separations from the ground state are usually very big, in most cases the **electronic partition function** is equal to the degeneracy of the electronic ground state.

### ► Why do you need to know this material?

The partition function contains thermodynamic information, but it needs to be extracted. Here we show how to extract one particular property: the average energy of molecules, which plays a central role in thermodynamics.

### ► What is the key idea?

The average energy of a molecule in a collection of independent molecules can be calculated from the molecular partition function alone.

### ► What do you need to know already?

You need know how to calculate the molecular partition function from calculated or spectroscopic data (Topic 15B) and its significance as a measure of the number of accessible states. The Topic also draws on expressions for the rotational and vibrational energies of molecules (Topics 12B and 12D).

This Topic sets up the basic equations that show how to use the molecular partition function to calculate the mean energy of a collection of independent molecules. In Topic 15E we see

how those mean energies are used to calculate thermodynamic properties. The equations for collections of interacting molecules are very similar (Topic 15D), but much more difficult to implement.

## 15C.1 The basic equations

We begin by considering a collection of  $N$  molecules that do not interact with one another. Any member of the collection can exist in a state  $i$  of energy  $\varepsilon_i$  measured from the lowest energy state of the molecule. The mean energy of a molecule,  $\langle \varepsilon \rangle$ , relative to its energy in its ground state is the total energy of the collection,  $E$ , divided by the total number of molecules:

$$\langle \varepsilon \rangle = \frac{E}{N} = \frac{1}{N} \sum_i N_i \varepsilon_i \quad (15C.1)$$

In Topic 15A it is shown that the overwhelmingly most probable population of a state in a collection at a temperature  $T$  is given by the Boltzmann distribution, eqn 15A.6a ( $N_i/N = (1/q)e^{-\beta\varepsilon_i}$ ), so we can write

$$\langle \varepsilon \rangle = \frac{1}{q} \sum_i \varepsilon_i e^{-\beta\varepsilon_i} \quad (15C.2)$$

with  $\beta = 1/kT$ . To manipulate this expression into a form involving only  $q$  we note that

$$\varepsilon_i e^{-\beta\varepsilon_i} = -\frac{d}{d\beta} e^{-\beta\varepsilon_i}$$

It follows that

$$\langle \varepsilon \rangle = -\frac{1}{q} \sum_i \frac{d}{d\beta} e^{-\beta\varepsilon_i} = -\frac{1}{q} \frac{d}{d\beta} \sum_i e^{-\beta\varepsilon_i} = -\frac{1}{q} \frac{dq}{d\beta} \quad (15C.3)$$

Several points in relation to eqn 15C.3 need to be made. Because  $\varepsilon_0 = 0$ , (we measure all energies from the lowest available level),  $\langle \varepsilon \rangle$  should be interpreted as the value of the mean energy relative to its ground-state energy. If the lowest energy of the molecule is in fact  $\varepsilon_{\text{gs}}$  rather than 0, then the true mean energy is  $\varepsilon_{\text{gs}} + \langle \varepsilon \rangle$ . For instance, for an harmonic oscillator, we would set  $\varepsilon_{\text{gs}}$  equal to the zero-point energy,  $\frac{1}{2}hc\tilde{\nu}$ . Secondly, because the partition function may depend on variables other

than the temperature (for example, the volume), the derivative with respect to  $\beta$  in eqn 15C.3 is actually a *partial* derivative with these other variables held constant. The complete expression relating the molecular partition function to the mean energy of a molecule is therefore

$$\langle \varepsilon \rangle = \varepsilon_{\text{gs}} - \frac{1}{q} \left( \frac{\partial q}{\partial \beta} \right)_V \quad \text{Mean molecular energy} \quad (15C.4a)$$

An equivalent form is obtained by noting that  $dx/x = d \ln x$ :

$$\langle \varepsilon \rangle = \varepsilon_{\text{gs}} - \left( \frac{\partial \ln q}{\partial \beta} \right)_V \quad \text{Mean molecular energy} \quad (15C.4b)$$

These two equations confirm that we need know only the partition function (as a function of temperature) to calculate the mean energy.

### Brief illustration 15C.1 Mean energy of a two-level system

If a molecule has only two available energy levels, one at 0 and the other at an energy  $\varepsilon$ , its partition function is

$$q = 1 + e^{-\beta\varepsilon}$$

Therefore, the mean energy of a collection of these molecules at a temperature  $T$  is

$$\langle \varepsilon \rangle = - \frac{1}{1 + e^{-\beta\varepsilon}} \frac{d(1 + e^{-\beta\varepsilon})}{d\beta} = \frac{\varepsilon e^{-\beta\varepsilon}}{1 + e^{-\beta\varepsilon}} = \frac{\varepsilon}{e^{\beta\varepsilon} + 1}$$

This function is plotted in Fig. 15C.1. Notice how the mean energy is zero at  $T=0$ , when only the lower state (at the zero

**Figure 15C.1** The total energy of a two-level system (expressed as a multiple of  $N\varepsilon$ ) as a function of temperature, on two temperature scales. The graph on the left shows the slow rise away from zero energy at low temperatures; the slope of the graph at  $T=0$  is 0. The graph on the right shows the slow rise to 0.5 as  $T \rightarrow \infty$  as both states become equally populated.

of energy) is occupied, and rises to  $\frac{1}{2}\varepsilon$  as  $T \rightarrow \infty$ , when the two levels become equally populated.

**Self-test 15C.1** Deduce an expression for the mean energy when each molecule can exist in states with energies 0,  $\varepsilon$ , and  $2\varepsilon$ .

Answer:  $\langle \varepsilon \rangle = \varepsilon(1 + 2x)x/(1 + x + x^2)$ ,  $x = e^{-\beta\varepsilon}$

## 15C.2 Contributions of the fundamental modes of motion

In the remainder of this Topic we establish expressions for three fundamental types of motion, translation (T), rotation (R), and vibration (V), and then see how to incorporate the electronic states of molecules (E) and the spin of electrons or nuclei (S).

### (a) The translational contribution

For a one-dimensional container of length  $X$ , for which  $q^T = X/\Lambda$  with  $\Lambda = h(\beta/2\pi m)^{1/2}$  (Topic 15B), we note that  $\Lambda$  is a constant multiplied by  $\beta^{1/2}$ , and obtain

$$\begin{aligned} \langle \varepsilon^T \rangle &= - \frac{1}{q^T} \left( \frac{\partial q^T}{\partial \beta} \right)_V = - \frac{\Lambda}{X} \left( \frac{\partial}{\partial \beta} \frac{X}{\Lambda} \right)_V \\ &= - \frac{\text{constant} \times \beta^{1/2}}{X} \times X \times \frac{d}{d\beta} \left( \frac{1}{\text{constant} \times \beta^{1/2}} \right) \\ &= - \beta^{1/2} \frac{d}{d\beta} \frac{1}{\beta^{1/2}} = \frac{1}{2\beta} \end{aligned}$$

That is,

$$\langle \varepsilon^T \rangle = \frac{1}{2} kT \quad \text{One dimension} \quad \text{Mean translational energy} \quad (15C.5a)$$

For a molecule free to move in three dimensions, the analogous calculation leads to

$$\langle \varepsilon^T \rangle = \frac{3}{2} kT \quad \text{Three dimensions} \quad \text{Mean translational energy} \quad (15C.5b)$$

### (b) The rotational contribution

The mean rotational energy of a linear molecule is obtained from the rotational partition function (eqn 15B.11):

$$q^R = \sum_J (2J+1) e^{-\beta h c \tilde{B} J(J+1)}$$

When the temperature is low (in the sense  $T < \theta^R = hc\tilde{B}/k$ ) the series must be summed term by term, which for a heteronuclear

diatomic molecule or other non-symmetrical linear molecule gives

$$q^R = 1 + 3e^{-2\beta hc\tilde{B}} + 5e^{-6\beta hc\tilde{B}} + \dots$$

Hence, because

$$\frac{dq^R}{d\beta} = -hc\tilde{B}(6e^{-2\beta hc\tilde{B}} + 30e^{-6\beta hc\tilde{B}} + \dots)$$

( $q^R$  is independent of  $V$ , so the partial derivative has been replaced by a complete derivative) we find

$$\langle \varepsilon^R \rangle = -\frac{1}{q^R} \frac{dq^R}{d\beta} = \frac{hc\tilde{B}(6e^{-2\beta hc\tilde{B}} + 30e^{-6\beta hc\tilde{B}} + \dots)}{1 + 3e^{-2\beta hc\tilde{B}} + 5e^{-6\beta hc\tilde{B}} + \dots}$$

*Unsymmetrical linear molecule*    **Mean rotational energy**    (15C.6a)

This ungainly function is plotted in Fig. 15C.2. At high temperatures ( $T \gg \theta^R$ ),  $q^R$  is given by eqn 15B.13b ( $q^R = T/\sigma\theta^R$ ) in the form  $q^R = 1/\sigma\beta hc\tilde{B}$ , where  $\sigma = 1$  for a heteronuclear diatomic molecule. It then follows that

$$\langle \varepsilon^R \rangle = -\frac{1}{q^R} \frac{dq^R}{d\beta} = -\sigma\beta hc\tilde{B} \frac{d}{d\beta} \left( \frac{1}{\sigma\beta hc\tilde{B}} \right) = -\beta \frac{d}{d\beta} \frac{1}{\beta}$$

and therefore that

$$\langle \varepsilon^R \rangle = \frac{1}{\beta} = kT$$

*Linear molecule, high temperature ( $T \gg \theta^R$ )*    **Mean rotational energy**    (15C.6b)

The high-temperature result, which is valid when many rotational states are occupied, is also in agreement with the equipartition theorem, because the classical expression for the energy of a linear rotor is  $E_k = \frac{1}{2} I_{\perp} \omega_a^2 + \frac{1}{2} I_{\perp} \omega_b^2$  and therefore has two quadratic contributions. (There is no rotation around the line of atoms.) It follows from the equipartition theorem (*Foundations B*) that the mean rotational energy is  $2 \times \frac{1}{2} kT = kT$ .

**Figure 15C.2** The mean rotational energy of a non-symmetrical linear rotor as a function of temperature. At high temperatures ( $T \gg \theta^R$ ), the energy is linearly proportional to the temperature, in accord with the equipartition theorem.

### Brief illustration 15C.2 Mean rotational energy

To estimate the mean energy of a nonlinear molecule we recognize that its rotational kinetic energy (the only contribution to its rotational energy) is  $E_k = \frac{1}{2} I_a \omega_a^2 + \frac{1}{2} I_b \omega_b^2 + \frac{1}{2} I_c \omega_c^2$ . As there are three quadratic contributions, its mean rotational energy is  $\frac{3}{2} kT$ . The molar contribution is  $\frac{3}{2} RT$ . At 25 °C, this contribution is 3.7 kJ mol<sup>-1</sup>, the same as the translational contribution, for a total of 7.4 kJ mol<sup>-1</sup>. A monatomic gas has no rotational contribution.

**Self-test 15C.2** How much energy does it take to raise the temperature of 1.0 mol H<sub>2</sub>O(g) from 100 °C to 200 °C? Consider only translational and rotational contributions to the heat capacity.

Answer: 2.5 KJ

### (c) The vibrational contribution

The vibrational partition function in the harmonic approximation is given in eqn 15B.15 ( $q^V = 1/(1 - e^{-\beta hc\tilde{\nu}})$ ). Because  $q^V$  is independent of the volume, it follows that

$$\frac{dq^V}{d\beta} = \frac{d}{d\beta} \left( \frac{1}{1 - e^{-\beta hc\tilde{\nu}}} \right) = -\frac{hc\tilde{\nu} e^{-\beta hc\tilde{\nu}}}{(1 - e^{-\beta hc\tilde{\nu}})^2}$$

(15C.7)

and hence from

$$\begin{aligned} \langle \varepsilon^V \rangle &= -\frac{1}{q^V} \frac{dq^V}{d\beta} = (1 - e^{-\beta hc\tilde{\nu}}) \frac{hc\tilde{\nu} e^{-\beta hc\tilde{\nu}}}{(1 - e^{-\beta hc\tilde{\nu}})^2} \\ &= \frac{hc\tilde{\nu} e^{-\beta hc\tilde{\nu}}}{1 - e^{-\beta hc\tilde{\nu}}} \end{aligned}$$

that

$$\langle \varepsilon^V \rangle = \frac{hc\tilde{\nu}}{e^{\beta hc\tilde{\nu}} - 1}$$

*Harmonic approximation*    **Mean vibrational energy**    (15C.8)

The zero-point energy,  $\frac{1}{2} hc\tilde{\nu}$ , can be added to the right-hand side if the mean energy is to be measured from 0 rather than the lowest attainable level (the zero-point level). The variation of the mean energy with temperature is illustrated in Fig. 15C.3. At high temperatures, when  $T \gg \theta^V$ , or  $\beta hc\tilde{\nu} \ll 1$  (recall from Topic 15B that  $\theta^V = hc\tilde{\nu}/k$ ), the exponential functions can be expanded ( $e^x = 1 + x + \dots$ ) and all but the leading terms discarded. This approximation leads to

$$\langle \varepsilon^V \rangle = \frac{hc\tilde{\nu}}{(1 + \beta hc\tilde{\nu} + \dots) - 1} \approx \frac{1}{\beta} = kT$$

*High temperature approximation ( $T \gg \theta^V$ )*    **Mean vibrational energy**    (15C.9)

**Figure 15C.3** The mean vibrational energy of a molecule in the harmonic approximation as a function of temperature. At high temperatures ( $T \gg \theta^V$ ), the energy is linearly proportional to the temperature, in accord with the equipartition theorem.

This result is in agreement with the value predicted by the classical equipartition theorem, because the energy of a one-dimensional oscillator is  $E = \frac{1}{2}mv_x^2 + \frac{1}{2}k_f x^2$  and the mean energy of each quadratic term is  $\frac{1}{2}kT$ . Bear in mind, however, that the condition  $T \gg \theta^V$  is rarely satisfied.

#### Brief illustration 15C.3 The mean vibrational energy

To calculate the mean vibrational energy of  $I_2$  molecules at 298.15 K we note from Table 12D.1 that their vibrational wavenumber is  $214.6 \text{ cm}^{-1}$ . Then, because at 298.15 K,  $kT/hc = 207.224 \text{ cm}^{-1}$ , from eqn 15C.8 with

$$\beta\epsilon = \frac{hc\tilde{\nu}}{kT} = \frac{214.6 \text{ cm}^{-1}}{207.244 \text{ cm}^{-1}} = 1.036$$

it follows from eqn 15C.8 that

$$\langle \epsilon^V \rangle / hc = \frac{214.6 \text{ cm}^{-1}}{e^{1.036} - 1} = 118.0 \text{ cm}^{-1}$$

The addition of the zero-point energy (corresponding to  $\frac{1}{2} \times 214.6 \text{ cm}^{-1}$ ) increases this value to  $225.3 \text{ cm}^{-1}$ . The equipartition result is  $207.224 \text{ cm}^{-1}$ , the discrepancy reflecting the fact that in this case it is not true that  $T \gg \theta^V$  and only the ground and first excited states are significantly populated.

**Self-test 15C.3** What must the temperature be before the energy estimated from the equipartition theorem is within 2 per cent of the energy given by eqn 15C.8?

Answer: 625 K; use a spreadsheet

When there are several normal modes that can be treated as harmonic, the overall vibrational partition function is the product of each individual partition function, and the total mean vibrational energy is the sum of the mean energy of each mode.

#### (d) The electronic contribution

We shall consider two types of electronic contribution: one arising from the electronically excited states of a molecule and one from the spin contribution.

In most cases of interest, the electronic states of atoms and molecules are so widely separated that only the electronic ground state is occupied. As we are adopting the convention that all energies are measured from the ground state of each mode, we can write

$$\langle \epsilon^E \rangle = 0 \quad \text{Mean electronic energy} \quad (15C.10)$$

In certain cases, there are thermally accessible states at the temperature of interest. In that case, the partition function and hence the mean electronic energy are best calculated by direct summation over the available states. Care must be taken to take any degeneracies into account, as we illustrate in the following *Example*.

#### Example 15C.1 Calculating the electronic contribution to the energy

A certain atom has a doubly degenerate electronic ground state and a fourfold degenerate excited state at  $600 \text{ cm}^{-1}$  above the ground state. What is its mean electronic energy at  $25^\circ \text{C}$  expressed as a wavenumber?

**Method** Write down the expression for the partition function at a general temperature  $T$  (in terms of  $\beta$ ) and then derive the mean energy by differentiating with respect to  $\beta$ . Finally, substitute the data. Use  $\epsilon = hc\tilde{\nu}$ ,  $\langle \epsilon^E \rangle = hc\langle \tilde{\nu}^E \rangle$ , and (from inside the front cover),  $kT/hc = 207.226 \text{ cm}^{-1}$  at  $25^\circ \text{C}$ .

**Answer** The partition function is  $q^E = 2 + 4e^{-\beta\epsilon}$ . The mean energy is therefore

$$\begin{aligned} \langle \epsilon^E \rangle &= -\frac{1}{q^E} \frac{dq^E}{d\beta} = -\frac{1}{2 + 4e^{-\beta\epsilon}} \frac{d}{d\beta} \left( 2 + 4e^{-\beta\epsilon} \right) \\ &= \frac{4\epsilon e^{-\beta\epsilon}}{2 + 4e^{-\beta\epsilon}} = \frac{\epsilon}{\frac{1}{2}e^{\beta\epsilon} + 1} \end{aligned}$$

and expressed as a wavenumber

$$\langle \tilde{\nu}^E \rangle = \frac{\tilde{\nu}}{\frac{1}{2}e^{hc\tilde{\nu}/kT} + 1}$$

From the data,

$$\langle \tilde{\nu}^E \rangle = \frac{600 \text{ cm}^{-1}}{\frac{1}{2}e^{600/207.226} + 1} = 59.7 \text{ cm}^{-1}$$

**Self-test 15C.4** Repeat the problem for an atom that has a threefold degenerate ground state and a sevenfold degenerate excited state  $400\text{ cm}^{-1}$  above.

Answer:  $101\text{ cm}^{-1}$

### (e) The spin contribution

An electron spin in a magnetic field  $\mathcal{B}$  has two possible energy states that depend on its orientation as expressed by the magnetic quantum number  $m_s$ , and which are given by

$$E_{m_s} = 2\mu_B \mathcal{B} m_s \quad \text{Electron spin energies} \quad (15C.11)$$

where  $\mu_B$  is the Bohr magneton (see inside the front cover). These energies are discussed in more detail in Topic 14A where we see that the integer 2 needs to be replaced by a number very close to 2. The lower state has  $m_s = -\frac{1}{2}$ , so the two energy levels available to the electron lie (according to our convention) at  $\varepsilon_{-1/2} = 0$  and at  $\varepsilon_{+1/2} = 2\mu_B \mathcal{B}$ . The spin partition function is therefore

$$q^S = \sum_{m_s} e^{-\beta \varepsilon_{m_s}} = 1 + e^{-2\beta \mu_B \mathcal{B}} \quad \text{Spin partition function} \quad (15C.12)$$

The mean energy of the spin is therefore

$$\begin{aligned} \langle \varepsilon^S \rangle &= -\frac{1}{q^S} \frac{dq^S}{d\beta} = -\frac{1}{1 + e^{-2\beta \mu_B \mathcal{B}}} \frac{d}{d\beta} \left( 1 + e^{-2\mu_B \mathcal{B} \beta} \right) \\ &= \frac{2\mu_B \mathcal{B} e^{-2\beta \mu_B \mathcal{B}}}{1 + e^{-2\beta \mu_B \mathcal{B}}} \end{aligned}$$

That is,

$$\langle \varepsilon^S \rangle = \frac{2\mu_B \mathcal{B}}{e^{2\beta \mu_B \mathcal{B}} + 1} \quad \text{Mean spin energy} \quad (15C.13)$$

This function is essentially the same as that plotted in Fig. 15C.1.

### Brief illustration 15C.4 The spin contribution to the energy

Suppose a collection of radicals is exposed to a magnetic field of 2.5 T (T denotes tesla). With  $\mu_B = 9.274 \times 10^{-24}\text{ J T}^{-1}$  and a temperature of  $25^\circ\text{C}$ ,

$$\begin{aligned} 2\mu_B \mathcal{B} &= 2 \times (9.274 \times 10^{-24}\text{ J T}^{-1}) \times 2.5\text{ T} = 4.6 \dots \times 10^{-23}\text{ J} \\ 2\beta \mu_B \mathcal{B} &= \frac{2(9.274 \times 10^{-24}\text{ J T}^{-1}) \times (2.5\text{ T})}{(1.381 \times 10^{-23}\text{ J K}^{-1}) \times (298\text{ K})} = 0.011 \dots \end{aligned}$$

The mean energy is therefore

$$\langle \varepsilon^S \rangle = \frac{4.6 \dots \times 10^{-23}\text{ J}}{e^{0.011 \dots} + 1} = 2.3 \times 10^{-23}\text{ J}$$

This energy is equivalent to  $14\text{ J mol}^{-1}$  (note joules, not kilojoules).

**Self-test 15C.5** Repeat the calculation for a species with  $S = 1$  in the same magnetic field.

Answer:  $0.0046\text{ zJ}$ ,  $28\text{ J mol}^{-1}$

## Check list of concepts

- 1. The mean molecular energy can be calculated from the molecular partition function.
- 2. The molecular partition function is calculated from molecular structural parameters obtained from spectroscopy or computation.

## Checklist of equations

### ► Why do you need to know this material?

Whereas Topics 15B and 15C deal with independent molecules, in practice molecules do interact. Therefore, this material is essential for constructing models of real gases, liquids, and solids and of any system in which intermolecular interactions cannot be neglected.

### ► What is the main idea?

A system composed of interacting molecules is described in terms of a canonical partition function, from which its thermodynamic properties may be deduced.

### ► What do you need to know already?

This material draws on the calculations in Topic 15A: the calculations here are analogous to those, and are not repeated in detail. This Topic also draws on the calculation of energies from partition functions (Topic 15C); here too the calculations are analogous to those presented there.

Here we consider the formalism appropriate to systems in which the molecules interact with one another, as in real gases and liquids. The crucial concept we need when treating systems of interacting particles is the ‘ensemble’. Like so many scientific terms, the term has basically its normal meaning of

‘collection’, but it has been sharpened and refined into a precise significance.

## 15D.1 The concept of ensemble

To set up an ensemble, we take a closed system of specified volume, composition, and temperature, and think of it as replicated  $\tilde{N}$  times (Fig. 15D.1). All the identical closed systems are regarded as being in thermal contact with one another, so they can exchange energy. The total energy of all the systems is  $\tilde{E}$  and, because they are in thermal equilibrium with one another, they all have the same temperature,  $T$ . The volume of each member of the ensemble is the same, so the energy levels available to the molecules are the same in each system, and each member contains the same number of molecules, so there is a fixed number of molecules to distribute within each system. This imaginary collection of replications of the actual system with a common temperature is called the **canonical ensemble**. The word ‘canon’ means ‘according to a rule’.

There are two other important ensembles. In the **microcanonical ensemble** the condition of constant temperature is replaced by the requirement that all the systems should have exactly the same energy: each system is individually isolated. In the **grand canonical ensemble** the volume and temperature

**Figure 15D.1** A representation of the canonical ensemble, in this case for  $\tilde{N} = 20$ . The individual replications of the actual system all have the same composition and volume. They are all in mutual thermal contact, and so all have the same temperature. Energy may be transferred between them as heat, and so they do not all have the same energy. The total  $\tilde{E}$  of all 20 replications is a constant because the ensemble is isolated overall.

of each system is the same, but they are open, which means that matter can be imagined as able to pass between the systems; the composition of each one may fluctuate, but now the property known as the chemical potential (Topic 5A) is the same in each system. In summary:

Ensemble	Common properties
Microcanonical	$V, E, N$
Canonical	$V, T, N$
Grand canonical	$V, T, \mu$

The microcanonical ensemble is the basis of the discussion in Topic 15A; we shall not consider the grand canonical ensemble explicitly.

The important point about an ensemble is that it is a collection of *imaginary* replications of the system, so we are free to let the number of members be as large as we like; when appropriate, we can let  $\tilde{N}$  become infinite. The number of members of the ensemble in a state with energy  $E_i$  is denoted  $\tilde{N}_i$ , and we can speak of the configuration of the ensemble (by analogy with the configuration of the system used in Topic 15A) and its weight,  $\tilde{\mathcal{W}}$ . Note that  $\tilde{N}$  is unrelated to  $N$ , the number of molecules in the actual system;  $\tilde{N}$  is the number of *imaginary* replications of that system.

### (a) Dominating configurations

Just as in Topic 15A, some of the configurations of the canonical ensemble will be very much more probable than others. For instance, it is very unlikely that the whole of the total energy,  $\tilde{E}$ , will accumulate in one system. By analogy with the discussion in Topic 15A, we can anticipate that there will be a dominating configuration, and that we can evaluate the thermodynamic properties by taking the average over the ensemble using that single, most probable, configuration. In the **thermodynamic limit** of  $\tilde{N} \rightarrow \infty$ , this dominating configuration is overwhelmingly the most probable, and it dominates the properties of the system virtually completely.

The quantitative discussion follows the argument in Topic 15A with the modification that  $N$  and  $N_i$  are replaced by  $\tilde{N}$  and  $\tilde{N}_i$ . The weight  $\tilde{\mathcal{W}}$  of a configuration  $\{\tilde{N}_0, \tilde{N}_1, \dots\}$  is

$$\tilde{\mathcal{W}} = \frac{\tilde{N}!}{\tilde{N}_1! \tilde{N}_2! \dots} \quad \text{Weight} \quad (15D.1)$$

The configuration of greatest weight, subject to the constraints that the total energy of the ensemble is constant at  $\tilde{E}$  and that the total number of members is fixed at  $\tilde{N}$ , is given by the **canonical distribution**:

$$\frac{\tilde{N}_i}{\tilde{N}} = \frac{e^{-\beta E_i}}{Q} \quad \text{Canonical distribution} \quad (15D.2a)$$

in which

$$Q = \sum_i e^{-\beta E_i} \quad \text{Definition} \quad \text{Canonical partition function} \quad (15D.2b)$$

where the sum is over all members of the ensemble, each one having an energy  $E_i$ . The quantity  $Q$ , which is a function of the temperature, is called the **canonical partition function**. Like the molecular partition function, the canonical partition function contains all the thermodynamic information about a system, but in this case, allowing for the possibility of interactions between the constituent molecules.

#### Brief illustration 15D.1 The canonical distribution

Suppose that we are considering a sample of a monatomic real gas that contains 1.00 mol atoms, then at 298 K its total energy is close to  $\frac{3}{2}nRT = \frac{3}{2}(1.00 \text{ mol}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K}) = 3.72 \text{ kJ}$ . Suppose that for an instant the molecules are present at separations where the total energy is 3.72 kJ and an instant later are present at separations where the total energy is lower than 3.72 kJ by 0.00 000 001 per cent (that is, by  $3.72 \times 10^{-7} \text{ J}$ ). To predict the ratio of numbers of members of the ensemble with these two energies we use eqn 15D.2a in the form

$$\begin{aligned} \frac{\tilde{N}(\text{lower})}{\tilde{N}(\text{higher})} &= e^{-(3.70 \times 10^{-7} \text{ J}) / (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} \\ &= e^{3.33 \times 10^7} \end{aligned}$$

At first sight, the number of members that have the lower energy vastly outweighs the number with the higher energy. That that is not necessarily the case is explained below.

**Self-test 15D.1** Repeat the calculation for members of the same ensemble with energies that differ by  $1.0 \times 10^{-20}$  per cent.

Answer:  $\tilde{N}(\text{lower})/\tilde{N}(\text{higher}) = e^{90} \approx 1 \times 10^{39}$

### (b) Fluctuations from the most probable distribution

The canonical distribution in eqn 15D.2a is only apparently an exponentially decreasing function of the energy of the system. We must appreciate that the equation gives the probability of occurrence of members in a single state  $i$  of the entire system of energy  $E_i$ . There may in fact be numerous states with almost identical energies. For example, in a gas the identities of the molecules moving slowly or quickly can change without necessarily affecting the total energy. The **density of states**, the number of states in an energy range divided by the width of the range (Fig. 15D.2), is a very sharply increasing function of energy. It follows that the probability of a member of an ensemble having a specified energy (as distinct from being in a specified state) is given by

**Figure 15D.2** The energy density of states is the number of states in an energy range divided by the width of the range.

**Figure 15D.3** To construct the form of the distribution of members of the canonical ensemble in terms of their energies, we multiply the probability that any one is in a state of given energy, eqn 15D.2a, by the number of states corresponding to that energy (a steeply rising function). The product is a sharply peaked function at the mean energy, which shows that almost all the members of the ensemble have that energy.

eqn 15D.2a, a sharply decreasing function, multiplied by a sharply increasing function (Fig. 15D.3). Therefore, the overall distribution is a sharply peaked function. We conclude that most members of the ensemble have an energy very close to the mean value.

#### Brief illustration 15D.2 The role of the density of states

A function that increases rapidly is  $x^N$ , with  $N$  a large value. A function that decreases rapidly is  $e^{-Nx}$ , once again, with  $N$  a large value. The product of these two functions, normalized so that the maxima for different values of  $N$  all coincide,

$$f(x) = e^N x^N e^{-Nx}$$

is plotted for three values of  $N$  in Fig. 15D.4. We see that the width of the product does indeed decrease as  $N$  increases.

**Figure 15D.4** The product of the two functions discussed in Brief illustration 15D.2, for three different values of  $N$ .

**Self-test 15D.2** Show that the product of the functions  $x^{2N}$  and  $e^{-Nx}$ , suitably normalized, behaves similarly.

Answer: Plot  $f(x) = (1/2)^{2N} e^{2N} x^{2N} e^{-Nx}$  for  $0 \leq x \leq 4$

## 15D.2 The mean energy of a system

Just as the molecular partition function can be used to calculate the mean value of a molecular property, so the canonical partition function can be used to calculate the mean energy of an entire system composed of molecules (that might or might not be interacting with one another). Thus,  $Q$  is more general than  $q$  because it does not assume that the molecules are independent. We can therefore use  $Q$  to discuss the properties of condensed phases and real gases where molecular interactions are important.

If the total energy of the ensemble is  $\tilde{E}$ , and there are  $\tilde{N}$  members, the average energy of a member is  $\langle E \rangle = \tilde{E} / \tilde{N}$ . Because the fraction,  $\tilde{p}_i$ , of members of the ensemble in a state  $i$  with energy  $E_i$  is given by the analogue of eqn 15A.6 ( $p_i = e^{-\beta E_i} / q$  with  $p_i = N_i / N$ ) as

$$\tilde{p}_i = \frac{e^{-\beta E_i}}{Q} \quad (15D.3)$$

it follows that

$$\langle E \rangle = \sum_i \tilde{p}_i E_i = \frac{1}{Q} \sum_i E_i e^{-\beta E_i} \quad (15D.4)$$

By the same argument that led to eqn 15C.4 ( $\langle \varepsilon \rangle = -(1/q)(\partial q / \partial \beta)_V$ , when  $\varepsilon_{gs} = 0$ ),

$$E = -\frac{1}{Q} \left( \frac{\partial Q}{\partial \beta} \right)_V = - \left( \frac{\partial \ln Q}{\partial \beta} \right)_V \quad \text{Mean energy of a system} \quad (15D.5)$$

As in the case of the mean molecular energy, we must add to this expression the ground-state energy of the entire system if that is not zero.

#### Brief illustration 15D.3 The expression for the energy

If the canonical partition function is a product of the molecular partition function of each molecule (which we see below is the case when the  $N$  molecules of the system are independent), then we can write  $Q = q^N$ , and infer that the energy of the system is

$$\langle E \rangle = -\frac{1}{q^N} \left( \frac{\partial q^N}{\partial \beta} \right)_V = -\frac{Nq^{N-1}}{q^N} \left( \frac{\partial q}{\partial \beta} \right)_V = -\frac{N}{q} \left( \frac{\partial q}{\partial \beta} \right)_V = N \langle \epsilon \rangle$$

That is, the mean energy of the system is  $N$  times the mean energy of a single molecule.

**Self-test 15D.3** Confirm that the same expression is obtained if  $Q = q^N/N!$ , which is another case described below.

### 15D.3 Independent molecules revisited

We shall now see how to recover the molecular partition function from the more general canonical partition function when the molecules are independent. We show in the following *Justification* that, when the molecules are independent and indistinguishable (in the sense to be described), the relation between  $Q$  and  $q$  is

$$Q = q^N \quad (15D.6)$$

#### Justification 15D.1 The relation between $Q$ and $q$

The total energy of a collection of  $N$  independent molecules is the sum of the energies of the molecules. Therefore, we can write the total energy of a state  $i$  of the system as

$$E_i = \epsilon_i(1) + \epsilon_i(2) + \dots + \epsilon_i(N)$$

In this expression,  $\epsilon_i(1)$  is the energy of molecule 1 when the system is in the state  $i$ ,  $\epsilon_i(2)$  the energy of molecule 2 when the system is in the same state  $i$ , and so on. The canonical partition function is then

$$Q = \sum_i e^{-\beta \epsilon_i(1) - \beta \epsilon_i(2) - \dots - \beta \epsilon_i(N)}$$

The sum over the states of the system can be reproduced by letting each molecule enter all its own individual states (although we meet an important proviso shortly). Therefore, instead of

summing over the states  $i$  of the system, we can sum over all the individual states  $j$  of molecule 1, all the states  $j$  of molecule 2, and so on. This rewriting of the original expression leads to

$$Q = \left( \sum_j e^{-\beta \epsilon_j} \right) \left( \sum_j e^{-\beta \epsilon_j} \right) \dots \left( \sum_j e^{-\beta \epsilon_j} \right) = q^N$$

If all the molecules are identical and free to move through space, we cannot distinguish them and the relation  $Q = q^N$  is not valid. Suppose that molecule 1 is in some state  $a$ , molecule 2 is in  $b$ , and molecule 3 is in  $c$ , then one member of the ensemble has an energy  $E = \epsilon_a + \epsilon_b + \epsilon_c$ . This member, however, is indistinguishable from one formed by putting molecule 1 in state  $b$ , molecule 2 in state  $c$ , and molecule 3 in state  $a$ , or some other permutation. There are six such permutations in all, and  $N!$  in general. In the case of indistinguishable molecules, it follows that we have counted too many states in going from the sum over system states to the sum over molecular states, so writing  $Q = q^N$  overestimates the value of  $Q$ . The detailed argument is quite involved, but at all except very low temperatures it turns out that the correction factor is  $1/N!$ . Therefore:

$$\text{For distinguishable independent molecules: } Q = q^N \quad (15D.7a)$$

$$\text{For indistinguishable independent molecules: } Q = q^N/N! \quad (15D.7b)$$

#### Brief illustration 15D.4 Indistinguishability

For molecules to be indistinguishable, they must be of the same kind: an Ar atom is never indistinguishable from a Ne atom. Their identity, however, is not the only criterion. Each identical molecule in a crystal lattice, for instance, can be 'named' with a set of coordinates. Identical molecules in a lattice can therefore be treated as distinguishable because their sites are distinguishable, and we use eqn 15D.7a. On the other hand, identical molecules in a gas are free to move to different locations, and there is no way of keeping track of the identity of a given molecule; we therefore use eqn 15D.7b.

**Self-test 15D.4** Are identical molecules in a liquid indistinguishable?

Answer: Yes

### 15D.4 The variation of energy with volume

When there are interactions between molecules, the energy of a collection depends on the average distance between them, and therefore on the volume that a fixed number occupy. This

dependence on volume is particularly important for the discussion of real gases (Topic 1C).

We need to evaluate  $(\partial\langle E\rangle/\partial V)_T$ , the variation in energy of a system with volume at constant temperature. (In Topics 2D and 3D, this quantity is identified with the ‘internal pressure’ of a gas and denoted  $\pi_T$ .) To proceed, we substitute eqn 15D.5 and obtain

$$\left(\frac{\partial E}{\partial V}\right)_T = -\left(\frac{\partial}{\partial V}\left(\frac{\partial \ln Q}{\partial \beta}\right)_V\right)_T \quad (15D.8)$$

We need to consider the translational contribution to  $Q$  since translational energy levels depend on volume, but to develop eqn 15D.8, we also need to find a way to build an intermolecular potential energy into the expression for  $Q$ .

The total kinetic energy of a gas is the sum of the kinetic energies of the individual molecules. Therefore, even in a real gas the canonical partition function factorizes into a part arising from the kinetic energy, which for the perfect gas is  $Q = V^N/\Lambda^{3N}N!$ , where  $\Lambda$  is the thermal wavelength, eqn 15B.7b ( $\Lambda = h/(2\pi mkT)^{1/2}$ ), and a factor called the **configuration integral**,  $\mathcal{Z}$ , which depends on the intermolecular potentials (don't confuse this  $\mathcal{Z}$  with the compression factor  $Z$  in Topic 1C). We therefore write

$$Q = \frac{\mathcal{Z}}{\Lambda^{3N}} \quad (15D.9)$$

with  $\mathcal{Z}$  replacing  $V^N/N!$  and expect  $\mathcal{Z}$  to equal  $V^N/N!$  for a perfect gas (see the next *Brief illustration*). It then follows that

$$\begin{aligned} \left(\frac{\partial E}{\partial V}\right)_T &= -\left(\frac{\partial}{\partial V}\left(\frac{\partial \ln(\mathcal{Z}/\Lambda^{3N})}{\partial \beta}\right)_V\right)_T \\ &= -\left(\frac{\partial}{\partial V}\left(\frac{\partial \ln \mathcal{Z}}{\partial \beta}\right)_V\right)_T - \left(\frac{\partial}{\partial V}\left(\frac{\partial \ln(1/\Lambda^{3N})}{\partial \beta}\right)_V\right)_T \\ &= -\left(\frac{\partial}{\partial V}\left(\frac{\partial \ln \mathcal{Z}}{\partial \beta}\right)_V\right)_T - \left(\frac{\partial}{\partial \beta}\left(\frac{\partial \ln(1/\Lambda^{3N})}{\partial V}\right)_T\right) \\ &= -\left(\frac{\partial}{\partial V}\left(\frac{\partial \ln \mathcal{Z}}{\partial \beta}\right)_V\right)_T = -\left(\frac{\partial}{\partial V}\frac{1}{\mathcal{Z}}\left(\frac{\partial \mathcal{Z}}{\partial \beta}\right)_V\right)_T \end{aligned} \quad (15D.10)$$

In the third line, to obtain and evaluate the blue term we have used the relation  $(\partial^2 f/\partial x \partial y) = (\partial^2 f/\partial y \partial x)$  and then noted that  $\Lambda$  is independent of volume, so its derivative with respect to volume is zero.

For a real gas of atoms (for which the intermolecular interactions are isotropic),  $\mathcal{Z}$  is related to the total potential energy

$E_p$  of interaction of all the particles, which depends on all their relative locations, by

$$\mathcal{Z} = \frac{1}{N!} \int e^{-\beta E_p} d\tau_1 d\tau_2 \cdots d\tau_N \quad \text{Configuration integral} \quad (15D.11)$$

where  $d\tau_i$  is the volume element for atom  $i$ . The physical origin of this term is that the probability of occurrence of each arrangement of molecules possible in the sample is given by a Boltzmann distribution in which the exponent is given by the potential energy corresponding to that arrangement.

#### Brief illustration 15D.5 A configuration integral

Equation 15D.11 is very difficult to manipulate in practice, even for quite simple intermolecular potentials, except for a perfect gas for which  $E_p = 0$ . In that case, the exponential function becomes 1 and

$$\mathcal{Z} = \frac{1}{N!} \int d\tau_1 d\tau_2 \cdots d\tau_N = \frac{1}{N!} \left(\int d\tau\right)^N = \frac{V^N}{N!}$$

just as it should be for a perfect gas.

**Self-test 15D.5** Go on to show that for a perfect gas,  $(\partial\langle E\rangle/\partial V)_T = 0$ .

Answer:  $\mathcal{Z}$  in this case is independent of temperature

If the potential has the form of a central hard sphere surrounded by a shallow attractive well (Fig. 15D.5), then detailed calculation, which is too involved to reproduce here, leads to

$$\left(\frac{\partial \langle E \rangle}{\partial V}\right)_T = \frac{an^2}{V^2} \quad \text{Attractive potential} \quad (15D.12)$$

**Figure 15D.5** The intermolecular potential energy of molecules in a real gas can be modelled by a central hard sphere of range  $b$  surrounded by a shallow attractive well with an area proportional to  $a$ . As discussed in the text, calculations based on this model yield results that are consistent with the van der Waals equation of state (Topic 1C).

where  $n$  is the amount of molecules present in the volume  $V$  and  $a$  is a constant that is proportional to the area under the attractive part of the potential. In *Example 3D.2* of Topic 3D we derive exactly the same expression (in the form  $\pi_T = an^2/V^2$ ) from the van der Waals equation of state. At this point we can conclude that if there are attractive interactions between

molecules in a gas, then its energy increases as it expands isothermally (because  $(\partial\langle E\rangle/\partial V)_T > 0$ , and the slope of  $\langle E\rangle$  with respect to  $V$  is positive). The energy rises because, at greater average separations, the molecules spend less time in regions where they interact favourably.

## Checklist of concepts

- 1. The **canonical ensemble** is an imaginary collection of replications of the actual system with a common temperature.
- 2. The **canonical distribution** gives the number of members of the ensemble with a specified total energy.
- 3. The mean energy of the members of the ensemble can be calculated from the **canonical partition function**.

## Checklist of equations

### ► Why do you need to know this material?

The importance of the molecular partition function is that it contains all the information needed to calculate the thermodynamic properties of a system of independent particles. In this respect, it plays a role in statistical thermodynamics very similar to that played by the wavefunction in quantum mechanics. The importance of this discussion is also the insight that a molecular interpretation provides into thermodynamic properties.

### ► What is the key idea?

The partition function contains all the thermodynamic information about a system and thus provides a bridge between spectroscopy and thermodynamics.

### ► What do you need to know already?

You need to know how to calculate a molecular partition function from structural data (Topic 15B); you should also

be familiar with the concepts of internal energy (Topic 2A) and entropy (Topic 3A). This Topic makes use of the calculations of mean molecular energies in Topic 15C.

In this Topic we see how to obtain any thermodynamic function once we know the partition function. The two fundamental properties of thermodynamics are the internal energy,  $U$ , and the entropy,  $S$ . Once these two properties have been calculated, it is possible to turn to the derived functions, such as the Gibbs energy,  $G$  (Topic 15F).

## 15E.1 The internal energy

We begin to unfold the importance of  $q$  by showing how to derive an expression for the internal energy of the system.

### (a) The calculation of internal energy

It is established in Topic 15C that the mean energy of a collection of independent molecules is related to the molecular partition function by

$$\langle \varepsilon \rangle = -\frac{1}{q} \left( \frac{\partial q}{\partial \beta} \right)_V \quad (15E.1)$$

with  $\beta = 1/kT$ . The total energy of a system composed of  $N$  molecules is therefore  $N\langle \varepsilon \rangle$  and so the internal energy,  $U(T) = U(0) + N\langle \varepsilon \rangle$  is related to the molecular partition function by

$$U(T) = U(0) + N\langle \varepsilon \rangle = U(0) - \frac{N}{q} \left( \frac{\partial q}{\partial \beta} \right)_V$$

*Independent molecules*   Internal energy   (15E.2a)

In many cases, the expression for  $\langle \varepsilon \rangle$  already established for each mode of motion in Topic 15C can be used and it is not necessary to go back to the expression for  $q$  except for some formal manipulations. An alternative form of this relation is

$$U(T) = U(0) - N \left( \frac{\partial \ln q}{\partial \beta} \right)_V$$

*Independent molecules*   Internal energy   (15E.2b)

A very similar expression is used for a system of interacting molecules. In that case we use the canonical partition function,  $Q$ , and write

$$U(T) = U(0) - \left( \frac{\partial \ln Q}{\partial \beta} \right)_V \quad \begin{array}{l} \text{Interacting} \\ \text{molecules} \end{array} \quad \begin{array}{l} \text{Internal} \\ \text{energy} \end{array} \quad (15E.2c)$$

### Brief illustration 15E.1 The internal energy of a collection of oscillators

It is established in Topic 15C (eqn 15C.8) that the mean energy of a collection of harmonic oscillators is  $\langle \varepsilon^V \rangle = hc\tilde{\nu} / (e^{\beta hc\tilde{\nu}} - 1)$ . It follows that the molar internal energy of such a collection is

$$U_m^V(T) = U_m^V(0) + \frac{N_A hc\tilde{\nu}}{e^{\beta hc\tilde{\nu}} - 1}$$

For  $I_2$  molecules at 298.15 K we note from Table 12D.1 that their vibrational wavenumber is  $214.6 \text{ cm}^{-1}$ . Then, because at 298.15 K,  $kT/hc = 207.224 \text{ cm}^{-1}$ ,  $hc\tilde{\nu} = 4.26 \text{ zJ}$ , and

$$\beta hc\tilde{\nu} = \frac{hc\tilde{\nu}}{kT} = \frac{214.6 \text{ cm}^{-1}}{207.224 \text{ cm}^{-1}} = 1.035 \dots$$

Then it follows that the vibrational contribution to the molar internal energy is

$$\begin{aligned} U_m^V(T) &= U_m^V(0) + \frac{(6.022 \times 10^{23} \text{ mol}^{-1}) \times (4.26 \times 10^{-21} \text{ J})}{e^{1.035 \dots} - 1} \\ &= U_m^V(0) + 1.41 \text{ kJ mol}^{-1} \end{aligned}$$

**Self-test 15E.1** What is the molar internal energy of a gas of linear molecules?

$$\text{Answer: } U_m(T) = U_m(0) + \frac{5}{2} RT$$

## (b) Heat capacity

The constant-volume heat capacity (Topic 2A) is defined as  $C_V = (\partial U / \partial T)_V$ . Thus, because the mean vibrational energy of a collection of harmonic oscillators (eqn 15C.8,  $\langle \varepsilon^V \rangle = hc\tilde{\nu} / (e^{\beta hc\tilde{\nu}} - 1)$ ) can be written in terms of the vibrational temperature  $\theta^V = hc\tilde{\nu} / k$  as

$$\langle \varepsilon^V \rangle = \frac{k\theta^V}{e^{\theta^V/T} - 1}$$

it follows that the vibrational contribution to the molar constant-volume heat capacity is

$$C_{V,m}^V = \frac{dN_A \langle \varepsilon^V \rangle}{dT} = R\theta^V \frac{d}{dT} \frac{1}{e^{\theta^V/T} - 1} = R \left( \frac{\theta^V}{T} \right)^2 \frac{e^{\theta^V/T}}{(e^{\theta^V/T} - 1)^2}$$

**Figure 15E.1** The temperature dependence of the vibrational heat capacity of a molecule in the harmonic approximation calculated by using eqn 15E.3. Note that the heat capacity is within 10 per cent of its classical value for temperatures greater than  $\theta^V$ .

This expression can be rearranged into

$$C_{V,m}^V = Rf(T) \quad f(T) = \left( \frac{\theta^V}{T} \right)^2 \left( \frac{e^{-\theta^V/2T}}{1 - e^{-\theta^V/T}} \right)^2$$

Vibrational contribution to  $C_V$  (15E.3)

The curve in Fig. 15E.1 shows how the vibrational heat capacity depends on temperature. Note that even when the temperature is only slightly above  $\theta^V$  the heat capacity is close to its equipartition value. Equation 15E.3 is essentially the same as the Einstein formula for the heat capacity of a solid (eqn 7A.9) with  $\theta^V$  the Einstein temperature,  $\theta_E$ . The only difference is that vibrations can take place in three dimensions in a solid.

It is sometimes more convenient to convert the derivative with respect to  $T$  into a derivative with respect to  $\beta$  by using

$$\frac{d}{dT} = \frac{d\beta}{dT} \frac{d}{d\beta} = -\frac{1}{kT^2} \frac{d}{d\beta} = -k\beta^2 \frac{d}{d\beta} \quad (15E.4)$$

It follows that

$$C_V = -k\beta^2 \left( \frac{\partial U}{\partial \beta} \right)_V = -Nk\beta^2 \left( \frac{\partial \langle \varepsilon \rangle}{\partial \beta} \right)_V \stackrel{\text{eqn 15E.1}}{=} Nk\beta^2 \left( \frac{\partial^2 \ln q}{\partial \beta^2} \right)_V$$

Heat capacity (15E.5)

When equipartition is valid, which is the case when  $T \gg \theta^M$ , with the characteristic temperature of the mode  $M$  ( $\theta^V = hc\tilde{\nu} / k$  for vibration,  $\theta^R = hc\tilde{B} / k$  for rotation), there is a much simpler route. We can then estimate the heat capacity by counting the numbers of modes that are active. In gases, all three translational modes are always active and contribute  $\frac{3}{2}R$  to the molar heat capacity. If we denote the number of active rotational modes by  $\nu^{R*}$  (so for most molecules at normal temperatures  $\nu^{R*} = 2$  for linear molecules, and 3 for nonlinear molecules),

then the rotational contribution is  $\frac{1}{2}\nu^{R^*}R$ . If the temperature is high enough for  $\nu^{V^*}$  vibrational modes to be active, then the vibrational contribution to the molar heat capacity is  $\nu^{V^*}R$ . In most cases  $\nu^{V^*} \approx 0$ . It follows that the total molar heat capacity of a gas is approximately

$$C_{V,m} = \frac{1}{2}(2 + \nu^{R^*} + 2\nu^{V^*})R \quad T \gg \theta^M \quad \text{Total heat capacity} \quad (15E.6)$$

### Brief illustration 15E.2 The constant-volume heat capacity

The characteristic temperatures (in round numbers) of the vibrations of  $\text{H}_2\text{O}$  are 5300 K, 2300 K, and 5400 K; the vibrations are therefore not excited at 373 K. The three rotational modes of  $\text{H}_2\text{O}$  have characteristic temperatures 40 K, 21 K, and 13 K, so they are fully excited, like the three translational modes. The translational contribution is  $\frac{3}{2}R = 12.5 \text{ J K}^{-1} \text{ mol}^{-1}$ . Fully excited rotations contribute a further  $12.5 \text{ J K}^{-1} \text{ mol}^{-1}$ . Therefore, a value close to  $25 \text{ J K}^{-1} \text{ mol}^{-1}$  is predicted. The experimental value is  $26.1 \text{ J K}^{-1} \text{ mol}^{-1}$ . The discrepancy is probably due to deviations from perfect gas behaviour.

**Self-test 15E.2** Estimate the molar constant-volume heat capacity of gaseous  $\text{I}_2$  at  $25^\circ\text{C}$  ( $\tilde{B} = 0.037 \text{ cm}^{-1}$ ; see Table 12D.1 for more data).

Answer:  $29 \text{ J K}^{-1} \text{ mol}^{-1}$

## 15E.2 The entropy

One of the most celebrated equations in statistical thermodynamics is the **Boltzmann formula** for the entropy:

$$S = k \ln \mathcal{W} \quad \text{Boltzmann formula for the entropy} \quad (15E.7)$$

In this expression, which is derived in the following *Justification*,  $\mathcal{W}$  is the weight of the most probable configuration of the system (as discussed in Topic 15A).

### Justification 15E.1 The Boltzmann formula

The internal energy  $U(T) = U(0) + N\langle \varepsilon \rangle$ , with  $\langle \varepsilon \rangle = (1/N) \sum_i N_i \varepsilon_i$  can be written

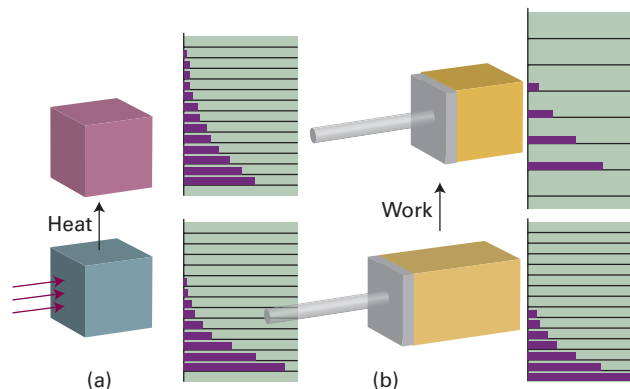

$$U(T) = U(0) + \sum_i N_i \varepsilon_i$$

A change in  $U(T)$  may arise from either a modification of the energy levels of a system (when  $\varepsilon_i$  changes to  $\varepsilon_i + d\varepsilon_i$ ) or from a modification of the populations (when  $N_i$  changes to  $N_i + dN_i$ ). The most general change is therefore

$$dU(T) = dU(0) + \sum_i N_i d\varepsilon_i + \sum_i \varepsilon_i dN_i$$

Because the energy levels do not change when a system is heated at constant volume (Fig. 15E.2), in the absence of all changes other than heating, only the third (blue) term on the right survives. We know from thermodynamics, specifically eqn 3D.1 ( $dU = TdS - pdV$ ), that under the same conditions  $dU = TdS$ . Therefore,

$$dS = \frac{dU}{T} = \frac{1}{T} \sum_i \varepsilon_i dN_i = k\beta \sum_i \varepsilon_i dN_i$$

**Figure 15E.2** (a) When a system is heated, the energy levels are unchanged but their populations are changed. (b) When work is done on a system, the energy levels themselves are changed. The levels in this case are the one-dimensional particle-in-a-box energy levels of Topic 8A: they depend on the size of the container and move apart as its length is decreased.

For changes in the most probable configuration (the only one we need consider), we know from eqn 15A.10 ( $\partial(\ln \mathcal{W})/\partial N_i + \alpha - \beta \varepsilon_i = 0$ ) that  $\beta \varepsilon_i = \partial(\ln \mathcal{W})/\partial N_i + \alpha$ ; therefore

$$dS = k \sum_i \left( \overbrace{\left( \frac{\partial \ln \mathcal{W}}{\partial N_i} \right)}^{d \ln \mathcal{W}} \right) dN_i + k\alpha \sum_i \overbrace{dN_i}^0 = k(d \ln \mathcal{W})$$

This relation strongly suggests the definition  $S = k \ln \mathcal{W}$ , as in eqn 15E.7.

### (a) Entropy and the partition function

The statistical entropy behaves in exactly the same way as the thermodynamic entropy. Thus, as the temperature is lowered, the value of  $\mathcal{W}$ , and hence of  $S$ , decreases because fewer configurations are consistent with the total energy. In the limit  $T \rightarrow 0$ ,  $\mathcal{W} = 1$ , so  $\ln \mathcal{W} = 0$ , because only one configuration (every molecule in the lowest level) is compatible with  $E = 0$ . It follows

that  $S \rightarrow 0$  as  $T \rightarrow 0$ , which is compatible with the Third Law of thermodynamics, that the entropies of all perfect crystals approach the same value as  $T \rightarrow 0$  (Topic 3B).

Now we relate the Boltzmann formula for the entropy to the partition function. As shown in the following *Justification*, the relation for a system of non-interacting *distinguishable* molecules is

$$S(T) = \frac{U(T) - U(0)}{T} + Nk \ln q \quad \text{Independent, distinguishable molecules} \quad \text{Entropy} \quad (15E.8a)$$

For indistinguishable molecules (like those in a gas of identical molecules)

$$S(T) = \frac{U(T) - U(0)}{T} + Nk \ln \frac{q}{N} \quad \text{Independent, indistinguishable molecules} \quad \text{Entropy} \quad (15E.8b)$$

The corresponding expression for interacting molecules is based on the canonical partition function, and is

$$S(T) = \frac{U(T) - U(0)}{T} + k \ln Q \quad \text{Interacting molecules} \quad \text{Entropy} \quad (15E.8c)$$

### Justification 15E.2 The statistical entropy

For a system composed of  $N$  distinguishable molecules, eqn 15A.3 ( $\ln \mathcal{W} = N \ln N - \sum_i N_i \ln N_i$ ) with  $N = \sum_i N_i$  is

$$\begin{aligned} \ln \mathcal{W} &= \sum_i N_i \ln N - \sum_i N_i \ln N_i \\ &= \sum_i N_i (\ln N - \ln N_i) = - \sum_i N_i \ln \frac{N_i}{N} \end{aligned}$$

Equation 15E.7 ( $S = k \ln \mathcal{W}$ ) then becomes

$$S = -k \sum_i N_i \ln \frac{N_i}{N}$$

The value of  $N_i/N$  for the most probable distribution is given by the Boltzmann distribution,  $N_i/N = e^{-\beta \epsilon_i} / q$ , and so

$$\ln \frac{N_i}{N} = \ln e^{-\beta \epsilon_i} - \ln q = -\beta \epsilon_i - \ln q$$

Therefore,

$$S = k\beta \overbrace{\sum_i N_i \epsilon_i}^{N\langle \epsilon \rangle} + k \sum_i N_i \ln q = Nk\beta \langle \epsilon \rangle + Nk \ln q$$

Finally, because  $N\langle \epsilon \rangle = U - U(0)$  and  $\beta = 1/kT$ , we obtain eqn 15E.8a.

To treat a system composed of  $N$  indistinguishable molecules, we need to reduce the weight  $\mathcal{W}$  by a factor of  $1/N!$  because the  $N!$  permutations of the molecules among the states result in the same state of the system. Then, because

$\ln(\mathcal{W}/N!) = \ln \mathcal{W} - \ln N!$ , the equation in the first line of this *Justification* becomes

$$\begin{aligned} \ln \mathcal{W} &= N \ln N - \sum_i N_i \ln N_i - \overbrace{\ln N!}^{N \ln N - N} \\ &= \sum_i N_i \ln N - \sum_i N_i \ln N_i - \overbrace{N \ln N + N}^{\sum_i N_i} \\ &= - \sum_i N_i \ln N_i + N \end{aligned}$$

where we have used Stirling's approximation to write  $\ln N! = N \ln N - N$ . As before, we replace  $N_i$  by the Boltzmann value,  $N_i = Ne^{-\beta \epsilon_i} / q$ :

$$\begin{aligned} \sum_i N_i \ln N_i &= \sum_i N_i (\ln N - \beta \epsilon_i - \ln q) \\ &= N \ln N - N\beta \langle \epsilon \rangle - N \ln q = -N\beta \langle \epsilon \rangle - N \ln \frac{q}{N} \end{aligned}$$

The entropy in this case is therefore

$$S = Nk\beta \langle \epsilon \rangle + Nk \ln \frac{q}{N} + Nk$$

Now note that  $Nk$  can be written  $Nk \ln e$  and  $Nk \ln q/N + Nk \ln e = Nk \ln qe/N$ , which gives eqn 15E.8b.

Equation 15E.8a expresses the entropy of a collection of independent molecules in terms of the internal energy and the molecular partition function. However, it is shown in Topic 15C that, to a good approximation, the energy of a molecule is a sum of independent contributions, such as translational (T), rotational (R), vibrational (V), and electronic (E), and therefore the partition function factorizes into a product of contributions. As a result, the entropy is also the sum of the individual contributions. For independent, distinguishable particles, each contribution is of the form of eqn 15E.8a, and for a mode M we write

$$S_M = \frac{\{U - U(0)\}^M}{T} + Nk \ln q^M \quad \text{Independent, distinguishable particles, } M \neq T \quad \text{Entropy due to mode M} \quad (15E.9)$$

This expression applies to  $M = R, V,$  and  $E$ ; the analogous version of eqn 15E.8b should be used for  $M = T$ , for the molecules are then indistinguishable.

### Brief illustration 15E.3 The entropy of a two-level system

From Topics 15B and 15C, the partition function and mean energy are  $q = 1 + e^{-\beta \epsilon}$  and  $\langle \epsilon^S \rangle = \epsilon / (e^{\beta \epsilon} + 1)$ . The contribution to the molar entropy, with  $1/T = k\beta$ , is therefore

$$S_m = R \left\{ \frac{\beta \epsilon}{1 + e^{\beta \epsilon}} + \ln(1 + e^{-\beta \epsilon}) \right\}$$

**Figure 15E.3** The temperature variation of the molar entropy of a collection of two-level systems expressed as a multiple of  $R=Nk$ . As  $T \rightarrow \infty$  the two states become equally populated and  $S_m$  approaches  $R \ln 2$ .

This awkward function is plotted in Fig. 15E.3. It should be noted that as  $T \rightarrow \infty$  (corresponding to  $\beta \rightarrow 0$ ), the molar entropy approaches  $R \ln 2$ .

**Self-test 15E.3** Derive an expression for the molar entropy of an equally spaced three-level system.

$$\text{Answer: } S_m/R = \beta\epsilon / (1 + e^{-\beta\epsilon} + e^{-2\beta\epsilon}) + \ln(1 + e^{-\beta\epsilon} + e^{-2\beta\epsilon})$$

## (b) The translational contribution

The expressions we have derived for the entropy accord with what we should expect for entropy if it is a measure of the spread of the populations of molecules over the available states. For instance, we show in the following *Justification* that the **Sackur–Tetrode equation** for the molar entropy of a monatomic perfect gas, where the only motion is translation in three dimensions, is

$$S_m = R \ln \left( \frac{V_m e^{5/2}}{N_A \Lambda^3} \right) \quad \text{Monatomic perfect gas} \quad \text{Sackur–Tetrode equation} \quad (15E.10a)$$

where  $\Lambda$  is the thermal wavelength ( $\Lambda = h/(2\pi mkT)^{1/2}$ ). To calculate the standard molar entropy, we note that  $V_m = RT/p$ , and set  $p = p^\ominus$ :

$$S_m^\ominus = R \ln \left( \frac{RT e^{5/2}}{p^\ominus N_A \Lambda^3} \right) = R \ln \left( \frac{kT e^{5/2}}{p^\ominus \Lambda^3} \right) \quad (15E.10b)$$

We have used  $R/N_A = k$ . These expressions are based on the high-temperature approximation of the partition functions, which assumes that many levels are occupied; therefore, they do not apply when  $T$  is equal to or very close to zero.

### Brief illustration 15E.4 The molar entropy of a gas

To calculate the standard molar entropy of gaseous argon at 25 °C, we use eqn 15E.10b with  $\Lambda = h/(2\pi mkT)^{1/2}$ . The mass of an Ar atom is  $m = 39.95m_u$ . At 25 °C, its thermal wavelength is 16.0 pm and  $kT = 4.12 \times 10^{-21}$  J. Therefore,

$$\begin{aligned} S_m^\ominus &= R \ln \left\{ \frac{(4.12 \times 10^{-21} \text{ J}) \times e^{5/2}}{(10^5 \text{ N m}^{-2}) \times (1.60 \times 10^{-11} \text{ m})^3} \right\} \\ &= 18.6R = 155 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

We can anticipate, on the basis of the number of accessible states for a lighter molecule, that the standard molar entropy of Ne is likely to be smaller than for Ar; its actual value is  $17.60R$  at 298 K.

**Self-test 15E.4** Calculate the translational contribution to the standard molar entropy of  $\text{H}_2$  at 25 °C.

Answer:  $14.2R$

The physical interpretation of these equations is as follows:

- Because the molecular mass appears in the numerator (because it appears in the denominator of  $\Lambda$ ), the molar entropy of a perfect gas of heavy molecules is greater than that of a perfect gas of light molecules under the same conditions. We can understand this feature in terms of the energy levels of a particle in a box being closer together for heavy particles than for light particles, so more states are thermally accessible.
- Because the molar volume appears in the numerator, the molar entropy increases with the molar volume of the gas. The reason is similar: large containers have more closely spaced energy levels than small containers, so once again more states are thermally accessible.
- Because the temperature appears in the numerator (because, like  $m$ , it appears in the denominator of  $\Lambda$ ), the molar entropy increases with increasing temperature. The reason for this behaviour is that more energy levels become accessible as the temperature is raised.

Physical interpretation

### Justification 15E.3 The Sackur–Tetrode equation

We start with eqn 15E.8b for a collection of independent, indistinguishable particles and write  $N = nN_A$ , where  $N_A$  is Avogadro's constant. The only mode of motion for a gas of atoms is translation and  $U - U(0) = \frac{3}{2}nRT$ . The partition

function is  $q = V/\Lambda^3$  (eqn 15B.7a), where  $\Lambda$  is the thermal wavelength. Therefore,

$$S = \frac{\overbrace{U - U(0)}^{\frac{3}{2}nRT}}{T} + Nk \ln \frac{q^N}{N} = \frac{3}{2}nR + Nk \ln \frac{V e}{n N_A \Lambda^3}$$

$$= nR \left\{ \frac{\ln e^{3/2}}{\frac{3}{2}} + \ln \frac{V_m e}{N_A \Lambda^3} \right\} = nR \ln \frac{V_m e^{5/2}}{N_A \Lambda^3}$$

where  $V_m = V/n$  is the molar volume of the gas and we have used  $\frac{3}{2} = \ln e^{\frac{3}{2}}$ . Division of both sides by  $n$  then results in eqn 15E.10a.

The Sackur–Tetrode equation written in the form

$$S = nR \ln \frac{V e^{5/2}}{n N_A \Lambda^3} = nR \ln aV, \quad a = \frac{e^{5/2}}{n N_A \Lambda^3}$$

implies that when a monatomic perfect gas expands isothermally from  $V_i$  to  $V_f$ , its entropy changes by

$$\Delta S = nR \ln aV_f - nR \ln aV_i$$

$$= nR \ln \frac{V_f}{V_i} \quad \text{Perfect gas, isothermal} \quad \text{Change of entropy on expansion} \quad (15E.11)$$

This expression is the same as that obtained starting from the thermodynamic definition of entropy (Topic 3A).

### (c) The rotational contribution

The rotational contribution to the molar entropy,  $S_m^R$ , can be calculated once we know the molecular partition function. For a linear molecule, the high-temperature limit of  $q$  is  $kT/\sigma hc\tilde{B}$  (eqn 15B.13b,  $q^R = T/\sigma\theta^R$  with  $\theta^R = hc\tilde{B}/k$ ) and the equipartition theorem gives the rotational contribution to the molar internal energy as  $RT$ ; therefore, from eqn 15E.8a:

$$S_m^R = \frac{\overbrace{U_m - U_m(0)}^{RT}}{T} + R \ln \overbrace{q^R}^{kT/\sigma hc\tilde{B}}$$

and the contribution at high temperatures is

$$S_m^R = R \left\{ 1 + \ln \frac{kT}{\sigma hc\tilde{B}} \right\} \quad \text{Linear molecule, high temperature } (T \gg \theta^R) \quad \text{Rotational contribution} \quad (15E.12a)$$

In terms of this rotational temperature,

$$S_m^R = R \left\{ 1 + \ln \frac{T}{\sigma\theta^R} \right\} \quad \text{Linear molecule, high temperature } (T \gg \theta^R) \quad \text{Rotational contribution} \quad (15E.12b)$$

This function is plotted in Fig. 15E.4. We see that:

- The rotational contribution to the entropy increases with temperature because more rotational states become accessible.
- The rotational contribution is large when  $\tilde{B}$  is small, because then the rotational energy levels are close together.

Physical interpretation

Thus, large, heavy molecules have a large rotational contribution to their entropy. As we show in the following *Brief illustration*, the rotational contribution to the molar entropy of  $^{35}\text{Cl}_2$  is  $58.6 \text{ J K}^{-1} \text{ mol}^{-1}$  whereas that for  $\text{H}_2$  is only  $12.7 \text{ J K}^{-1} \text{ mol}^{-1}$ . We can regard  $\text{Cl}_2$  as a more rotationally disordered gas than  $\text{H}_2$ , in the sense that at a given temperature  $\text{Cl}_2$  occupies a greater number of rotational states than  $\text{H}_2$  does.

Figure 15E.4 The variation of the rotational contribution to the entropy of a linear molecule ( $\sigma = 1$ ) using the high-temperature approximation and the exact expression (the latter evaluated up to  $J = 20$ ).

#### Brief illustration 15E.5 The rotational contribution to the entropy

The rotational contribution for  $^{35}\text{Cl}_2$  at  $25^\circ\text{C}$ , for instance, is calculated by noting that  $\sigma = 2$  for this homonuclear diatomic molecule and taking  $\tilde{B} = 0.2441 \text{ cm}^{-1}$  (corresponding to  $24.42 \text{ m}^{-1}$ ). The rotational temperature of the molecule is

$$\theta^R = \frac{(6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1}) \times (24.42 \text{ m}^{-1})}{1.381 \times 10^{-23} \text{ J K}^{-1}}$$

$$= 0.351 \text{ K}$$

Therefore,

$$S_m^R = R \left\{ 1 + \ln \frac{298 \text{ K}}{2 \times (0.351 \text{ K})} \right\} = 7.05R = 58.6 \text{ J K}^{-1} \text{ mol}^{-1}$$

**Self-test 15E.5** Calculate the rotational contribution to the molar entropy of  $\text{H}_2$ .

Answer:  $12.7 \text{ J K}^{-1} \text{ mol}^{-1}$

Equation 15E.12 is valid at high temperatures ( $T \gg \theta^R$ ); to track the rotational contribution down to low temperatures it would be necessary to use the full form of the rotational partition function (Topic 15B; see Problem 15E.10); the resulting curve has the form shown in Fig. 15E.4. We see, in fact, that the approximate curve matches the exact curve very well for  $T/\theta^R$  greater than about 1.

#### (d) The vibrational contribution

The vibrational contribution to the molar entropy,  $S_m^V$ , is obtained by combining the expression for the molecular partition function (eqn 15B.15,  $q^V = 1/(1 - e^{-\beta\epsilon})$ ) with the expression for the mean energy (eqn 15C.8,  $\langle \epsilon^V \rangle = \epsilon/(e^{\beta\epsilon} - 1)$ ), to obtain

$$S_m^V = \frac{\overbrace{U_m - U_m(0)}^{N_A \langle \epsilon^V \rangle}}{\underbrace{T}_{1/k\beta}} + R \ln q^V = \frac{\overbrace{N_A k \beta \epsilon}^R}{e^{\beta\epsilon} - 1} + R \ln \frac{1}{1 - e^{-\beta\epsilon}}$$

$$= R \left\{ \frac{\beta\epsilon}{e^{\beta\epsilon} - 1} - \ln(1 - e^{-\beta\epsilon}) \right\}$$

Now we recognize that  $\epsilon = hc\tilde{\nu}$  and obtain

$$S_m^V = R \left\{ \frac{\beta hc\tilde{\nu}}{e^{\beta hc\tilde{\nu}} - 1} - \ln(1 - e^{-\beta hc\tilde{\nu}}) \right\} \quad \text{Vibrational contribution to the entropy} \quad (15E.13a)$$

Once again it is convenient to express this formula in terms of a characteristic temperature, in this case the vibrational temperature  $\theta^V = hc\tilde{\nu}/k$ :

$$S_m^V = R \left\{ \frac{\theta^V/T}{e^{\theta^V/T} - 1} - \ln(1 - e^{-\theta^V/T}) \right\} \quad \text{Vibrational contribution to the entropy} \quad (15E.13b)$$

This function is plotted in Fig. 15E.5. As usual, it is helpful to interpret it, with the graph in mind:

- Both terms multiplying  $R$  become zero as  $T \rightarrow 0$ , so the entropy is zero at  $T=0$ .
- The molar entropy rises as the temperature is increased as more vibrational states become accessible.
- The molar entropy is higher at a given temperature for molecules with heavy atoms or low force constant than one with light atoms or high force constant. The vibrational energy levels are closer together in the former case than in the latter, so more are thermally accessible

Physical interpretation

#### Brief illustration 15E.6 The vibrational contribution to the entropy

The vibrational wavenumber of  $I_2$  is  $214.5 \text{ cm}^{-1}$ , corresponding to  $2.145 \times 10^4 \text{ m}^{-1}$ , so its vibrational temperature is 309 K. Therefore, at 25 °C, for instance,  $\beta\epsilon = 1.036$ , so

$$S_m^V = R \left\{ \frac{309/298}{e^{309/298} - 1} - \ln(1 - e^{-309/298}) \right\} = 1.01R = 8.38 \text{ J K}^{-1} \text{ mol}^{-1}$$

**Self-test 15E.6** Calculate the vibrational contribution to the molar entropy of  $^1\text{H}_2$  at 25 °C ( $\theta^V = 6332 \text{ K}$ ).

Answer:  $0.11 \mu\text{J K}^{-1}$

**Figure 15E.5** The temperature variation of the molar entropy of a collection of harmonic oscillators expressed as a multiple of  $R=Nk$ . The molar entropy approaches zero as  $T \rightarrow 0$ , and increases without limit as  $T \rightarrow \infty$ .

#### (e) Residual entropies

Entropies may be calculated from spectroscopic data; they may also be measured experimentally (Topic 3B). In many cases there is good agreement, but in some the experimental entropy is less than the calculated value. One possibility is that the experimental determination failed to take a phase transition into account and a contribution of the form  $\Delta_{\text{trs}}H/T_{\text{trs}}$  was incorrectly omitted from the sum. Another possibility is that some disorder is present in the solid even at  $T=0$ . The entropy at  $T=0$  is then greater than zero and is called the **residual entropy**.

The origin and magnitude of the residual entropy can be explained by considering a crystal composed of AB molecules, where A and B are similar atoms (such as CO, with its very small electric dipole moment). There may be so little energy difference between ... AB AB AB AB ..., ... AB BA BA AB ..., and other arrangements that the molecules adopt the orientations AB and BA at random in the solid. We can readily calculate the entropy arising from residual disorder by using the Boltzmann formula  $S = k \ln \mathcal{W}$ . To do so, we suppose that two orientations are equally probable, and that the sample consists of  $N$  molecules. Because the same energy can be achieved in  $2^N$  different ways (because each molecule can take either of two orientations), the total number of ways of achieving the same energy is  $\mathcal{W} = 2^N$ . It follows that

$$S = k \ln 2^N = Nk \ln 2 = nR \ln 2 \quad (15E.14a)$$

We can therefore expect a residual molar entropy of  $R \ln 2 = 5.8 \text{ J K}^{-1} \text{ mol}^{-1}$  for solids composed of molecules that can adopt either of two orientations at  $T=0$ . If  $s$  orientations are possible, the residual molar entropy will be

$$S_m(0) = R \ln s \quad \text{Residual entropy} \quad (15E.14b)$$

For CO, the measured residual entropy is  $5 \text{ J K}^{-1} \text{ mol}^{-1}$ , which is close to  $R \ln 2$ , the value expected for a random structure of the form ... CO CO OC CO OC OC ....

### Brief illustration 15E.7 Residual entropy

Consider a sample of ice with  $N \text{ H}_2\text{O}$  molecules. Each O atom is surrounded tetrahedrally by four H atoms, two of which are attached by short  $\sigma$  bonds, the other two being attached by long hydrogen bonds (Fig. 15E.6). It follows that each of the  $2N$  H atoms can be in one of two positions (either close to or far from an O atom as shown in Fig. 15E.6), resulting in  $2^{2N}$  possible arrangements.

**Figure 15E.6** The possible locations of H atoms around a central O atom in an ice crystal are shown by the white spheres. Only one of the locations on each bond may be occupied by an atom, and two H atoms must be close to the O atom and two H atoms must be distant from it.

**Figure 15E.7** The six possible arrangements of H atoms in the locations identified in Fig. 15E.6. Occupied locations are denoted by grey spheres and unoccupied locations by white spheres.

However, not all these arrangements are acceptable. Indeed, of the  $2^4 = 16$  ways of arranging four H atoms around one O atom, only 6 have two short and two long OH distances and hence are acceptable (Fig. 15E.7). Therefore, the number of permitted arrangements is  $\mathcal{W} = 2^{2N} (6/16)^N = (\frac{3}{2})^N$ . It then follows that the residual entropy is  $S(0) \approx k \ln (\frac{3}{2})^N = kN \ln \frac{3}{2}$ , and its molar value is  $S(0) \approx R \ln \frac{3}{2} = 3.4 \text{ J K}^{-1} \text{ mol}^{-1}$ , which is in good agreement with the experimental value of  $3.4 \text{ J K}^{-1} \text{ mol}^{-1}$ . The model, however, is not exact because it ignores the possibility that next-nearest neighbours and those beyond can influence the local arrangement of bonds.

**Self-test 15E.7** Estimate the molar residual entropy of  $\text{FCIO}_3$ ; each molecule can adopt four orientations with about the same energy.

Answer:  $R \ln 4 = 11.5 \text{ J K}^{-1} \text{ mol}^{-1}$ ; experimental:  $10.1 \text{ J K}^{-1} \text{ mol}^{-1}$

## Checklist of concepts

1. The **internal energy** is proportional to the derivative of the partition function with respect to temperature.
2. The **constant-volume heat capacity** can be calculated from the molecular partition function.
3. The **total heat capacity** of a molecular substance is the sum of the contribution of each mode.
4. The **statistical entropy** is defined by the **Boltzmann formula** and may be expressed in terms of the molecular partition function
5. The **residual entropy** is a nonzero entropy at  $T=0$  arising from molecular disorder.

## Checklist of equations

### ► Why do you need to know this material?

The power of chemical thermodynamics stems from its deployment of a variety of derived functions, particularly the enthalpy and Gibbs energy. It is therefore important to relate these to structural features through partition functions. One hugely important quantity that is illuminated in this way is the equilibrium constant.

### ► What is the key idea?

The partition function provides a link between spectroscopic and structural data and the derived functions of thermodynamics, particularly the equilibrium constant.

### ► What do you need to know already?

This Topic develops the discussion of internal energy and entropy (Topic 15E). You need to know the relations between those properties and the enthalpy (Topic 2B) and the Helmholtz and Gibbs energies (Topic 3C). The final section makes use of the relation between standard Gibbs energy and the equilibrium constant (Topic 6A).

Classical thermodynamics makes extensive use of various derived functions. Thus, in thermochemistry it focuses on the enthalpy and, provided the pressure and temperature are constant, in discussions of spontaneity it focuses on the Gibbs energy. In this Topic we see how these properties can be related to and understood in terms of partition functions. All these properties are derived from the internal energy and the

entropy, which in terms of the canonical partition function are given by

$$U(T) = U(0) - \left( \frac{\partial \ln Q}{\partial \beta} \right)_V \quad \text{Internal energy} \quad (15F.1a)$$

$$S(T) = \frac{U(T) - U(0)}{T} + k \ln Q \quad \text{Entropy} \quad (15F.1b)$$

These two general expressions can be adapted for collections of independent molecules by writing  $Q = q^N$  for distinguishable molecules and  $Q = q^N/N!$  for indistinguishable molecules (as in a gas).

## 15F.1 The derivations

The Helmholtz energy,  $A$ , is defined as  $A = U - TS$ . This relation implies that  $A(0) = U(0)$ , so substitution of the expressions for  $U(T)$  and  $S(T)$  leads to the very simple expression

$$A(T) = A(0) - kT \ln Q \quad \text{Helmholtz energy} \quad (15F.2)$$

An infinitesimal change in conditions changes the Helmholtz energy by  $dA = -pdV - SdT$  (this is the analogue of the expression for  $dG$  derived in Topic 3D (eqn 3D.7,  $dG = Vdp - SdT$ ). Therefore, it follows that on imposing constant temperature ( $dT=0$ ), the pressure and the Helmholtz energy are related by  $p = -(\partial A / \partial V)_T$ . It then follows from eqn 15F.2 that

$$p = kT \left( \frac{\partial \ln Q}{\partial V} \right)_T \quad \text{Pressure} \quad (15F.3)$$

This relation is entirely general, and may be used for any type of substance, including perfect gases, real gases, and liquids. Because  $Q$  is in general a function of the volume, temperature, and amount of substance, eqn 15F.3 is an equation of state of the kind discussed in Topic 1C.

### Example 15F.1 Deriving an equation of state

Derive an expression for the pressure of a gas of independent particles.

**Method** We should suspect that the pressure is that given by the perfect gas law. To proceed systematically, substitute the

explicit formula for  $Q$  for a gas of independent, indistinguishable molecules.

**Answer** For a gas of independent molecules,  $Q = q^N/N!$  with  $q = V/\Lambda^3$ :

$$\begin{aligned} p &= kT \left( \frac{\partial \ln Q}{\partial V} \right)_T = \frac{kT}{Q} \left( \frac{\partial Q}{\partial V} \right)_T = \frac{N! kT}{q^N} \left( \frac{\partial (q^N/N!)}{\partial V} \right)_T \\ &= \frac{kT}{q^N} \left( \frac{\partial q^N}{\partial V} \right)_T = \frac{NkT}{q} \left( \frac{\partial q}{\partial V} \right)_T \\ &= \frac{NkT}{V/\Lambda^3} \left( \frac{\partial (V/\Lambda^3)}{\partial V} \right)_T = \frac{NkT}{V} = \frac{nN_A kT}{V} = \frac{nRT}{V} \end{aligned}$$

The calculation shows that the equation of state of a gas of independent particles is indeed the perfect gas law,  $pV = nRT$ .

**Self-test 15F.1** Derive the equation of state of a sample for which  $Q = q^N f/N!$ , with  $q = V/\Lambda^3$ , where  $f$  depends on the volume.

$$\text{Answer: } p = nRT/V + kT(\partial \ln f / \partial V)_T$$

At this stage we can use the expressions for  $U$  and  $p$  in the definition  $H = U + pV$  to obtain an expression for the enthalpy,  $H$ , of any substance:

$$H(T) = H(0) - \left( \frac{\partial \ln Q}{\partial \beta} \right)_V + kTV \left( \frac{\partial \ln Q}{\partial V} \right)_T \quad \text{Enthalpy} \quad (15F.4)$$

The fact that eqn 15F.4 is rather cumbersome is a sign that the enthalpy is not a fundamental property: as shown in Topic 2B, it is more of an accounting convenience. For a gas of independent particles  $U - U(0) = \frac{3}{2}nRT$  and  $pV = nRT$ . Therefore, for such a gas,

$$H - H(0) = \frac{5}{2}nRT \quad (15F.5)$$

One of the most important thermodynamic functions for chemistry is the Gibbs energy,  $G = H - TS = A + pV$ . We can now express this function in terms of the partition function by combining the expressions for  $A$  and  $p$ :

$$G(T) = G(0) - kT \ln Q + kTV \left( \frac{\partial \ln Q}{\partial V} \right)_T \quad \text{Gibbs energy} \quad (15F.6)$$

This expression takes a simple form for a gas of independent molecules because  $pV$  in the expression  $G = A + pV$  can be replaced by  $nRT$ :

$$G(T) = G(0) - kT \ln Q + nRT \quad (15F.7)$$

Furthermore, because  $Q = q^N/N!$ , and therefore  $\ln Q = N \ln q - \ln N!$ , it follows by using Stirling's approximation ( $\ln N! = N \ln N - N$ ) that we can write

$$\begin{aligned} G(T) &= G(0) - NkT \ln q + kT \ln N! + nRT \quad (15F.8) \\ &= G(0) - nRT \ln q + kT(N \ln N - N) + nRT \\ &= G(0) - nRT \ln \frac{q}{N} \end{aligned}$$

with  $N = nN_A$ . Now we see another interpretation of the Gibbs energy: because  $q$  is the number of thermally accessible states and  $N$  is the number of molecules, the difference  $G(T) - G(0)$  is proportional to the logarithm of the average number of thermally accessible states per molecule.

It will turn out to be convenient to define the **molar partition function**,  $q_m = q/n$  (with units  $\text{mol}^{-1}$ ), for then

$$G(T) = G(0) - nRT \ln \frac{q_m}{N_A} \quad \text{Independent molecules} \quad \text{Gibbs energy} \quad (15F.9)$$

To use this expression,  $G(0)$  is identified with the energy of the system when all the molecules are in their ground state,  $E_0$ . To calculate the standard Gibbs energy, the partition function has its standard value,  $q_m^\ominus$ , which is evaluated by setting the molar volume in the translational contribution equal to the standard molar volume, so  $q_m^\ominus = (V_m^\ominus/\Lambda^3) q^R q^V$  with  $V_m^\ominus = RT/p^\ominus$ .

### Example 15F.2 Calculating a standard Gibbs energy of formation from partition functions

Calculate the standard Gibbs energy of formation of  $\text{H}_2\text{O}(\text{g})$  at  $25^\circ\text{C}$ .

**Method** Write the chemical equation for the formation reaction, and then the expression for the standard Gibbs energy of formation in terms of the Gibbs energy of each molecule; then express those Gibbs energies in terms of the molecular partition function of each species. Ignore molecular vibration as it is unlikely to be excited at  $25^\circ\text{C}$ . Take numerical values from the *Resource section* together with the following rotational constants of  $\text{H}_2\text{O}$ : 27.877, 14.512, and  $9.285 \text{ cm}^{-1}$ . Take for the atomization energy of  $\text{H}_2\text{O}$  the value  $-237 \text{ kJ mol}^{-1}$ .

**Answer** The chemical reaction is  $\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$ . Therefore,

$$\Delta_f G^\ominus = G_m^\ominus(\text{H}_2\text{O}, \text{g}) - G_m^\ominus(\text{H}_2, \text{g}) - \frac{1}{2} G_m^\ominus(\text{O}_2, \text{g})$$

Now write the standard molar Gibbs energies in terms of the standard molar partition functions of each species  $J$ :

$$\begin{aligned} G_m^\ominus(J) &= E_{0,m}(J) - RT \ln \frac{q_m^\ominus(J)}{N_A} \\ q_m^\ominus(J) &= q_m^{\text{T}\ominus}(J) q^{\text{R}}(J) = \frac{V_m^\ominus}{\Lambda(J)^3} q^{\text{R}}(J) \end{aligned}$$

Therefore

$$\begin{aligned}\Delta_f G^\ominus &= \left\{ E_{0,m}(\text{H}_2\text{O}) - RT \ln \frac{q_m^\ominus(\text{H}_2\text{O})}{N_A} \right\} \\ &\quad - \left\{ E_{0,m}(\text{H}_2) - RT \ln \frac{q_m^\ominus(\text{H}_2)}{N_A} \right\} \\ &\quad - \frac{1}{2} \left\{ E_{0,m}(\text{O}_2) - RT \ln \frac{q_m^\ominus(\text{O}_2)}{N_A} \right\} \\ &= \Delta E_{0,m} - RT \ln \frac{\overbrace{\left\{ \frac{V_m^\ominus}{N_A} \Lambda(\text{H}_2\text{O})^3 \right\} q^R(\text{H}_2\text{O})}^{q_m^\ominus(\text{H}_2\text{O})/N_A}}{\underbrace{\left\{ \frac{V_m^\ominus}{N_A} \Lambda(\text{H}_2) \right\}^3 q^R(\text{H}_2)}_{q_m^\ominus(\text{H}_2)/N_A}} \times \left[ \frac{\left\{ \frac{V_m^\ominus}{N_A} \Lambda(\text{O}_2) \right\}^3 q^R(\text{O}_2)}{q_m^\ominus(\text{O}_2)/N_A} \right]^{1/2} \\ &= \Delta E_m - RT \ln \frac{N_A^{1/2} \{ \Lambda(\text{H}_2) \Lambda(\text{O}_2)^{1/2} / \Lambda(\text{H}_2\text{O}) \}^3}{V_m^{\ominus 1/2} \{ q^R(\text{H}_2) q^R(\text{O}_2)^{1/2} / q^R(\text{H}_2\text{O}) \}}\end{aligned}$$

where

$$\Delta E_{0,m} = E_{0,m}(\text{H}_2\text{O}) - E_{0,m}(\text{H}_2) - \frac{1}{2} E_{0,m}(\text{O}_2)$$

At this point we introduce the thermal wavelengths and the rotational partition functions from Topic 15B:

$$\Lambda(J) = \frac{h}{\{2\pi m(J)kT\}^{1/2}}$$

Linear molecule,  $\sigma=2$ 
Nonlinear molecule,  $\sigma=2$

$$q^R = \frac{kT}{2hc\tilde{B}} \quad \text{and} \quad q^R = \frac{1}{2} \left( \frac{kT}{hc} \right)^{3/2} \left( \frac{\pi}{\tilde{A}\tilde{B}\tilde{C}} \right)^{1/2}$$

Now substitute the data, and find

$$\begin{aligned}\Lambda(\text{H}_2) &= 71.21 \text{ pm} & \Lambda(\text{O}_2) &= 17.87 \text{ pm} & \Lambda(\text{H}_2\text{O}) &= 23.82 \text{ pm} \\ q^R(\text{H}_2) &= 1.702 & q^R(\text{O}_2) &= 71.60 & q^R(\text{H}_2\text{O}) &= 42.13\end{aligned}$$

It then follows that

$$\Delta_f G^\ominus = \Delta E_{0,m} - RT \ln 0.0291 = \Delta E_{0,m} + 8.77 \text{ kJ mol}^{-1}$$

Now use  $\Delta E_{0,m} = -237 \text{ kJ mol}^{-1}$  and obtain  $\Delta_f G^\ominus = -228 \text{ kJ mol}^{-1}$ . The value quoted in Table 2C.1 of the *Resource section* is  $-228.57 \text{ kJ mol}^{-1}$ .

**Self-test 15E.2** Estimate the standard Gibbs energy of formation of  $\text{NH}_3(\text{g})$  at  $25^\circ\text{C}$ . Take the atomization energy to be  $+79 \text{ kJ mol}^{-1}$ .

Answer:  $-16 \text{ kJ mol}^{-1}$

## 15F.2 Equilibrium constants

The Gibbs energy of a gas of independent molecules is given by eqn 15F.9 in terms of the molar partition function,  $q_m = q/n$ . The equilibrium constant  $K$  of a reaction is related to the standard Gibbs energy of reaction by eqn 6A.14 of Topic 6A ( $\Delta_r G^\ominus = -RT \ln K$ ). To calculate the equilibrium constant, we need to combine these two equations. We shall consider gas phase reactions in which the equilibrium constant is expressed in terms of the partial pressures of the reactants and products.

### (a) The relation between $K$ and the partition function

To find an expression for the standard reaction Gibbs energy we need expressions for the standard molar Gibbs energies,  $G^\ominus/n$ , of each species. It then follows that, as shown in the following *Justification*, the equilibrium constant for the reaction  $aA + bB \rightarrow cC + dD$  is given by the expression

$$K = \frac{(q_{C,m}^\ominus/N_A)^c (q_{D,m}^\ominus/N_A)^d}{(q_{A,m}^\ominus/N_A)^a (q_{B,m}^\ominus/N_A)^b} e^{-\Delta_r E_0/RT} \quad (15F.10a)$$

where  $\Delta_r E_0$  is the difference in molar energies of the ground states of the products and reactants (this term is defined more precisely in the *Justification*), and is calculated from the bond dissociation energies of the species (Fig. 15F.1). In terms of the (signed) stoichiometric numbers introduced in Topic 2B, we would write

$$K = \left\{ \prod_j \left( \frac{q_{j,m}^\ominus}{N_A} \right)^{\nu_j} \right\} e^{-\Delta_r E_0/RT} \quad \text{Equilibrium constant} \quad (15F.10b)$$

Figure 15F.1 The definition of  $\Delta_r E_0$  for the calculation of equilibrium constants.

#### Justification 15F.1 The equilibrium constant in terms of the partition function 1

The standard molar reaction Gibbs energy for the reaction is

$$\begin{aligned}\Delta_r G^\ominus &= cG_m^\ominus(C) + dG_m^\ominus(D) - \{aG_m^\ominus(A) + bG_m^\ominus(B)\} \\ &= cG_m^\ominus(C, 0) + dG_m^\ominus(D, 0) - \{aG_m^\ominus(A, 0) + bG_m^\ominus(B, 0)\} \\ &\quad - RT \left\{ c \ln \frac{q_{C,m}^\ominus}{N_A} + d \ln \frac{q_{D,m}^\ominus}{N_A} - a \ln \frac{q_{A,m}^\ominus}{N_A} - b \ln \frac{q_{B,m}^\ominus}{N_A} \right\}\end{aligned}$$

Because  $G(J,0) = E_{0,m}(J)$ , the molar ground state energy of the species J, the first (blue) term on the right is

$$cE_{0,m}(C,0) + dE_{0,m}(D,0) - \{aE_{0,m}(A,0) + bE_{0,m}(B,0)\} = \Delta_r E_0$$

Then, by using  $a \ln x = \ln x^a$  and  $\ln x + \ln y = \ln xy$ , we can write

$$\begin{aligned} \Delta_r G^\ominus &= \Delta_r E_0 - RT \ln \frac{(q_{C,m}^\ominus/N_A)^c (q_{D,m}^\ominus/N_A)^d}{(q_{A,m}^\ominus/N_A)^a (q_{B,m}^\ominus/N_A)^b} \\ &= -RT \left\{ -\frac{\Delta_r E_0}{RT} + \ln \frac{(q_{C,m}^\ominus/N_A)^c (q_{D,m}^\ominus/N_A)^d}{(q_{A,m}^\ominus/N_A)^a (q_{B,m}^\ominus/N_A)^b} \right\} \end{aligned}$$

At this stage we can pick out an expression for  $K$  by comparing this equation with  $(\Delta_r G^\ominus = -RT \ln K)$ , which gives

$$\ln K = -\frac{\Delta_r E_0}{RT} + \ln \frac{(q_{C,m}^\ominus/N_A)^c (q_{D,m}^\ominus/N_A)^d}{(q_{A,m}^\ominus/N_A)^a (q_{B,m}^\ominus/N_A)^b}$$

This expression is easily rearranged into eqn 15F.10a by forming the exponential of both sides.

## (b) A dissociation equilibrium

We illustrate the application of eqn 15F.10 to an equilibrium in which a diatomic molecule  $X_2$  dissociates into its atoms:

According to eqn 15F.10 (with  $a=1$ ,  $b=0$ ,  $c=2$ , and  $d=0$ ):

$$K = \frac{(q_{X,m}^\ominus/N_A)^2}{q_{X_2,m}^\ominus/N_A} e^{-\Delta_r E_0/RT} = \frac{(q_{X,m}^\ominus)^2}{q_{X_2,m}^\ominus N_A} e^{-\Delta_r E_0/RT} \quad (15F.11a)$$

with

$$\Delta_r E_0 = 2E_{0,m}(X,0) - E_{0,m}(X_2,0) = N_A hc \tilde{D}_0(X-X) \quad (15F.11b)$$

where  $N_A hc \tilde{D}_0(X-X)$  is the (molar) dissociation energy of the X–X bond. The standard molar partition functions of the atoms X are

$$q_{X,m}^\ominus = g_X \times \frac{\overbrace{q^E}^{\text{electronic}} \overbrace{q^T}^{\text{translational}}}{\overbrace{V_m^\ominus}^{\text{molar volume}} \overbrace{A_X^3}^{\text{area}} \overbrace{p^\ominus}^{\text{pressure}}} = \frac{g_X RT}{p^\ominus A_X^3}$$

where  $g_X$  is the degeneracy of the electronic ground state of X. The diatomic molecule  $X_2$  also has rotational and vibrational degrees of freedom, so its standard molar partition function is

$$q_{X_2,m}^\ominus = g_{X_2} \frac{V_m^\ominus}{A_{X_2}^3} q_{X_2}^R q_{X_2}^V = \frac{g_{X_2} RT q_{X_2}^R q_{X_2}^V}{p^\ominus A_{X_2}^3}$$

where  $g_{X_2}$  is the degeneracy of the electronic ground state of  $X_2$ . It follows that

$$\begin{aligned} K &= \frac{(g_X RT/p^\ominus A_X^3)^2}{g_{X_2} N_A RT q_{X_2}^R q_{X_2}^V / p^\ominus A_{X_2}^3} e^{-N_A hc \tilde{D}_0/RT} \\ &= \frac{g_X^2 k T A_{X_2}^3}{g_{X_2} p^\ominus q_{X_2}^R q_{X_2}^V A_X^6} e^{-hc \tilde{D}_0/kT} \end{aligned} \quad (15F.12)$$

where we have used  $R/N_A = k$ . All the quantities in this expression can be calculated from spectroscopic data.

### Example 15F.3 Evaluating an equilibrium constant

Evaluate the equilibrium constant for the dissociation  $\text{Na}_2(g) \rightleftharpoons 2\text{Na}(g)$  at 1000 K.

**Method** Assemble the data from the *Resource section*, noting that Na has a double ground state. Use eqn 15F.12 and the expressions for the partition functions assembled in Topic 15B.

**Answer** Use the following data:  $\tilde{B} = 0.1547 \text{ cm}^{-1}$ ,  $\tilde{\nu} = 159.2 \text{ cm}^{-1}$ ,  $N_A hc \tilde{D}_0 = 70.4 \text{ kJ mol}^{-1}$ . For a homonuclear diatomic molecule,  $\sigma = 2$ . The partition functions and other quantities required are as follows:

$$\begin{aligned} \Lambda(\text{Na}_2) &= 8.14 \text{ pm} & \Lambda(\text{Na}) &= 11.5 \text{ pm} \\ q^R(\text{Na}_2) &= 2246 & q^V(\text{Na}_2) &= 4.885 \\ g(\text{Na}) &= 2 & g(\text{Na}_2) &= 1 \end{aligned}$$

Then, from eqn 15F.12,

$$\begin{aligned} K &= \frac{2^2 \times (1.381 \times 10^{-19} \text{ J K}^{-1}) \times (1000 \text{ K}) \times (8.14 \times 10^{-12} \text{ m})}{(10^5 \text{ Pa}) \times 2246 \times 4.885 \times (1.15 \times 10^{-11} \text{ m})} \times e^{-8.47\dots} \\ &= 2.45 \end{aligned}$$

where we have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$  and  $1 \text{ Pa} = 1 \text{ kg m}^{-1} \text{ s}^{-2}$ .

**Self-test 15F.3** Evaluate  $K$  at 1500 K. Is the answer consistent with the dissociation being endothermic?

Answer: 52; yes

## (c) Contributions to the equilibrium constant

We are now in a position to appreciate the physical basis of equilibrium constants. To see what is involved, consider a simple  $R \rightleftharpoons P$  gas-phase equilibrium (R for reactants, P for products).

Figure 15F.2 shows two sets of energy levels; one set of states belongs to R, and the other belongs to P. The populations of the states are given by the Boltzmann distribution, and are independent of whether any given state happens to belong to R or to P. We can therefore imagine a single Boltzmann distribution

**Figure 15F.2** The array of R(eactants) and P(roducts) energy levels. At equilibrium all are accessible (to differing extents, depending on the temperature), and the equilibrium composition of the system reflects the overall Boltzmann distribution of populations. As  $\Delta_r E_0$  increases, R becomes dominant.

spreading, without distinction, over the two sets of states. If the spacings of R and P are similar (as in Fig. 15F.2), and P lies above R, the diagram indicates that R will dominate in the equilibrium mixture. However, if P has a high density of states (a large number of states in a given energy range, as in Fig. 15F.3), then, even though its zero-point energy lies above that of R, the species P might still dominate at equilibrium.

It is quite easy to show (see the following *Justification*) that the ratio of numbers of R and P molecules at equilibrium is given by

$$\frac{N_P}{N_R} = \frac{q_P}{q_R} e^{-\Delta_r E_0/RT} \quad (15F.13a)$$

and therefore that the equilibrium constant for the reaction is

$$K = \frac{q_P}{q_R} e^{-\Delta_r E_0/RT} \quad (15F.13b)$$

just as would be obtained from eqn 15F.12.

### Justification 15F.2 The equilibrium constant in terms of the partition function 2

The population in a state  $i$  of the composite (R,P) system is  $N_i = N e^{-\beta \epsilon_i} / q$ , where  $N$  is the total number of molecules. The total number of R molecules is the sum of these populations taken over the states belonging to R; these states we label  $r$  with energies  $\epsilon_r$ . The total number of P molecules is the sum over the states belonging to P; these states we label  $p$  with energies  $\epsilon'_p$  (the prime is explained in a moment):

$$N_R = \sum_r N_r = \frac{N}{q} \sum_r e^{-\beta \epsilon_r} \quad N_P = \sum_p N_p = \frac{N}{q} \sum_p e^{-\beta \epsilon'_p}$$

The sum over the states of R is its partition function,  $q_R$ , so  $N_R = N q_R / q$ . The sum over the states of P is also a partition

function, but the energies are measured from the ground state of the combined system, which is the ground state of R. However, because  $\epsilon'_p = \epsilon_p + \Delta \epsilon_0$ , where  $\Delta \epsilon_0$  is the separation of zero-point energies (as in Fig. 15F.3),

$$\begin{aligned} N_P &= \frac{N}{q} \sum_p e^{-\beta(\epsilon_p + \Delta \epsilon_0)} = \frac{N}{q} \left( \sum_p e^{-\beta \epsilon_p} \right) e^{-\beta \Delta \epsilon_0} = \frac{N q_P}{q} e^{-\beta \Delta \epsilon_0} \\ &= \frac{N q_P}{q} e^{-\Delta_r E_0/RT} \end{aligned}$$

The switch from  $\Delta \epsilon_0/k$  to  $\Delta_r E_0/R$  in the last step is the conversion of molecular energies to molar energies.

**Figure 15F.3** It is important to take into account the densities of states of the molecules. Even though P might lie above R in energy (that is,  $\Delta_r E_0$  is positive), P might have so many states that its total population dominates in the mixture. In classical thermodynamic terms, we have to take entropies into account as well as enthalpies when considering equilibria.

The equilibrium constant of the  $R \rightleftharpoons P$  reaction is proportional to the ratio of the numbers of the two types of molecule. Therefore,

$$K = \frac{N_P}{N_R} = \frac{q_P}{q_R} e^{-\Delta_r E_0/RT}$$

as in eqn 15F.13b. For an  $R \rightleftharpoons P$  equilibrium, the  $V$  factors in the partition functions cancel, so the appearance of  $q$  in place of  $q^\ominus$  has no effect. In the case of a more general reaction, the conversion from  $q$  to  $q^\ominus$  comes about at the stage of converting the pressures that occur in  $K$  to numbers of molecules.

The content of eqn 15F.13 can be seen most clearly by exaggerating the molecular features that contribute to it. We shall suppose that R has only a single accessible level, which implies that  $q_R = 1$ . We also suppose that P has a large number of evenly, closely spaced levels (Fig. 15F.4). The partition function of P is then  $q_P = kT/\epsilon$ . In this model system, the equilibrium constant is

$$K = \frac{kT}{\varepsilon} e^{-\Delta_r E_0/RT} \quad (15F.14)$$

When  $\Delta_r E_0$  is very large, the exponential term dominates and  $K \ll 1$ , which implies that very little P is present at equilibrium. When  $\Delta_r E_0$  is small but still positive,  $K$  can exceed 1 because the factor  $kT/\varepsilon$  may be large enough to overcome the small size of the exponential term. The size of  $K$  then reflects the predominance of P at equilibrium on account of its high density of states. At low temperatures  $K \ll 1$  and the system consists entirely of R. At high temperatures the exponential function approaches 1 and the pre-exponential factor is large. Hence P becomes dominant. We see that, in this endothermic reaction (endothermic because P lies above R), a rise in temperature favours P, because its states become accessible. This behaviour is what we saw, from the outside, in Topic 6B.

The model also shows why the Gibbs energy,  $G$ , and not just the enthalpy, determines the position of equilibrium. It shows

Figure 15F.4 The model used in the text for exploring the effects of energy separations and densities of states on equilibria. The products P can dominate provided  $\Delta_r E_0$  is not too large and P has an appreciable density of states.

that the density of states (and hence the entropy) of each species as well as their relative energies controls the distribution of populations and hence the value of the equilibrium constant.

## Checklist of concepts

- 1. The **thermodynamic functions**  $A$ ,  $p$ ,  $H$ , and  $G$  can be calculated from the canonical partition function.
- 2. For a perfect gas,  $G$  depends on the logarithm of the molecular partition function.
- 3. The **equilibrium constant** can be written in terms of the partition function.
- 4. The equilibrium constant for dissociation of a diatomic molecule in the gas phase may be calculated from spectroscopic data.
- 5. The **physical basis of chemical equilibrium** can be understood in terms of a competition between energy separations and densities of states.

## Checklist of equations

Property	Equation	Comment	Equation number
Helmholtz energy	$A(T) = A(0) - kT \ln Q$		15F.2
Pressure	$p = kT(\partial \ln Q / \partial V)_T$		15F.3
Enthalpy	$H(T) = H(0) - (\partial \ln Q / \partial \beta)_V + kTV(\partial \ln Q / \partial V)_T$		15F.4
Gibbs energy	$G(T) = G(0) - kT \ln Q + kTV(\partial \ln Q / \partial V)_T$		15F.6
	$G(T) = G(0) - nRT \ln(q_m / N_A)$	Perfect gas	15F.9
Equilibrium constant	$K = \left\{ \prod_j (q_{j,m}^\ominus / N_A)^{\nu_j} \right\} e^{-\Delta_r E_0 / RT}$	Perfect gas	15F.10b

# CHAPTER 15 Statistical thermodynamics

Assume that all gases are perfect and that data refer to 298 K unless otherwise stated.

## TOPIC 15A The Boltzmann distribution

### Discussion questions

**15A.1** Discuss the relationship between ‘population’, ‘configuration’, and ‘weight’. What is the significance of the most probable configuration?

**15A.2** What is the significance and importance of the principle of equal *a priori* probabilities?

**15A.3** What is temperature?

**15A.4** Summarize the role of the Boltzmann distribution in chemistry.

### Exercises

**15A.1(a)** Calculate the weight of the configuration in which 16 objects are distributed in the arrangement 0, 1, 2, 3, 8, 0, 0, 0, 2.

**15A.1(b)** Calculate the weight of the configuration in which 21 objects are distributed in the arrangement 6, 0, 5, 0, 4, 0, 3, 0, 2, 0, 0, 1.

**15A.2(a)** Evaluate  $8!$  by using (i) the exact formula, (ii) Stirling’s approximation, eqn 15A.2b; (iii) the more accurate version of Stirling’s approximation, eqn 15A.2a.

**15A.2(b)** Evaluate  $10!$  by using (i) the exact formula, eqn 15A.2b; (ii) Stirling’s approximation, (iii) the more accurate version of Stirling’s approximation, eqn 15A.2a.

**15A.3(a)** What are the relative populations of the states of a two-level system when the temperature is infinite?

**15A.3(b)** What are the relative populations of the states of a two-level system as the temperature approaches zero?

**15A.4(a)** What is the temperature of a two-level system of energy separation equivalent to  $400\text{ cm}^{-1}$  when the population of the upper state is one-third that of the lower state?

**15A.4(b)** What is the temperature of a two-level system of energy separation equivalent to  $300\text{ cm}^{-1}$  when the population of the upper state is one-half that of the lower state?

**15A.5(a)** Calculate the relative populations of a linear rotor in the levels with  $J=0$  and  $J=5$ , given that  $\tilde{B}=2.71\text{ cm}^{-1}$  and a temperature of 298 K.

**15A.5(b)** Calculate the relative populations of a spherical rotor in the levels with  $J=0$  and  $J=5$ , given that  $\tilde{B}=2.71\text{ cm}^{-1}$  and a temperature of 298 K.

**15A.6(a)** A certain molecule has a non-degenerate excited state lying at  $540\text{ cm}^{-1}$  above the non-degenerate ground state. At what temperature will 10 per cent of the molecules be in the upper level?

**15A.6(b)** A certain molecule has a doubly degenerate excited state lying at  $360\text{ cm}^{-1}$  above the non-degenerate ground state. At what temperature will 15 per cent of the molecules be in the upper level?

### Problems

**15A.1** A sample consisting of five molecules has a total energy  $5\varepsilon$ . Each molecule is able to occupy states of energy  $j\varepsilon$ , with  $j=0, 1, 2, \dots$  (a) Calculate the weight of the configuration in which the molecules are distributed evenly over the available states. (b) Draw up a table with columns headed by the energy of the states and write beneath them all configurations that are consistent with the total energy. Calculate the weights of each configuration and identify the most probable configurations.

**15A.2** A sample of nine molecules is numerically tractable but on the verge of being thermodynamically significant. Draw up a table of configurations for  $N=9$ , total energy  $9\varepsilon$  in a system with energy levels  $j\varepsilon$  (as in Problem 15A.1). Before evaluating the weights of the configurations, guess (by looking for the most ‘exponential’ distribution of populations) which of the configurations will turn out to be the most probable. Go on to calculate the weights and identify the most probable configuration.

**15A.3** Use mathematical software to evaluate  $\mathcal{W}$  for  $N=20$  for a series of distributions over a uniform ladder of energy levels, ensuring that the total energy is constant. Identify the configuration of greatest weight and compare it to the distribution predicted by the Boltzmann expression. Explore what happens as the value of the total energy is changed.

**15A.4** A certain atom has a doubly degenerate ground state and an upper level of four degenerate states at  $450\text{ cm}^{-1}$  above the ground state. In an atomic beam study of the atoms it was observed that 30 per cent of the atoms were in the upper level, and the translational temperature of the beam was 300 K. Are the electronic states of the atoms in thermal equilibrium with the translational states?

**15A.5** Explore the consequences of using the full version of Stirling’s approximation,  $x! \approx (2\pi)^{1/2} x^{x+1/2} e^{-x}$ , in the development of the expression for the configuration of greatest weight. Does the more accurate approximation have a significant effect on the form of the Boltzmann distribution?

**15A.6** The most probable configuration is characterised by a parameter we know as the ‘temperature’. The temperatures of the system specified in Problems 15A.1 and 15A.2 must be such as to give a mean value of  $\varepsilon$  for the energy of each molecule and a total energy  $N\varepsilon$  for the system. (a) Show that the temperature can be obtained by plotting  $p_j$  against  $j$ , where  $p_j$  is the (most probable) fraction of molecules in the state with energy  $j\varepsilon$ . Apply the procedure to the system in Problem 15A.2. What is the temperature of the system when  $\varepsilon$  corresponds to  $50\text{ cm}^{-1}$ ? (b) Choose configurations other than

the most probable, and show that the same procedure gives a worse straight line, indicating that a temperature is not well-defined for them.

**15A.7\*** The variation of the atmospheric pressure  $p$  with altitude  $h$  is predicted by the *barometric formula* to be  $p = p_0 e^{-h/H}$  where  $p_0$  is the pressure at sea level and  $H = RT/Mg$  with  $M$  the average molar mass of air and  $T$  the average temperature. Obtain the barometric formula from the Boltzmann distribution. Recall that the potential energy of a particle at height  $h$  above the surface of the Earth is  $mgh$ . Convert the barometric formula from pressure to number density,  $\mathcal{N}$ . Compare the relative number densities,  $\mathcal{N}(h)/\mathcal{N}(0)$ , for  $\text{O}_2$  and  $\text{H}_2\text{O}$  at  $h = 8.0$  km, a typical cruising altitude for commercial aircraft.

**15A.8\*** Planets lose their atmospheres over time unless they are replenished. A complete analysis of the overall process is very complicated and depends upon the radius of the planet, temperature, atmospheric composition, and other factors. Prove that the atmosphere of planets cannot be in an equilibrium state by demonstrating that the Boltzmann distribution leads to a uniform finite number density as  $r \rightarrow \infty$ . *Hint:* Recall that in a gravitational field the potential energy is  $V(r) = -GMm/r$ , where  $G$  is the gravitational constant,  $M$  is the mass of the planet, and  $m$  the mass of the particle.

## TOPIC 15B Molecular partition functions

### Discussion questions

**15B.1** Describe the physical significance of the partition function.

**15B.2** Describe how the mean energy of a system composed of two levels varies with temperature.

**15B.3** What is the difference between a 'state' and an 'energy level'? Why is it important to make this distinction?

**15B.4** Why and when is it necessary to include a symmetry number in the calculation of a partition function?

### Exercises

**15B.1(a)** Calculate (i) the thermal wavelength, (ii) the translational partition function at 300 K and 3000 K of a molecule of molar mass  $150 \text{ g mol}^{-1}$  in a container of volume  $1.00 \text{ cm}^3$ .

**15B.1(b)** Calculate (i) the thermal wavelength, (ii) the translational partition function of a Ne atom in a cubic box of side  $1.00 \text{ cm}$  at 300 K and 3000 K.

**15B.2(a)** Calculate the ratio of the translational partition functions of  $\text{H}_2$  and He at the same temperature and volume.

**15B.2(b)** Calculate the ratio of the translational partition functions of Ar and Ne at the same temperature and volume.

**15B.3(a)** The bond length of  $\text{O}_2$  is  $120.75 \text{ pm}$ . Use the high-temperature approximation to calculate the rotational partition function of the molecule at 300 K.

**15B.3(b)** The bond length of  $\text{N}_2$  is  $109.75 \text{ pm}$ . Use the high-temperature approximation to calculate the rotational partition function of the molecule at 300 K.

**15B.4(a)** The NOF molecule is an asymmetric rotor with rotational constants  $3.1752 \text{ cm}^{-1}$ ,  $0.3951 \text{ cm}^{-1}$ , and  $0.3505 \text{ cm}^{-1}$ . Calculate the rotational partition function of the molecule at (i)  $25^\circ\text{C}$ , (ii)  $100^\circ\text{C}$ .

**15B.4(b)** The  $\text{H}_2\text{O}$  molecule is an asymmetric rotor with rotational constants  $27.877 \text{ cm}^{-1}$ ,  $14.512 \text{ cm}^{-1}$ , and  $9.285 \text{ cm}^{-1}$ . Calculate the rotational partition function of the molecule at (i)  $25^\circ\text{C}$ , (ii)  $100^\circ\text{C}$ .

**15B.5(a)** The rotational constant of CO is  $1.931 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.5(b)** The rotational constant of HI is  $6.511 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.6(a)** The rotational constant of  $\text{CH}_4$  is  $5.241 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation but ignoring the role of nuclear statistics) and plot its value as a function of temperature. At what

temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.6(b)** The rotational constant of  $\text{CCl}_4$  is  $0.0572 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation but ignoring the role of nuclear statistics) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.7(a)** The rotational constants of  $\text{CH}_3\text{Cl}$  are  $\tilde{A} = 5.097 \text{ cm}^{-1}$  and  $\tilde{B} = 0.443 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation but ignoring the role of nuclear statistics) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.7(b)** The rotational constants of  $\text{NH}_3$  are  $\tilde{A} = 6.196 \text{ cm}^{-1}$  and  $\tilde{B} = 9.444 \text{ cm}^{-1}$ . Evaluate the rotational partition function explicitly (without approximation but ignoring the role of nuclear statistics) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.8(a)** Give the symmetry number for each of the following molecules: (i) CO, (ii)  $\text{O}_2$ , (iii)  $\text{H}_2\text{S}$ , (iv)  $\text{SiH}_4$ , and (v)  $\text{CHCl}_3$ .

**15B.8(b)** Give the symmetry number for each of the following molecules: (i)  $\text{CO}_2$ , (ii)  $\text{O}_3$ , (iii)  $\text{SO}_3$ , (iv)  $\text{SF}_6$ , and (v)  $\text{Al}_2\text{Cl}_6$ .

**15B.9(a)** Estimate the rotational partition function of ethene at  $25^\circ\text{C}$  given that  $\tilde{A} = 4.828 \text{ cm}^{-1}$ ,  $\tilde{B} = 1.0012 \text{ cm}^{-1}$ , and  $\tilde{C} = 0.8282 \text{ cm}^{-1}$ . Take the symmetry number into account.

**15B.9(b)** Evaluate the rotational partition function of pyridine,  $\text{C}_5\text{H}_5\text{N}$ , at  $25^\circ\text{C}$  given that  $\tilde{A} = 0.2014 \text{ cm}^{-1}$ ,  $\tilde{B} = 0.1936 \text{ cm}^{-1}$ ,  $\tilde{C} = 0.0987 \text{ cm}^{-1}$ . Take the symmetry number into account.

**15B.10(a)** The vibrational wavenumber of  $\text{Br}_2$  is  $323.2 \text{ cm}^{-1}$ . Evaluate the vibrational partition function explicitly (without approximation) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

**15B.10(b)** The vibrational wavenumber of  $\text{I}_2$  is  $214.5 \text{ cm}^{-1}$ . Evaluate the vibrational partition function explicitly (without approximation) and plot its value as a function of temperature. At what temperature is the value within 5 per cent of the value calculated from the approximate formula?

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**15B.11(a)** Calculate the vibrational partition function of CS<sub>2</sub> at 500 K given the wavenumbers 658 cm<sup>-1</sup> (symmetric stretch), 397 cm<sup>-1</sup> (bend; two modes), 1535 cm<sup>-1</sup> (asymmetric stretch).

**15B.11(b)** Calculate the vibrational partition function of HCN at 900 K given the wavenumbers 3311 cm<sup>-1</sup> (symmetric stretch), 712 cm<sup>-1</sup> (bend; two modes), 2097 cm<sup>-1</sup> (asymmetric stretch).

**15B.12(a)** Calculate the vibrational partition function of CCl<sub>4</sub> at 500 K given the wavenumbers 459 cm<sup>-1</sup> (symmetric stretch, A), 217 cm<sup>-1</sup> (deformation, E), 776 cm<sup>-1</sup> (deformation, T), 314 cm<sup>-1</sup> (deformation, T).

**15B.12(b)** Calculate the vibrational partition function of Cl<sub>4</sub> at 500 K given the wavenumbers 178 cm<sup>-1</sup> (symmetric stretch, A), 90 cm<sup>-1</sup> (deformation, E), 555 cm<sup>-1</sup> (deformation, T), 125 cm<sup>-1</sup> (deformation, T).

## Problems

**15B.1** This problem is best done using mathematical software. Equation 15B.15 is the partition function for a harmonic oscillator. Consider a Morse oscillator (Topic 2D) in which the energy levels are given by eqn 2D.12:

$$E_v = \left(v + \frac{1}{2}\right)hc\tilde{\nu} - \left(v + \frac{1}{2}\right)^2 hc x_e \tilde{\nu}$$

Evaluate the partition function for this oscillator, remembering to measure energies from the lowest level and to note that there is only a finite number of bound-state levels. Plot the partition function against temperature for a variety of values of  $x_e$ , and—on the same graph—compare your results with that for an harmonic oscillator.

**15B.2** Explore the conditions under which the ‘integral’ approximation for the translational partition function is not valid by considering the translational partition function of an H atom in a one-dimensional box of side comparable to that of a typical nanoparticle, 100 nm. Estimate the temperature at which, according to the integral approximation,  $q = 10$  and evaluate the exact partition function at that temperature.

**15B.3** (a) Calculate the electronic partition function of a tellurium atom at (i) 298 K, (ii) 5000 K by direct summation using the following data:

Term	Degeneracy	Wavenumber/cm <sup>-1</sup>
Ground	5	0
1	1	4707
2	3	4751
3	5	10 559

(b) What proportion of the Te atoms are in the ground term and in the term labelled 2 at the two temperatures?

**15B.4** The four lowest electronic levels of a Ti atom are <sup>3</sup>F<sub>2</sub>, <sup>3</sup>F<sub>3</sub>, <sup>3</sup>F<sub>4</sub>, and <sup>5</sup>F<sub>1</sub>, at 0, 170, 387, and 6557 cm<sup>-1</sup>, respectively. There are many other electronic states at higher energies. The boiling point of titanium is 3287 °C. What are the relative populations of these levels at the boiling point? *Hint*: the degeneracies of the levels are  $2J + 1$ .

**15B.5\*** J. Sugar and A. Musgrove (*J. Phys. Chem. Ref. Data* 22, 1213 (1993)) have published tables of energy levels for germanium atoms and cations from Ge<sup>+</sup> to Ge<sup>+31</sup>. The lowest-lying energy levels in neutral Ge are as follows:

	<sup>3</sup> P <sub>0</sub>	<sup>3</sup> P <sub>1</sub>	<sup>3</sup> P <sub>2</sub>	<sup>1</sup> D <sub>2</sub>	<sup>1</sup> S <sub>0</sub>
( <i>E</i> / <i>hc</i> )/cm <sup>-1</sup>	0	557.1	1410.0	7125.3	16367.3

**15B.13(a)** A certain atom has a fourfold degenerate ground level, a non-degenerate electronically excited level at 2500 cm<sup>-1</sup>, and a twofold degenerate level at 3500 cm<sup>-1</sup>. Calculate the partition function of these electronic states at 1900 K. What is the relative population of each level at 1900 K?

**15B.13(b)** A certain atom has a triply degenerate ground level, a non-degenerate electronically excited level at 850 cm<sup>-1</sup>, and a fivefold degenerate level at 1100 cm<sup>-1</sup>. Calculate the partition function of these electronic states at 2000 K. What is the relative population of each level at 2000 K?

Calculate the electronic partition function at 298 K and 1000 K by direct summation. *Hint*: the degeneracy of a level *J* is  $2J + 1$ .

**15B.6** The pure rotational microwave spectrum of HCl has absorption lines at the following wavenumbers (in cm<sup>-1</sup>): 21.19, 42.37, 63.56, 84.75, 105.93, 127.12, 148.31, 169.49, 190.68, 211.87, 233.06, 254.24, 275.43, 296.62, 317.80, 338.99, 360.18, 381.36, 402.55, 423.74, 444.92, 466.11, 487.30, 508.48. Calculate the rotational partition function at 25 °C by direct summation.

**15B.7** Calculate, by explicit summation, the vibrational partition function and the vibrational contribution to the energy of I<sub>2</sub> molecules at (a) 100 K, (b) 298 K given that its vibrational energy levels lie at the following wavenumbers above the zero-point energy level: 0, 213.30, 425.39, 636.27, 845.93 cm<sup>-1</sup>. What proportion of I<sub>2</sub> molecules are in the ground and first two excited levels at the two temperatures?

**15B.8\*** Consider the electronic partition function of a perfect atomic hydrogen gas at a density of  $1.99 \times 10^{-4}$  kg m<sup>-3</sup> and 5780 K. These are the mean conditions within the Sun’s photosphere, the surface layer of the Sun that is about 190 km thick. (a) Show that this partition function, which involves a sum over an infinite number of quantum states that are solutions to the Schrödinger equation for an isolated atomic hydrogen atom, is infinite. (b) Develop a theoretical argument for truncating the sum and estimate the maximum number of quantum states that contribute to the sum. (c) Calculate the equilibrium probability that an atomic hydrogen electron is in each quantum state. Are there any general implications concerning electronic states that will be observed for other atoms and molecules? Is it wise to apply these calculations in the study of the Sun’s photosphere?

**15B.9** A formal way of arriving at the value of the symmetry number is to note that  $\sigma$  is the order (the number of elements) of the *rotational subgroup* of the molecule, the point group of the molecule with all but the identity and the rotations removed. The rotational subgroup of H<sub>2</sub>O is {*E*, *C*<sub>2</sub>}, so  $\sigma = 2$ . The rotational subgroup of NH<sub>3</sub> is {*E*, 2*C*<sub>3</sub>}, so  $\sigma = 3$ . This recipe makes it easy to find the symmetry numbers for more complicated molecules. The rotational subgroup of CH<sub>4</sub> is obtained from the *T* character table as {*E*, 8*C*<sub>3</sub>, 3*C*<sub>2</sub>}, so  $\sigma = 12$ . For benzene, the rotational subgroup of *D*<sub>6h</sub> is {*E*, 2*C*<sub>6</sub>, 2*C*<sub>3</sub>, *C*<sub>2</sub>, 3*C*<sub>2</sub>, 3*C*<sub>2</sub>'}, so  $\sigma = 12$ . (a) Estimate the rotational partition function of ethene at 25 °C given that  $\tilde{A} = 4.828$  cm<sup>-1</sup>,  $\tilde{B} = 1.0012$  cm<sup>-1</sup>, and  $\tilde{C} = 0.8282$  cm<sup>-1</sup>. (b) Evaluate the rotational partition function of pyridine, C<sub>5</sub>H<sub>5</sub>N, at room temperature ( $\tilde{A} = 0.2014$  cm<sup>-1</sup>,  $\tilde{B} = 0.1936$  cm<sup>-1</sup>,  $\tilde{C} = 0.0987$  cm<sup>-1</sup>).

## TOPIC 15C Molecular energies

### Discussion question

**15C.1** Identify the conditions under which energies predicted from the equipartition theorem coincide with energies computed by using partition functions.

### Exercises

**15C.1(a)** Compute the mean energy at 298 K of a two-level system of energy separation equivalent to  $500\text{ cm}^{-1}$ .

**15C.1(b)** Compute the mean energy at 400 K of a two-level system of energy separation equivalent to  $600\text{ cm}^{-1}$ .

**15C.2(a)** Evaluate, by explicit summation, the mean rotational energy of CO and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{B}(\text{CO}) = 1.931\text{ cm}^{-1}$ .

**15C.2(b)** Evaluate, by explicit summation, the mean rotational energy of HI and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{B}(\text{HI}) = 6.511\text{ cm}^{-1}$ .

**15C.3(a)** Evaluate, by explicit summation, the mean rotational energy of  $\text{CH}_4$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{B}(\text{CH}_4) = 5.241\text{ cm}^{-1}$ .

**15C.3(b)** Evaluate, by explicit summation, the mean rotational energy of  $\text{CCl}_4$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{B}(\text{CCl}_4) = 0.0572\text{ cm}^{-1}$ .

**15C.4(a)** Evaluate, by explicit summation, the mean rotational energy of  $\text{CH}_3\text{Cl}$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{A} = 5.097\text{ cm}^{-1}$  and  $\tilde{B} = 0.443\text{ cm}^{-1}$ .

**15C.4(b)** Evaluate, by explicit summation, the mean rotational energy of  $\text{NH}_3$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value?  $\tilde{A} = 6.196\text{ cm}^{-1}$  and  $\tilde{B} = 9.444\text{ cm}^{-1}$ .

**15C.5(a)** Evaluate, by explicit summation, the mean vibrational energy of  $\text{Br}_2$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use  $\tilde{\nu} = 323.2\text{ cm}^{-1}$ .

**15C.5(b)** Evaluate, by explicit summation, the mean vibrational energy of  $\text{I}_2$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use  $\tilde{\nu} = 214.5\text{ cm}^{-1}$ .

**15C.6(a)** Evaluate, by explicit summation, the mean vibrational energy of  $\text{CS}_2$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use the wavenumbers  $658\text{ cm}^{-1}$  (symmetric stretch),  $397\text{ cm}^{-1}$  (bend; two modes),  $1535\text{ cm}^{-1}$  (asymmetric stretch). The A modes are non-degenerate, E modes are doubly degenerate, and T modes are triply degenerate.

**15C.6(b)** Evaluate, by explicit summation, the mean vibrational energy of HCN and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use the wavenumbers  $3311\text{ cm}^{-1}$  (symmetric stretch),  $712\text{ cm}^{-1}$  (bend; two modes),  $2097\text{ cm}^{-1}$  (asymmetric stretch). A modes are non-degenerate, E modes are doubly degenerate, and T modes are triply degenerate.

**15C.7(a)** Evaluate, by explicit summation, the mean vibrational energy of  $\text{CCl}_4$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use the wavenumbers  $459\text{ cm}^{-1}$  (symmetric stretch, A),  $217\text{ cm}^{-1}$  (deformation, E),  $776\text{ cm}^{-1}$  (deformation, T),  $314\text{ cm}^{-1}$  (deformation, T).

**15C.7(b)** Evaluate, by explicit summation, the mean vibrational energy of  $\text{Cl}_4$  and plot its value as a function of temperature. At what temperature is the equipartition value within 5 per cent of the accurate value? Use the wavenumbers  $178\text{ cm}^{-1}$  (symmetric stretch, A),  $90\text{ cm}^{-1}$  (deformation, E),  $555\text{ cm}^{-1}$  (deformation, T),  $125\text{ cm}^{-1}$  (deformation, T).

**15C.8(a)** Calculate the mean contribution to the electronic energy at 1900 K for a sample composed of the atoms specified in Exercise 15B.13(a).

**15C.8(b)** Calculate the mean contribution to the electronic energy at 2000 K for a sample composed of the atoms specified in Exercise 15B.13(b).

### Problems

**15C.1** An electron trapped in an infinitely deep spherical well of radius  $R$ , such as may be encountered in the investigation of nanoparticles, has energies given by the expression  $E_{nl} = \hbar^2 X_{nl}^2 / 2m_e R^2$ , with  $X_{nl}$  the value obtained by searching for the zeroes of the spherical Bessel functions. The first six values (with a degeneracy of the corresponding energy level equal to  $2l + 1$ ) are as follows:

$n$	1	1	1	2	1	2
$l$	0	1	2	0	3	1
$X_{nl}$	3.142	4.493	5.763	6.283	6.988	7.725

Evaluate the partition function and mean energy of an electron as a function of temperature. Choose the temperature range and radius to be so low that only these six energy levels need be considered. *Hint:* Remember to measure energies from the lowest level.

**15C.2** The NO molecule has a doubly degenerate excited electronic level  $121.1\text{ cm}^{-1}$  above the doubly degenerate electronic ground term. Calculate and plot the electronic partition function of NO from  $T = 0$  to 1000 K. Evaluate (a) the term populations and (b) the mean electronic energy at 300 K.

**15C.3** Consider a system with energy levels  $\epsilon_j = j\epsilon$  and  $N$  molecules. (a) Show that if the mean energy per molecule is  $a\epsilon$ , then the temperature is given by

$$\beta = \frac{1}{\epsilon} \ln \left( 1 + \frac{1}{a} \right)$$

Evaluate the temperature for a system in which the mean energy is  $\epsilon$ , taking  $\epsilon$  equivalent to  $50\text{ cm}^{-1}$ . (b) Calculate the molecular partition function  $q$  for the system when its mean energy is  $a\epsilon$ .

**15C.4** Deduce an expression for the root mean square energy,  $\langle \varepsilon^2 \rangle^{1/2}$ , in terms of the partition function and hence an expression for the root mean square

deviation from the mean,  $\Delta\varepsilon = (\langle \varepsilon^2 \rangle - \langle \varepsilon \rangle^2)^{1/2}$ . Evaluate the resulting expression for a harmonic oscillator.

## TOPIC 15D The canonical ensemble

### Discussion questions

**15D.1** Why is the concept of a canonical ensemble required?

**15D.2** Explain what is meant by an ensemble and why it is useful in statistical thermodynamics.

**15D.3** Under what circumstances may identical particles be regarded as distinguishable?

**15D.4** What is meant by the 'thermodynamic limit'?

### Exercises

**15D.1(a)** Identify the systems for which it is essential to include a factor of  $1/N!$  on going from  $Q$  to  $q$ : (i) a sample of helium gas, (ii) a sample of carbon monoxide gas, (iii) a solid sample of carbon monoxide, (iv) water vapour.

**15D.1(b)** Identify the systems for which it is essential to include a factor of  $1/N!$  on going from  $Q$  to  $q$ : (i) a sample of carbon dioxide gas, (ii) a sample of graphite, (iii) a sample of diamond, (iv) ice.

### Problem

**15D.1\*** For a perfect gas, the canonical partition function,  $Q$ , is related to the molecular partition function  $q$  by  $Q = q^N/N!$ . In Topic 15F it is established

that  $p = kT(\partial \ln Q/\partial V)_T$ . Use the expression for  $q$  to derive the perfect gas law  $pV = nRT$ .

## TOPIC 15E The internal energy and the entropy

### Discussion questions

**15E.1** Describe the molecular features that determine the magnitudes of the constant-volume molar heat capacity of a molecular substance.

**15E.2** Discuss and illustrate the proposition that  $1/T$  is a more natural measurement of temperature than  $T$  itself.

**15E.3** Discuss the relationship between the thermodynamic and statistical definitions of entropy.

**15E.4** Justify the differences between the partition-function expression for the entropy for distinguishable particles and the expression for indistinguishable particles.

**15E.5** Account for the temperature and volume dependence of the entropy of a perfect gas in terms of the Boltzmann distribution.

**15E.6** Explain the origin of residual entropy.

### Exercises

**15E.1(a)** Use the equipartition theorem to estimate the constant-volume molar heat capacity of (i)  $I_2$ , (ii)  $CH_4$ , (iii)  $C_6H_6$  in the gas phase at 25 °C.

**15E.1(b)** Use the equipartition theorem to estimate the constant-volume molar heat capacity of (i)  $O_3$ , (ii)  $C_2H_6$ , (iii)  $CO_2$  in the gas phase at 25 °C.

**15E.2(a)** Estimate the values of  $\gamma = C_p/C_V$  for gaseous ammonia and methane. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at 25 °C?

**15E.2(b)** Estimate the value of  $\gamma = C_p/C_V$  for carbon dioxide. Do this calculation with and without the vibrational contribution to the energy. Which is closer to the expected experimental value at 25 °C?

**15E.3(a)** The ground level of Cl is  $^2P_{3/2}$  and a  $^2P_{1/2}$  level lies 881  $cm^{-1}$  above it. Calculate the electronic contribution to the heat capacity of Cl atoms at (i) 500 K and (ii) 900 K.

**15E.3(b)** The first electronically excited state of  $O_2$  is  $^1\Delta_g$  and lies 7918.1  $cm^{-1}$  above the ground state, which is  $^3\Sigma_g^-$ . Calculate the electronic contribution to the heat capacity of  $O_2$  at 400 K.

**15E.4(a)** Plot the molar heat capacity of a collection of harmonic oscillators as a function of  $T/\theta^v$ , and predict the vibrational heat capacity of ethyne at (i) 298 K, (ii) 500 K. The normal modes (and their degeneracies in parentheses) occur at wavenumbers 612(2), 729(2), 1974, 3287, and 3374  $cm^{-1}$ .

**15E.4(b)** Plot the molar entropy of a collection of harmonic oscillators as a function of  $T/\theta^v$ , and predict the standard molar entropy of ethyne at (i) 298 K, (ii) 500 K. For data, see the preceding exercise.

**15E.5(a)** Calculate the standard molar entropy at 298 K of (i) gaseous helium, (ii) gaseous xenon.

**15E.5(b)** Calculate the translational contribution to the standard molar entropy at 298 K of (i) H<sub>2</sub>O(g), (ii) CO<sub>2</sub>(g).

**15E.6(a)** At what temperature is the standard molar entropy of helium equal to that of xenon at 298 K?

**15E.6(b)** At what temperature is the translational contribution to the standard molar entropy of CO<sub>2</sub>(g) equal to that of H<sub>2</sub>O(g) at 298 K?

**15E.7(a)** Calculate the rotational partition function of H<sub>2</sub>O at 298 K from its rotational constants 27.878 cm<sup>-1</sup>, 14.509 cm<sup>-1</sup>, and 9.287 cm<sup>-1</sup> and use your result to calculate the rotational contribution to the molar entropy of gaseous water at 25 °C.

**15E.7(b)** Calculate the rotational partition function of SO<sub>2</sub> at 298 K from its rotational constants 2.027 36 cm<sup>-1</sup>, 0.344 17 cm<sup>-1</sup>, and 0.293 535 cm<sup>-1</sup> and use your result to calculate the rotational contribution to the molar entropy of sulfur dioxide at 25 °C.

## Problems

**15E.1** The NO molecule has a doubly degenerate electronic ground state and a doubly degenerate excited state at 121.1 cm<sup>-1</sup>. Calculate and plot the electronic contribution to the molar heat capacity of the molecule up to 500 K.

**15E.2** Explore whether a magnetic field can influence the heat capacity of a paramagnetic molecule by calculating the electronic contribution to the heat capacity of an NO<sub>2</sub> molecule in a magnetic field. Estimate the total constant-volume heat capacity using equipartition, and calculate the percentage change in heat capacity brought about by a 5.0 T magnetic field at (a) 50 K, (b) 298 K.

**15E.3** The energy levels of a CH<sub>3</sub> group attached to a larger fragment are given by the expression for a particle on a ring, provided the group is rotating freely. What is the high-temperature contribution to the heat capacity and entropy of such a freely rotating group at 25 °C? The moment of inertia of CH<sub>3</sub> about its three-fold rotation axis (the axis that passes through the C atom and the centre of the equilateral triangle formed by the H atoms) is 5.341 × 10<sup>-47</sup> kg m<sup>2</sup>.

**15E.4** Calculate the temperature dependence of the heat capacity of *p*-H<sub>2</sub> (in which only rotational states with even values of *J* are populated) at low temperatures on the basis that its rotational levels *J* = 0 and *J* = 2 constitute a system that resembles a two-level system except for the degeneracy of the upper level. Use  $\tilde{B}$  = 60.864 cm<sup>-1</sup> and sketch the heat capacity curve. The experimental heat capacity of *p*-H<sub>2</sub> does in fact show a peak at low temperatures.

**15E.5\*** In a spectroscopic study of buckminsterfullerene C<sub>60</sub>, F. Negri et al. (*J. Phys. Chem.* **100**, 10849 (1996)) reviewed the wavenumbers of all the vibrational modes of the molecule:

Mode	Number	Degeneracy	Wavenumber/cm <sup>-1</sup>
A <sub>g</sub>	1	1	976
T <sub>1u</sub>	4	3	525, 578, 1180, and 1430
T <sub>2u</sub>	5	3	354, 715, 1037, 1190, 1540
G <sub>u</sub>	6	4	345, 757, 776, 963, 1315, 1410
H <sub>u</sub>	7	5	403, 525, 667, 738, 1215, 1342, 1566

How many modes have a vibrational temperature  $\theta^V$  below 1000 K? Estimate the molar constant-volume heat capacity of C<sub>60</sub> at 1000 K, counting as active all modes with  $\theta^V$  below this temperature.

**15E.6** Use mathematical software to evaluate the heat capacity of the bound states of a Morse oscillator (see Problem 15B.1). Plot the heat capacity as a function of temperature. Can you devise a way to include the unbound states that lie above the dissociation limit?

**15E.7** Although expressions like  $\langle \epsilon \rangle = -d \ln q / d\beta$  are useful for formal manipulations in statistical thermodynamics, and for expressing

**15E.8(a)** The ground state of the Co<sup>2+</sup> ion in CoSO<sub>4</sub>·7H<sub>2</sub>O may be regarded as <sup>4</sup>T<sub>9/2</sub>. The entropy of the solid at temperatures below 1 K is derived almost entirely from the electron spin. Estimate the molar entropy of the solid at these temperatures.

**15E.8(b)** Estimate the contribution of the spin to the molar entropy of a solid sample of a d-metal complex with  $S = \frac{5}{2}$ .

**15E.9(a)** Predict the standard molar entropy of methanoic acid (formic acid, HCOOH) at (i) 298 K, (ii) 500 K. The normal modes occur at wavenumbers 3570, 2943, 1770, 1387, 1229, 1105, 625, 1033, 638 cm<sup>-1</sup>.

**15E.9(b)** Predict the standard molar entropy of ethyne at (i) 298 K, (ii) 500 K. The normal modes (and their degeneracies in parentheses) occur at wavenumbers 612(2), 729(2), 1974, 3287, and 3374 cm<sup>-1</sup>.

thermodynamic functions in neat formulas, they are sometimes more trouble than they are worth in practical applications. When presented with a table of energy levels, it is often much more convenient to evaluate the following sums directly:

$$q = \sum_j e^{-\beta \epsilon_j} \quad \dot{q} = \sum_j \beta \epsilon_j e^{-\beta \epsilon_j} \quad \ddot{q} = \sum_j (\beta \epsilon_j)^2 e^{-\beta \epsilon_j}$$

(a) Derive expressions for the internal energy, heat capacity, and entropy in terms of these three functions. (b) Apply the technique to the calculation of the electronic contribution to the constant-volume molar heat capacity of magnesium vapour at 5000 K using the following data:

Term	<sup>1</sup> S	<sup>3</sup> P <sub>0</sub>	<sup>3</sup> P <sub>1</sub>	<sup>3</sup> P <sub>2</sub>	<sup>1</sup> P <sub>1</sub>	<sup>3</sup> S <sub>1</sub>
Degeneracy	1	1	3	5	3	3
$\tilde{\nu}$ /cm <sup>-1</sup>	0	21 850	21 870	21 911	35 051	41 197

**15E.8** Show how the heat capacity of a linear rotor is related to the following sum:

$$\xi(\beta) = \frac{1}{q^2} \sum_{J, J'} \{ \epsilon(J) - \epsilon(J') \}^2 g(J') e^{-\beta \{ \epsilon(J) + \epsilon(J') \}}$$

by

$$C = \frac{1}{2} N k \beta^2 \xi(\beta)$$

where the  $\epsilon(J)$  are the rotational energy levels and  $g(J)$  their degeneracies. Then go on to show graphically that the total contribution to the heat capacity of a linear rotor can be regarded as a sum of contributions due to transitions 0 → 1, 0 → 2, 1 → 2, 1 → 3, etc. In this way, construct Fig. 15.1 for the rotational heat capacities of a linear molecule.

**15E.9** Set up a calculation like that in Problem 15E.8 to analyse the vibrational contribution to the heat capacity in terms of excitations between levels and illustrate your results graphically in terms of a diagram like that in Fig. 15.1.

**15E.10** Use the accurate expression for the rotational partition function calculated in Problem 15B.6 for HCl(g) to calculate the rotational contribution to the molar entropy over a range of temperature and plot the contribution as a function of temperature.

**15E.11** Calculate the standard molar entropy of N<sub>2</sub>(g) at 298 K from its rotational constant  $\tilde{B}$  = 1.9987 cm<sup>-1</sup> and its vibrational wavenumber  $\tilde{\nu}$  = 2358 cm<sup>-1</sup>. The thermochemical value is 192.1 J K<sup>-1</sup> mol<sup>-1</sup>. What does this suggest about the solid at  $T = 0$ ?

**Figure 15.1** Contributions to the rotational heat capacity of a linear molecule.

**15E.12\*** J.G. Dojahn et al. (*J. Phys. Chem.* **100**, 9649 (1996)) characterized the potential energy curves of the ground and electronic states of homonuclear diatomic halogen anions. The ground state of  $F_2^-$  is  $^2\Sigma_u^+$  with a fundamental vibrational wavenumber of  $450.0\text{ cm}^{-1}$  and equilibrium internuclear distance of  $190.0\text{ pm}$ . The first two excited states are at  $1.609$  and  $1.702\text{ eV}$  above the ground state. Compute the standard molar entropy of  $F_2^-$  at  $298\text{ K}$ .

**15E.13\*** Treat carbon monoxide as a perfect gas and apply equilibrium statistical thermodynamics to the study of its properties, as specified below, in the temperature range  $100\text{--}1000\text{ K}$  at  $1\text{ bar}$ .  $\tilde{\nu} = 2169.8\text{ cm}^{-1}$ ,  $\tilde{B} = 1.931\text{ cm}^{-1}$ , and  $hcD_0 = 11.09\text{ eV}$ ; neglect anharmonicity and centrifugal distortion.

(a) Examine the probability distribution of molecules over available rotational and vibrational states. (b) Explore numerically the differences, if any, between the rotational molecular partition function as calculated with the discrete energy distribution with that calculated with the classical, continuous energy distribution. (c) Calculate the individual contributions to  $U_m(T) - U_m(100\text{ K})$ ,  $C_{V,m}(T)$ , and  $S_m(T) - S_m(100\text{ K})$  made by the translational, rotational, and vibrational degrees of freedom.

**15E.14** The energy levels of a Morse oscillator are given in Problem 15B.1. Set up the expression for the molar entropy of a collection of Morse oscillators and plot it as a function of temperature for a series of anharmonicities. Take into account only the finite number of bound states. On the same graph plot the entropy of an harmonic oscillator and investigate how the two diverge.

**15E.15** Explore how the entropy of a collection of two-level systems behaves when the temperature is formally allowed to become negative. You should also construct a graph in which the temperature is replaced by the variable  $\beta = 1/kT$ . Account for the appearance of the graphs physically.

**15E.16** Derive the Sackur–Tetrode equation for a monatomic gas confined to a two-dimensional surface, and hence derive an expression for the standard molar entropy of condensation to form a mobile surface film.

**15E.17\*** For  $H_2$  at very low temperatures, only translational motion contributes to the heat capacity. At temperatures above  $\theta^R = hc\tilde{B}/k$ , the rotational contribution to the heat capacity becomes significant. At still higher temperatures, above  $\theta^V = hv/k$ , the vibrations contribute. But at this latter temperature, dissociation of the molecule into the atoms must be considered. (a) Explain the origin of the expressions for  $\theta^R$  and  $\theta^V$ , and calculate their values for hydrogen. (b) Obtain an expression for the molar constant-pressure heat capacity of hydrogen at all temperatures taking into account the dissociation of hydrogen. (c) Make a plot of the molar constant-pressure heat capacity as a function of temperature in the high-temperature region where dissociation of the molecule is significant.

**15E.18** The heat capacity ratio of a gas determines the speed of sound in it through the formula  $c_s = (\gamma RT/M)^{1/2}$ , where  $\gamma = C_p/C_v$  and  $M$  is the molar mass of the gas. Deduce an expression for the speed of sound in a perfect gas of (a) diatomic, (b) linear triatomic, (c) nonlinear triatomic molecules at high temperatures (with translation and rotation active). Estimate the speed of sound in air at  $25^\circ\text{C}$ .

**15E.19** An average human DNA molecule has  $5 \times 10^8$  binucleotides (rungs on the DNA ladder) of four different kinds. If each rung were a random choice of one of these four possibilities, what would be the residual entropy associated with this typical DNA molecule?

**15E.20** It is possible to write an approximate expression for the partition function of a protein molecule by including contributions from only two states: the native and denatured forms of the polymer. Proceeding with this crude model gives us insight into the contribution of denaturation to the heat capacity of a protein. According to this model, the total energy of a system of  $N$  protein molecules is

$$E = \frac{N\epsilon e^{-\epsilon/kT}}{1 + e^{-\epsilon/kT}}$$

where  $\epsilon$  is the energy separation between the denatured and native forms. (a) Show that the constant-volume molar heat capacity is

$$C_{V,m} = f(T)R \quad f(T) = \frac{(\epsilon/kT)^2 e^{-\epsilon/kT}}{(1 + e^{-\epsilon/kT})^2}$$

(b) Plot the variation of  $C_{V,m}$  with temperature. (c) If the function  $C_{V,m}(T)$  has a maximum or minimum, derive an expression for the temperature at which it occurs.

## TOPIC 15F Derived functions

### Discussion questions

**15F.1** Suggest a physical interpretation of the relation between pressure and the partition function.

**15F.2** Suggest a physical interpretation of the relation between equilibrium constant and the partition functions of the reactants and products in a reaction.

### Exercises

**15F.1(a)** A  $CO_2$  molecule is linear, and its vibrational wavenumbers are  $1388.2\text{ cm}^{-1}$ ,  $2349.2\text{ cm}^{-1}$ , and  $667.4\text{ cm}^{-1}$ , the last being doubly degenerate and the others non-degenerate. The rotational constant of the molecule is

**15F.3** How does a statistical analysis of the equilibrium constant account for the latter's temperature dependence?

$0.3902\text{ cm}^{-1}$ . Calculate the rotational and vibrational contributions to the molar Gibbs energy at  $298\text{ K}$ .

**15F.1(b)** An  $\text{O}_3$  molecule is angular, and its vibrational wavenumbers are  $1110\text{ cm}^{-1}$ ,  $705\text{ cm}^{-1}$ , and  $1042\text{ cm}^{-1}$ . The rotational constants of the molecule are  $3.553\text{ cm}^{-1}$ ,  $0.4452\text{ cm}^{-1}$ , and  $0.3948\text{ cm}^{-1}$ . Calculate the rotational and vibrational contributions to the molar Gibbs energy at 298 K.

**15F.2(a)** Use the information in Exercise 15E.3(a) to calculate the electronic contribution to the molar Gibbs energy of Cl atoms at (i) 500 K and (ii) 900 K.

**15F.2(b)** Use the information in Exercise 15E.3(b) to calculate the electronic contribution to the molar Gibbs energy of  $\text{O}_2$  at 400 K.

## Problems

**15F.1** Calculate and plot as a function of temperature, in the range 300 K to 1000 K, the equilibrium constant for the reaction  $\text{CD}_4(\text{g}) + \text{HCl}(\text{g}) \rightleftharpoons \text{CHD}_3(\text{g}) + \text{DCl}(\text{g})$  using the following data (numbers in parentheses are degeneracies):

Molecule	$\tilde{\nu}/\text{cm}^{-1}$	$\tilde{B}/\text{cm}^{-1}$	$\tilde{A}/\text{cm}^{-1}$
$\text{CHD}_3$	2993 (1), 2142 (1), 1003 (3), 1291 (2), 1036 (2)	3.28	2.63
$\text{CD}_4$	2109 (1), 1092 (2), 2259 (3), 996 (3)	2.63	
HCl	2991 (1)	10.59	
DCl	2145 (1)	5.445	

**15F.2** The exchange of deuterium between acid and water is an important type of equilibrium, and we can examine it using spectroscopic data on the molecules. Calculate the equilibrium constant at (a) 298 K and (b) 800 K for the gas-phase exchange reaction  $\text{H}_2\text{O} + \text{DCl} \rightleftharpoons \text{HDO} + \text{HCl}$  from the following data:

Molecule	$\tilde{\nu}/\text{cm}^{-1}$	$\tilde{A}/\text{cm}^{-1}$	$\tilde{B}/\text{cm}^{-1}$	$\tilde{C}/\text{cm}^{-1}$
$\text{H}_2\text{O}$	3656.7, 1594.8, 3755.8	27.88	14.51	9.29
HDO	2726.7, 1402.2, 3707.5	23.38	9.102	6.417
HCl	2991		10.59	
DCl	2145		5.449	

**15F.3** Determine whether a magnetic field can influence the value of an equilibrium constant. Consider the equilibrium  $\text{I}_2(\text{g}) \rightleftharpoons 2\text{I}(\text{g})$  at 1000 K,

**15F.3(a)** Calculate the equilibrium constant of the reaction  $\text{I}_2(\text{g}) \rightleftharpoons 2\text{I}(\text{g})$  at 1000 K from the following data for  $\text{I}_2$ ,  $\tilde{\nu} = 214.36\text{ cm}^{-1}$ ,  $\tilde{B} = 0.0373\text{ cm}^{-1}$ ,  $hc\tilde{D}_e = 1.5422\text{ eV}$ . The ground state of the I atoms is  $^2\text{P}_{3/2}$ , implying fourfold degeneracy.

**15F.3(b)** Calculate the equilibrium constant at 298 K for the gas-phase isotopic exchange reaction  $^{279}\text{Br}^{81}\text{Br} \rightleftharpoons ^{79}\text{Br}^{79}\text{Br} + ^{81}\text{Br}^{81}\text{Br}$ . The  $\text{Br}_2$  molecule has a non-degenerate ground state, with no other electronic states nearby. Base the calculation on the wavenumber of the vibration of  $^{79}\text{Br}^{81}\text{Br}$ , which is  $323.33\text{ cm}^{-1}$ .

and calculate the ratio of equilibrium constants  $K(\mathcal{B})/K$ , where  $K(\mathcal{B})$  is the equilibrium constant when a magnetic field  $\mathcal{B}$  is present and removes the degeneracy of the four states of the  $^2\text{P}_{3/2}$  level. Data on the species are given in Exercise 15F.3(a). The electronic  $g$  value of the atoms is  $\frac{4}{3}$ . Calculate the field required to change the equilibrium constant by 1 per cent.

**15F.4\*** R. Viswanathan et al. (*J. Phys. Chem.* **100**, 10784 (1996)) studied thermodynamic properties of several boron–silicon gas-phase species experimentally and theoretically. These species can occur in the high-temperature chemical vapour deposition (CVD) of silicon-based semiconductors. Among the computations they reported was computation of the Gibbs energy of  $\text{BSi}(\text{g})$  at several temperatures based on a  $^4\Sigma^-$  ground state with equilibrium internuclear distance of 190.5 pm and fundamental vibrational wavenumber of  $772\text{ cm}^{-1}$  and a  $^2\text{P}_0$  first excited level  $8000\text{ cm}^{-1}$  above the ground level. Compute the standard molar Gibbs energy  $G_m^\ominus(2000\text{ K}) - G_m^\ominus(0)$ .

**15F.5\*** The molecule  $\text{Cl}_2\text{O}_2$ , which is believed to participate in the seasonal depletion of ozone over Antarctica, has been studied by several means. M. Birk et al. (*J. Chem. Phys.* **91**, 6588 (1989)) report its rotational constants ( $B$ ) as 13 109.4, 2409.8, and 2139.7 MHz. They also report that its rotational spectrum indicates a molecule with a symmetry number of 2. J. Jacobs et al. (*J. Amer. Chem. Soc.* **116**, 1106 (1994)) report its vibrational wavenumbers as 753, 542, 310, 127, 646, and  $419\text{ cm}^{-1}$ . Compute  $G_m^\ominus(200\text{ K}) - G_m^\ominus(0)$  of  $\text{Cl}_2\text{O}_2$ .

**15F.6\*** J. Hutter et al. (*J. Amer. Chem. Soc.* **116**, 750 (1994)) examined the geometric and vibrational structure of several carbon molecules of formula  $\text{C}_n$ . Given that the ground state of  $\text{C}_3$ , a molecule found in interstellar space and in flames, is an angular singlet with moments of inertia 39.340, 39.032, and  $0.3082m_u\text{ \AA}^2$  (where  $1\text{ \AA} = 10^{-10}\text{ m}$ ) and with vibrational wavenumbers of 63.4, 1224.5, and  $2040\text{ cm}^{-1}$ , compute  $G_m^\ominus(10.0\text{ K}) - G_m^\ominus(0)$  and  $G_m^\ominus(100.0\text{ K}) - G_m^\ominus(0)$  for  $\text{C}_3$ .

## Integrated activity

**15.1** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site for this book to: (a) Consider a three-level system with levels 0,  $\epsilon$ , and  $2\epsilon$ . Plot the partition function against  $kT/\epsilon$ . (b) Plot the function  $dS/dT$  for a two-level system, the temperature coefficient of its entropy, against  $kT/\epsilon$ . Is there a temperature at which this coefficient passes through a maximum? If you find

a maximum, explain its physical origins. (c) Plot the temperature dependence of the vibrational contribution to the molecular partition function for several values of the vibrational wavenumber. Estimate from your plots the temperature above which the harmonic oscillator is in the high-temperature limit.

# CHAPTER 16

## Molecular interactions

In this chapter we examine molecular interactions and interpret them in terms of electric properties of molecules. We see here, and in more detail in Chapter 17, that molecular interactions govern the structures and functions of molecular assemblies.

### 16A Electric properties of molecules

The chapter begins with an account of the electric properties of molecules, such as ‘electric dipole moments’ and ‘polarizabilities’. All these properties reflect the degree to which the nuclei of atoms exert control over the electrons in a molecule, either by causing electrons to accumulate in particular regions, or by permitting them to respond more or less strongly to the effects of external electric fields.

### 16B Interactions between molecules

This Topic describes the basic theory of several important molecular interactions, with a special focus on ‘van der Waals interactions’ between closed-shell molecules. Also discussed are ‘hydrogen bonding’ and the ‘hydrophobic interaction’. All liquids and solids are bound together by one or more of the cohesive interactions we explore in this Topic. Moreover, these interactions are also important for the structural organization of macromolecules.

### 16C Liquids

This Topic begins with the basic theory of molecular interactions in liquids, then turns to a description of the properties of liquid surfaces. We see how important effects, such as ‘surface tension’, ‘capillary action’, the formation of ‘surface films’, and condensation, can be explained by thermodynamics arguments.

### What is the impact of this material?

Molecular interactions play important roles in biochemistry and biomedicine. In *Impact* I16.1 we focus on the binding of a drug, a small molecule or protein, to a specific receptor site of a target molecule, such as a larger protein or nucleic acid. The chemical result of the formation of this assembly is the inhibition of the progress of disease. We also discuss (in *Impact* I16.2) an example where manipulation of molecular interactions could have significant technological consequences: the design of assemblies that can store and deliver hydrogen gas efficiently, thereby making it a viable fuel for commercial development of a host of devices.

### ► Why do you need to know this material?

Because the molecular interactions responsible for the formation of condensed phases and large molecular assemblies arise from the electric properties of molecules, you need to know how the electronic structures of molecules lead to these properties.

### ► What is the key idea?

The nuclei of atoms exert control over the electrons in a molecule, and can cause electrons to accumulate in particular regions, or permit them to respond more or less strongly to external fields.

### ► What do you need to know already?

You need to be familiar with the Coulomb law (*Foundations B*), molecular geometry, and molecular orbital theory, especially the relevance of the energy gap between a HOMO and LUMO (Topic 10E).

The electric properties of molecules are responsible for many of the properties of bulk matter. The small imbalances of charge distributions in molecules allow them to interact with one another and to respond to externally applied fields.

## 16A.1 Electric dipole moments

An **electric dipole** consists of two electric charges  $+Q$  and  $-Q$  with a separation  $R$ . A **point electric dipole** is an electric dipole in which  $R$  is very small compared with its distance from the observer. The **electric dipole moment** is a vector  $\mu$  (1) that points from the negative charge to the positive charge and has a magnitude given by

$$\mu = QR \quad \text{Definition} \quad \text{Magnitude of the electric dipole moment} \quad (16A.1)$$

Although the SI unit of dipole moment is coulomb metre (C m), it is still commonly reported in the non-SI unit debye, D, named after Peter Debye, a pioneer in the study of dipole moments of molecules:

$$1\text{D} = 3.335\,64 \times 10^{-30} \text{C m} \quad (16A.2)$$

The magnitude of the dipole moment formed by a pair of charges  $+e$  and  $-e$  separated by 100 pm is  $1.6 \times 10^{-29} \text{C m}$ , corresponding to 4.8 D. The magnitudes of the dipole moments of small molecules are typically about 1 D.<sup>1</sup>

A **polar molecule** is a molecule with a permanent electric dipole moment. A **permanent dipole moment** stems from the partial charges on the atoms in the molecule that arise from differences in electronegativity or, in more sophisticated treatments, variations in electron density through the molecule (Topic 10E). Nonpolar molecules acquire an **induced dipole moment** in an electric field on account of the distortion the field causes in their electronic distributions and nuclear positions. However, this induced moment is only temporary, and disappears as soon as the perturbing field is removed. Polar molecules also have their existing dipole moments temporarily modified by an applied field.

All heteronuclear diatomic molecules are polar, and typical values of  $\mu$  are 1.08 D for HCl and 0.42 D for HI (Table 16A.1). Molecular symmetry is of the greatest importance in deciding

<sup>1</sup> The conversion factor in eqn 16A.2 stems from the original definition of the debye in terms of c.g.s. units: 1 D is the dipole moment of two equal and opposite charges of magnitude 1 e.s.u. separated by 1 Å.

**Table 16A.1\*** Dipole moments ( $\mu$ ) and polarizability volumes ( $\alpha'$ )

	$\mu/\text{D}$	$\alpha'/(10^{-30} \text{ m}^3)$
$\text{CCl}_4$	0	10.5
$\text{H}_2$	0	0.819
$\text{H}_2\text{O}$	1.85	1.48
$\text{HCl}$	1.08	2.63
$\text{HI}$	0.42	5.45

\* More values will be found in the *Resource section*.

whether a polyatomic molecule is polar or not (see also Topic 11A). Indeed, molecular symmetry is more important than the question of whether or not the atoms in the molecule belong to the same element. For this reason, and as we see in the following *Brief illustration*, homonuclear polyatomic molecules may be polar if they have low symmetry and the atoms are in inequivalent positions.

#### Brief illustration 16A.1 Symmetry and the polarity of molecules

The angular molecule ozone (2) is homonuclear. However, it is polar because the central O atom is different from the outer two (it is bonded to two atoms, which are bonded only to one). Moreover, the dipole moments associated with each bond make an angle to each other and do not cancel. The heteronuclear linear triatomic molecule  $\text{CO}_2$  is nonpolar because, although there are partial charges on all three atoms, the dipole moment associated with the OC bond points in the opposite direction to the dipole moment associated with the CO bond, and the two cancel (3).

**Self-test 16A.1** Is  $\text{SO}_2$  polar?

Answer: Yes

The dipole moment of a polyatomic molecule can be resolved into contributions from various groups of atoms in the molecule and their relative locations (Fig. 16A.1). Thus, 1,4-dichlorobenzene is nonpolar by symmetry on account of the cancellation of two equal but opposing C–Cl moments (exactly as in carbon dioxide). 1,2-Dichlorobenzene, however, has a dipole moment which is approximately the resultant of two chlorobenzene dipole moments arranged at  $60^\circ$  to each other. This technique of ‘vector addition’ can be applied with fair success to other series of related molecules, and the magnitude of the resultant moment  $\mu_{\text{res}}$  of  $\mu_1$  and  $\mu_2$  that make an

**Figure 16A.1** The resultant dipole moments (purple in (c) and (d)) of the dichlorobenzene isomers, (b) to (d), can be obtained approximately by vectorial addition of two chlorobenzene dipole moments (shown in (a), with  $\mu_{\text{obs}} = 1.57 \text{ D}$ ). (The point groups of the molecules are also indicated.)

angle  $\theta$  to each other (4) is approximately (see *Mathematical background 5* following Chapter 9)

$$\mu_{\text{res}} \approx (\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos \theta)^{1/2} \quad (16A.3a)$$

4 Addition of dipole moments

When the two contributing dipole moments have the same magnitude (as in the dichlorobenzenes), this equation simplifies to

$$\mu_{\text{res}} \approx \{2\mu_1^2(1 + \cos \theta)\}^{1/2} \stackrel{1 + \cos \theta = 2\cos^2 \frac{1}{2}\theta}{=} 2\mu_1 \cos \frac{1}{2}\theta \quad (16A.3b)$$

#### Brief illustration 16A.2 Molecular dipole moments

Consider *ortho* (1,2-) and *meta* (1,3-) disubstituted benzenes, for which  $\theta_{\text{ortho}} = 60^\circ$  and  $\theta_{\text{meta}} = 120^\circ$ . It follows from eqn 16A.3b that the ratio of the magnitudes of the electric dipole moments is:

$$\frac{\mu_{\text{res,ortho}}}{\mu_{\text{res,meta}}} = \frac{\cos \frac{1}{2}\theta_{\text{ortho}}}{\cos \frac{1}{2}\theta_{\text{meta}}} = \frac{\cos \frac{1}{2}(60^\circ)}{\cos \frac{1}{2}(120^\circ)} = \frac{3^{1/2}/2}{1/2} = 3^{1/2} \approx 1.7$$

**Self-test 16A.2** Calculate the resultant of two dipole moments of magnitude 1.5 D and 0.80 D that make an angle of  $109.5^\circ$  to each other.

Answer: 1.4 D

A more reliable approach to the calculation of dipole moments is to take into account the locations and magnitudes of the partial charges on all the atoms. These partial charges are included in the output of many molecular structure software packages. To calculate the  $x$ -component, for instance, we need to know the partial charge on each atom and the atom's  $x$ -coordinate relative to a point in the molecule and form the sum

$$\mu_x = \sum_j Q_j x_j \quad (16A.4a)$$

Here  $Q_j$  is the partial charge of atom  $J$ ,  $x_j$  is the  $x$ -coordinate of atom  $J$ , and the sum is over all the atoms in the molecule. Analogous expressions are used for the  $y$ - and  $z$ -components. For an electrically neutral molecule, the origin of the coordinates is arbitrary, so it is best chosen to simplify the measurements. In common with all vectors, the magnitude of  $\mu$  is related to the three components  $\mu_x$ ,  $\mu_y$ , and  $\mu_z$  by

$$\mu = (\mu_x^2 + \mu_y^2 + \mu_z^2)^{1/2} \quad (16A.4b)$$

### Example 16A.1 Calculating a molecular dipole moment

Estimate the magnitude and orientation of the electric dipole moment of the amide group shown in 5 by using the partial charges (as multiples of  $e$ ) and the locations of the atoms shown, with distances in picometres.

**Method** Use eqn 16A.4a to calculate each of the components of the dipole moment and then eqn 16A.4b to assemble the three components into the magnitude of the dipole moment. Note that the partial charges are multiples of the fundamental charge,  $e = 1.609 \times 10^{-19}$  C.

**Answer** The expression for  $\mu_x$  is

$$\begin{aligned} \mu_x &= (-0.36e) \times (132 \text{ pm}) + (0.45e) \times (0 \text{ pm}) + (0.18e) \times (182 \text{ pm}) \\ &\quad + (-0.38e) \times (-62.0 \text{ pm}) \\ &= 8.8e \text{ pm} \\ &= 8.8 \times (1.602 \times 10^{-19} \text{ C}) \times (10^{-12} \text{ m}) = 1.4 \times 10^{-30} \text{ C m} \end{aligned}$$

corresponding to  $\mu_x = +0.42$  D. The expression for  $\mu_y$  is:

$$\begin{aligned} \mu_y &= (-0.36e) \times (0 \text{ pm}) + (0.45e) \times (0 \text{ pm}) + (0.18e) \times (-87 \text{ pm}) \\ &\quad + (-0.38e) \times (107 \text{ pm}) \\ &= -56e \text{ pm} \\ &= -19.0 \times 10^{-30} \text{ C m} \end{aligned}$$

It follows that  $\mu_y = -2.7$  D. The amide group is planar, so  $\mu_z = 0$  and

$$\mu = \{(0.42 \text{ D})^2 + (-2.7 \text{ D})^2\}^{1/2} = 2.7 \text{ D}$$

We can find the orientation of the dipole moment by arranging an arrow of length 2.7 units of length to have  $x$ ,  $y$ , and  $z$  components of 0.42,  $-2.7$ , and 0 units; the orientation is superimposed on 5.

**Self-test 16A.3** Calculate the magnitude of the electric dipole moment of formaldehyde by using the information in 6.

Answer: 2.3 D

Molecules may have higher **multipoles**, or arrays of point charges (Fig. 16A.2). Specifically, an  **$n$ -pole** is an array of point charges with an  $n$ -pole moment but no lower moment. Thus, a **monopole** ( $n=1$ ) is a point charge, and the monopole moment is what we normally call the overall charge. A **dipole** ( $n=2$ ), as we have seen, is an array of charges that has no monopole moment (no net charge). A **quadrupole** ( $n=3$ ) consists of an array of point charges that has neither net charge nor dipole moment (as for  $\text{CO}_2$  molecules, 3). An **octupole** ( $n=4$ ) consists of an array of point charges that sum to zero and which has neither a dipole moment nor a quadrupole moment (as for  $\text{CH}_4$  molecules, 7).

**Figure 16A.2** Typical charge arrays corresponding to electric multipoles. The field arising from an arbitrary finite charge distribution can be expressed as the superposition of the fields arising from a superposition of multipoles.

## 16A.2 Polarizabilities

The failure of nuclear charges to control the surrounding electrons totally means that those electrons can respond to external fields. Therefore, an applied electric field can distort a molecule as well as align its permanent electric dipole moment. The magnitude  $\mu^*$  of the **induced dipole moment**,  $\mu^*$ , is generally proportional to the field strength,  $\mathcal{E}$ , and we write

$$\mu^* = \alpha \mathcal{E} \quad \text{Definition} \quad \text{Polarizability} \quad (16A.5a)$$

The constant of proportionality  $\alpha$  is the **polarizability** of the molecule. The greater the polarizability, the larger is the induced dipole moment for a given applied field. In a formal treatment, we should use vector quantities and allow for the possibility that the induced dipole moment might not lie parallel to the applied field, in which case the scalar  $\alpha$  is replaced by  $\boldsymbol{\alpha}$ , a  $3 \times 3$  matrix. We ignore this complication.

When the applied field is very strong (as in tightly focused laser beams), the magnitude of the induced dipole moment is not strictly linear in the strength of the field, and we write

$$\mu^* = \alpha \mathcal{E} + \frac{1}{2} \beta \mathcal{E}^2 + \dots \quad \text{Definition} \quad \text{Hyperpolarizability} \quad (16A.5b)$$

The coefficient  $\beta$  is the (first) **hyperpolarizability** of the molecule.

Polarizability has the units (coulomb metre)<sup>2</sup> per joule ( $\text{C}^2 \text{m}^2 \text{J}^{-1}$ ). That collection of units is awkward, so  $\alpha$  is often expressed as a **polarizability volume**,  $\alpha'$  by using the relation

$$\alpha' = \frac{\alpha}{4\pi\epsilon_0} \quad \text{Definition} \quad \text{Polarizability volume} \quad (16A.6)$$

where  $\epsilon_0$  is the vacuum permittivity (*Foundations B*). Because the units of  $4\pi\epsilon_0$  are coulomb-squared per joule per metre ( $\text{C}^2 \text{J}^{-1} \text{m}^{-1}$ ), it follows that  $\alpha'$  has the dimensions of volume (hence its name). Polarizability volumes are similar in magnitude to actual molecular volumes (of the order of  $10^{-30} \text{m}^3$ ,  $10^{-3} \text{nm}^3$ ,  $1 \text{\AA}^3$ ).

### Brief illustration 16A.3 The induced dipole moment

The polarizability volume of  $\text{H}_2\text{O}$  is  $1.48 \times 10^{-30} \text{m}^3$ . It follows from eqns 16A.4a and 16A.5 that  $\mu^* = 4\pi\epsilon_0 \alpha' \mathcal{E}$  and the magnitude of the dipole moment of the molecule (in addition to the permanent dipole moment) induced by an applied electric field of strength  $1.0 \times 10^5 \text{V m}^{-1}$  is

$$\mu^* = 4\pi \times (8.854 \times 10^{-12} \text{J}^{-1} \text{C}^2 \text{m}^{-1}) \times (1.48 \times 10^{-30} \text{m}^3) \\ \times (1.0 \times 10^5 \text{J C}^{-1} \text{m}^{-1})$$

$1 \text{V} = 1 \text{J C}^{-1}$

$$\hat{=} 31.6 \times 10^{-35} \text{C m} = 4.9 \times 10^{-6} \text{D} = 4.9 \mu\text{D}$$

**Self-test 16A.4** What strength of electric field is required to induce an electric dipole moment of magnitude  $1.0 \mu\text{D}$  in a molecule of polarizability volume  $2.6 \times 10^{-30} \text{m}^3$  (like  $\text{CO}_2$ )?

Answer:  $11 \text{kV m}^{-1}$

The polarizability volumes of some molecules are given in Table 16A.1. As shown in the following *Justification*, polarizability volumes correlate with the HOMO–LUMO separations in atoms and molecules (Topic 10E). The electron distribution can be distorted readily if the LUMO lies close to the HOMO in energy, so the polarizability is then large. If the LUMO lies high above the HOMO, an applied field cannot perturb the electron distribution significantly, and the polarizability is low. Molecules with small HOMO–LUMO gaps are typically large, and have numerous electrons.

### Justification 16A.1 Polarizability and molecular structure

The quantum mechanical expression for the molecular polarizability in the  $z$ -direction is<sup>2</sup>

$$\alpha = 2 \sum_{n \neq 0} \frac{|\mu_{z,n0}|^2}{E_n^{(0)} - E_0^{(0)}}$$

where  $\mu_{z,n0} = \int \psi_n^* \hat{\mu}_z \psi_0 d\tau$  is the  $z$ -component of the *transition* electric dipole moment, a measure of the extent to which electric charge is shifted when an electron migrates from the ground state to create an excited state. The sum is over the excited states, with energies  $E_n$ . The content of this equation can be appreciated by approximating the excitation energies by a mean value  $\Delta E$  (an indication of the HOMO–LUMO separation) and supposing that the most important transition dipole moment is approximately equal to the charge of an electron multiplied by the molecular radius  $R$ . Then

$$\alpha \approx \frac{2e^2 R^2}{\Delta E}$$

This expression shows that  $\alpha$  increases with the size of the molecule and with the ease with which it can be excited (the smaller the value of  $\Delta E$ ).

If the excitation energy is approximated by the energy needed to remove an electron to infinity from a distance  $R$  from a single positive charge, we can write  $\Delta E \approx e^2/4\pi\epsilon_0 R$ . When this expression is substituted into  $\alpha \approx 2e^2 R^2/\Delta E$  to obtain  $\alpha \approx 2(4\pi\epsilon_0)R^3$ , then both sides are divided by  $4\pi\epsilon_0$  and the factor of 2 ignored in this approximation, we obtain  $\alpha' \approx R^3$ , which is of the same order of magnitude as the molecular volume.

<sup>2</sup> For a derivation of this equation see our *Physical chemistry: Quanta, matter, and change* (2014).

For most molecules, the polarizability is anisotropic, by which is meant that its value depends on the orientation of the molecule relative to the field. The polarizability volume of benzene when the field is applied perpendicular to the ring is  $0.0067 \text{ nm}^3$  and it is  $0.0123 \text{ nm}^3$  when the field is applied in the plane of the ring. The anisotropy of the polarizability determines whether a molecule is rotationally Raman active (Topic 12C).

### 16A.3 Polarization

The **polarization**,  $P$ , of a sample is the electric dipole moment density, the mean electric dipole moment of the molecules,  $\langle \mu \rangle$ , multiplied by the number density,  $\mathcal{N}$ :

$$P = \langle \mu \rangle \mathcal{N} \quad \text{Definition} \quad \text{Polarization} \quad (16A.7)$$

In the following pages we refer to the sample as a **dielectric**, by which is meant a polarizable, non-conducting medium.

#### (a) The frequency dependence of the polarization

The polarization of an isotropic fluid sample is zero in the absence of an applied field because the molecules adopt ceaselessly changing random orientations due to thermal motion, so  $\langle \mu \rangle = 0$ . In the presence of a weak electric field, the orientations of the molecular dipoles fluctuate but we show in the following *Justification* that the mean value of the dipole moment for the sample at a temperature  $T$  is

$$\langle \mu_z \rangle = \frac{\mu^2 \mathcal{E}}{3kT} \quad \text{Weak electric field} \quad \text{Mean value of the dipole moment} \quad (16A.8)$$

where  $z$  is the direction of the applied field  $\mathcal{E}$ . At very high electric fields the orientations of molecular dipole moments fluctuate about the field direction to a lesser extent and the mean dipole moment approaches its maximum value of  $\langle \mu_z \rangle = \mu$ .

#### Justification 16A.2 The thermally averaged dipole moment

The probability  $dp$  that a dipole has an orientation in the range  $\theta$  to  $\theta + d\theta$  is given by the Boltzmann distribution (Topic 15A), which in this case is

$$dp = \frac{e^{-E(\theta)/kT} \sin \theta d\theta}{\int_0^\pi e^{-E(\theta)/kT} \sin \theta d\theta}$$

where  $E(\theta)$  is the energy of the dipole in the field:  $E(\theta) = -\mu\mathcal{E} \cos \theta$ , with  $0 \leq \theta \leq \pi$ . The average value of the component of the dipole moment parallel to the applied electric field is therefore

$$\langle \mu_z \rangle = \int \mu \cos \theta dp = \mu \int \cos \theta d\theta = \frac{\mu \int_0^\pi e^{x \cos \theta} \cos \theta \sin \theta d\theta}{\int_0^\pi e^{x \cos \theta} \sin \theta d\theta}$$

with  $x = \mu\mathcal{E}/kT$ . The integral takes on a simpler appearance when we write  $y = \cos \theta$  and  $dy = -\sin \theta d\theta$ , and change the limits of integration to  $y = -1$  (at  $\theta = \pi$ ) and  $y = 1$  (at  $\theta = 0$ ):

$$\langle \mu_z \rangle = \frac{\mu \int_{-1}^1 y e^{xy} dy}{\int_{-1}^1 e^{xy} dy}$$

Integral E.4  
Integral E.3

It is then straightforward algebra to obtain

$$\langle \mu_z \rangle = \mu L(x) \quad L(x) = \frac{e^x + e^{-x}}{e^x - e^{-x}} - \frac{1}{x} \quad x = \frac{\mu\mathcal{E}}{kT}$$

$L(x)$  is called the **Langevin function**.

Under most circumstances,  $x$  is very small (for example, if  $\mu = 1 \text{ D}$  and  $T = 300 \text{ K}$ , then  $x$  exceeds 0.01 only if the field strength exceeds  $100 \text{ kV cm}^{-1}$ , and most measurements are done at much lower strengths). The exponentials in the Langevin function can be expanded as  $e^x = 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \dots$  when the field is so weak that  $x \ll 1$ , the largest term that survives is

$$L(x) = \frac{1}{3}x + \dots$$

Therefore, the average molecular dipole moment is given by eqn 16A.8.

When the applied field changes direction slowly, the permanent dipole moment has time to reorient—the whole molecule rotates into a new direction—and follows the field. However, when the frequency of the field is high, a molecule cannot change direction fast enough to follow the change in direction of the applied field and the permanent dipole moment then makes no contribution to the polarization of the sample. We say that the **orientation polarization**, the polarization arising from the permanent dipole moments, is lost at such high frequencies. Because a molecule takes about 1 ps to turn through about 1 radian in a fluid, the loss of the contribution of orientation polarization to the total polarization occurs when measurements are made at frequencies greater than about  $10^{11} \text{ Hz}$  (in the microwave region).

The next contribution to the polarization to be lost as the frequency is raised is the **distortion polarization**, the polarization that arises from the distortion of the positions of the nuclei by the applied field. The molecule is bent and stretched by the applied field, and the molecular dipole moment changes accordingly. The time taken for a molecule to bend is approximately the inverse of the molecular

vibrational frequency, so the distortion polarization disappears when the frequency of the radiation is increased through the infrared.

The disappearance of polarization occurs in stages: as shown in the following *Justification*, each successive stage occurs as the incident frequency rises above the frequency of a particular mode of vibration. At even higher frequencies, in the visible region, only the electrons are mobile enough to respond to the rapidly changing direction of the applied field. The polarization that remains is now due entirely to the distortion of the electron distribution, and the surviving contribution to the molecular polarizability is called the **electronic polarizability**.

### Justification 16A.3 The frequency dependence of polarizabilities

The quantum mechanical expression for the polarizability of a molecule in the presence of an electric field that is oscillating at a frequency  $\omega$  in the  $z$ -direction is<sup>3</sup>

$$\alpha(\omega) = \frac{2}{\hbar} \sum_{n \neq 0} \frac{\omega_{n0} |\mu_{z,0n}|^2}{\omega_{n0}^2 - \omega^2}$$

The quantities in this expression (which is valid provided that  $\omega$  is not close to  $\omega_{n0}$ ) are the same as those in *Justification* 16A.1, with  $\hbar\omega_{n0} = E_n - E_0$ . As  $\omega \rightarrow 0$ , the equation reduces to the expression for the static polarizability in *Justification* 16A.1. As  $\omega$  becomes very high (and much higher than any excitation frequency of the molecule so that the  $\omega_{n0}^2$  in the denominator can be ignored), the polarizability becomes

$$\alpha(\omega) = -\frac{2}{\hbar\omega^2} \sum_n \omega_{n0} |\mu_{0n}|^2 \rightarrow 0 \quad \text{as } \omega \rightarrow \infty$$

That is, when the incident frequency is much higher than any excitation frequency, the polarizability becomes zero. The argument applies to each type of excitation, vibrational as well as electronic, and accounts for the successive decreases in polarizability as the frequency is increased.

### (b) Molar polarization

When two charges  $Q_1$  and  $Q_2$  are separated by a distance  $r$  in a vacuum, the Coulomb potential energy of their interaction is (*Foundations* B)

$$V = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \quad (16A.9a)$$

<sup>3</sup> For a derivation of this equation see our *Physical chemistry: Quanta, matter, and change* (2014).

When the same two charges are immersed in a medium (such as air or a liquid), their potential energy is reduced to

$$V = \frac{Q_1 Q_2}{4\pi\epsilon r} \quad (16A.9b)$$

where  $\epsilon$  is the **permittivity** of the medium. The permittivity is normally expressed in terms of the dimensionless **relative permittivity**,  $\epsilon_r$  (formerly and still widely called the *dielectric constant*) of the medium:

$$\epsilon_r = \frac{\epsilon}{\epsilon_0} \quad \text{Definition Relative permittivity} \quad (16A.10)$$

The relative permittivity can have a very significant effect on the strength of the interactions between ions in solution. For instance, water has a relative permittivity of 78 at 25°C, so the interionic Coulombic interaction energy is reduced by nearly two orders of magnitude from its vacuum value. Some of the consequences of this reduction for electrolyte solutions are explored in Topic 5F.

The relative permittivity of a substance is large if its molecules are polar or highly polarizable. The quantitative relation between the relative permittivity and the electric properties of the molecules is obtained by considering the polarization of a medium, and is expressed by the **Debye equation**:

$$\frac{\epsilon_r - 1}{\epsilon_r + 2} = \frac{\rho P_m}{M} \quad \text{Debye equation} \quad (16A.11)$$

where  $\rho$  is the mass density of the sample,  $M$  is the molar mass of the molecules, and  $P_m$  is the **molar polarization**, which is defined as

$$P_m = \frac{N_A}{3\epsilon_0} \left( \alpha + \frac{\mu^2}{3kT} \right) \quad \text{Definition Molar polarization} \quad (16A.12)$$

(where  $\alpha$  is the polarizability, not the polarizability volume  $\alpha'$ ). The term  $\mu^2/3kT$  stems from the thermal averaging of the electric dipole moment in the presence of the applied field (eqn 16A.8). The corresponding expression without the contribution from the permanent dipole moment is called the **Clausius–Mossotti equation**:

$$\frac{\epsilon_r - 1}{\epsilon_r + 2} = \frac{\rho N_A \alpha}{3M\epsilon_0} \quad \text{Clausius–Mossotti equation} \quad (16A.13)$$

The Clausius–Mossotti equation is used when there is no contribution from permanent electric dipole moments to the polarization, either because the molecules are non-polar or because the frequency of the applied field is so high that the molecules cannot orientate quickly enough to follow the change in direction of the field.

**Example 16A.2** Determining dipole moment and polarizability

The relative permittivity of a substance is measured by comparing the capacitance of a capacitor with and without the sample present ( $C$  and  $C_0$ , respectively) and using  $\epsilon_r = C/C_0$ . The relative permittivity of camphor (8) was measured at a series of temperatures with the results given below. Determine the dipole moment and the polarizability volume of the molecule.

**8** Camphor

$\theta/^\circ\text{C}$	$\rho/(\text{g cm}^{-3})$	$\epsilon_r$
0	0.99	12.5
20	0.99	11.4
40	0.99	10.8
60	0.99	10.0
80	0.99	9.50
100	0.99	8.90
120	0.97	8.10
140	0.96	7.60
160	0.95	7.11
200	0.91	6.21

**Method** The relative permittivity depends on the molar polarization (eqn 16A.11), which in turn depends on the temperature, polarizability, and the magnitude of the permanent dipole moment (eqn 16A.12). It follows that the polarizability and permanent electric dipole moment of the molecules in a sample can be determined by:

- Measuring  $\epsilon_r$  at a series of temperatures, calculate  $(\epsilon_r - 1)/(\epsilon_r + 2)$  at each temperature, and then multiply by  $M/\rho$  to form  $P_m$  from eqn 16A.11;
- Plotting  $P_m$  against  $1/T$ . Because eqn 16A.16 rearranges to

$$P_m = \frac{\overbrace{N_A \alpha}^{\text{intercept}}}{3\epsilon_0} + \frac{\overbrace{N_A \mu^2}^{\text{slope}}}{9\epsilon_0 k} \times \frac{1}{T}$$

The slope of the graph is  $N_A \mu^2 / 9\epsilon_0 k$  and its intercept at  $1/T = 0$  is  $N_A \alpha / 3\epsilon_0$ .

**Answer** For camphor,  $M = 152.23 \text{ g mol}^{-1}$ . We can therefore use the data to draw up the following table:

$\theta/^\circ\text{C}$	$(10^3 \text{ K})/T$	$\epsilon_r$	$(\epsilon_r - 1)/(\epsilon_r + 2)$	$P_m/(\text{cm}^3 \text{ mol}^{-1})$
0	3.66	12.5	0.793	122
20	3.41	11.4	0.776	119
40	3.19	10.8	0.766	118
60	3.00	10.0	0.750	115
80	2.83	9.50	0.739	114
100	2.68	8.90	0.725	111
120	2.54	8.10	0.703	110
140	2.42	7.60	0.688	109
160	2.31	7.11	0.670	107
200	2.11	6.21	0.634	106

The points are plotted in Fig. 16A.3. The intercept on the vertical axis lies at  $P_m/(\text{cm}^3 \text{ mol}^{-1}) = 82.9$ , so  $N_A \alpha / 3\epsilon_0 = 82.9 \text{ cm}^3 \text{ mol}^{-1} = 8.29 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}$ ; it then follows that

$$\alpha = \frac{3 \times \overbrace{(8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1})}^{\epsilon_0}}{\underbrace{6.02 \times 10^{23} \text{ mol}^{-1}}_{N_A}} \times \overbrace{8.29 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1}}^{\text{intercept}}$$

$$= 3.53 \times 10^{-38} \text{ C}^2 \text{ m}^2 \text{ J}^{-1}$$

**Figure 16A.3** The plot of  $P_m/(\text{cm}^3 \text{ mol}^{-1})$  against  $(10^3 \text{ K})/T$  used in Example 16A.2 for the determination of the polarizability and the magnitude of the dipole moment of camphor.

From eqn 16A.6, it follows that  $\alpha' = 3.18 \times 10^{-28} \text{ m}^3 = 3.18 \times 10^{-23} \text{ cm}^3$ . The slope is 10.7, so  $N_A \mu^2 / 9\epsilon_0 k = 10.7 \text{ cm}^3 \text{ mol}^{-1} \text{ K} = 1.07 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1} \text{ K}$ , so from the expression for  $P_m$  in the Method it follows that

$$\mu = \left( \frac{9 \times \overbrace{(8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1})}^{\epsilon_0} \times \overbrace{(1.381 \times 10^{-23} \text{ J K}^{-1})}^k}{\underbrace{6.022 \times 10^{23} \text{ mol}^{-1}}_{N_A}} \right)^{1/2}$$

$$\times \left( \overbrace{1.07 \times 10^{-4} \text{ m}^3 \text{ mol}^{-1} \text{ K}}^{\text{slope}} \right)^{1/2}$$

$$= 4.42 \times 10^{-31} \text{ C m} = 0.134 \text{ D}$$

Because the Debye equation describes molecules that are free to rotate, the data show that camphor, which does not melt until 175 °C, is rotating even in the solid. It is an approximately spherical molecule.

**Self-test 16A.5** The relative permittivity of chlorobenzene is 5.71 at 20 °C and 5.62 at 25 °C. Assuming a constant density (1.11 g cm<sup>-3</sup>), estimate its polarizability volume and the magnitude of its dipole moment.

Answer:  $1.4 \times 10^{-23}$  cm<sup>3</sup>, 1.2 D

According to Maxwell's theory of electromagnetic radiation, the refractive index at a (visible or ultraviolet) specified

wavelength is related to the relative permittivity at that frequency by:

$$n_r = \epsilon_r^{1/2} \quad \text{Relation between refractive index and relative permittivity} \quad (16A.14)$$

where the refractive index,  $n_r$ , of the medium is the ratio of the speed of light in a vacuum,  $c$ , to its speed  $c'$  in the medium:  $n_r = c/c'$ . A beam of light changes direction ('bends') when it passes from a region of one refractive index to a region with a different refractive index. Therefore, the molar polarization,  $P_m$ , and the molecular polarizability,  $\alpha$ , can be measured at frequencies typical of visible light (about  $10^{15}$  to  $10^{16}$  Hz) by measuring the refractive index of the sample and using the Clausius–Mossotti equation.

## Checklist of concepts

- 1. An **electric dipole** consists of two electric charges  $+Q$  and  $-Q$  separated by a vector  $R$ .
- 2. The **electric dipole moment**  $\mu$  is a vector that points from the negative charge to the positive charge of a dipole; its magnitude is  $\mu$ .
- 3. A **polar molecule** is a molecule with a permanent electric dipole moment.
- 4. Molecules may have higher electric multipoles: an ***n*-pole** is an array of point charges with an  $n$ -pole moment but no lower moment.
- 5. The **polarizability** is a measure of the ability of an electric field to induce a dipole moment in a molecule.
- 6. **Polarizabilities** (and polarizability volumes) correlate with the HOMO–LUMO separations in atoms and molecules.
- 7. For most molecules, the polarizability is anisotropic.
- 8. The **polarization** of a medium is the electric dipole moment density.
- 9. **Orientation polarization** is the polarization arising from the permanent dipole moments.
- 10. **Distortion polarization** is the polarization arising from the distortion of the positions of the nuclei by the applied field.
- 11. **Electronic polarizability** is the polarizability due to the distortion of the electron distribution.

## Checklist of equations

Property	Equation	Comment	Equation number
Magnitude of the electric dipole moment	$\mu = QR$	Definition	16A.1
Magnitude of the resultant of two dipole moments	$\mu_{\text{res}} \approx (\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos \theta)^{1/2}$		16A.3a
Magnitude of the induced dipole moment	$\mu^* = \alpha \mathcal{E}$	Linear approximation; $\alpha$ is the polarizability	16A.5a
	$\mu^* = \alpha \mathcal{E} + \frac{1}{2} \beta \mathcal{E}^2$	Quadratic approximation; $\beta$ is the hyperpolarizability	16A.5b

### ► Why do you need to know this material?

You need to understand the many types of molecular interactions responsible for the formation of condensed phases and large molecular assemblies. The molecular interactions described here are of prime importance for solving one of the great problems of molecular biology: how complex molecules, like proteins and nucleic acids, fold into their three-dimensional structures.

### ► What is the key idea?

Attractive interactions result in cohesion, but repulsive interactions prevent the complete collapse of matter to nuclear densities.

### ► What do you need to know already?

You need to be familiar with elementary aspects of electrostatics, specifically the Coulomb interaction (*Foundations B*), and the relationships between the structure and electric properties of a molecule, specifically its dipole moment and polarizability (Topic 16A).

We begin by examining the interactions between the partial charges of polar molecules. Then we discuss **van der Waals interactions**: attractive interactions between closed-shell molecules that depend on the separation of the molecules as the inverse sixth power ( $V \propto 1/r^6$ ), although this precise criterion is often relaxed to include all non-bonding interactions. Finally, we see that repulsive interactions arise from Coulomb forces and, indirectly, from the Pauli principle (Topic 9B) and the exclusion of electrons from regions of space where the orbitals of neighbouring species overlap.

## 16B.1 Interactions between partial charges

In general, atoms in molecules have partial charges arising from the spatial variation in electron density in the ground state. If these charges were separated by a medium, they would attract or repel each other in accord with Coulomb's law, and we would write (as in Topic 16A):

$$V = \frac{Q_1 Q_2}{4\pi\epsilon r} \quad \text{Coulomb potential energy in a medium} \quad (16B.1)$$

where  $Q_1$  and  $Q_2$  are the partial charges,  $r$  is their separation, and  $\epsilon$  is the permittivity of the medium lying between the charges. The following *Brief illustration* examines effect of the permittivity of the medium on the strength of the interaction.

### Brief illustration 16B.1 The interaction energy of two partial charges

Different values of the permittivity of the medium take into account the possibility that other parts of the molecule, or

other molecules, lie between the charges. For example, the energy of interaction between a partial charge of  $-0.36$  (that is,  $Q_1 = -0.36e$ ) on the N atom of an amide group and the partial charge of  $+0.45$  ( $Q_2 = +0.45e$ ) on the carbonyl C atom at a distance of  $3.0$  nm, on the assumption that the medium between them is a vacuum, is

$$\begin{aligned} V &= \frac{(-0.36e) \times (0.45e)}{4\pi\epsilon_0 \times (3.0\text{ nm})} \\ &= -\frac{0.36 \times 0.45 \times (1.602 \times 10^{-19}\text{ C})^2}{4\pi \times (8.854 \times 10^{-12}\text{ J}^{-1}\text{C}^{-2}\text{m}^{-1}) \times (3.0 \times 10^{-9}\text{ m})} \\ &= -1.2 \times 10^{-20}\text{ J} \end{aligned}$$

where  $\epsilon_0$  is the vacuum permittivity. This energy (after multiplication by Avogadro's constant) corresponds to  $-7.5$  kJ mol $^{-1}$ . However, if the medium has a 'typical' relative permittivity  $\epsilon_r = \epsilon/\epsilon_0 = 3.5$  (Topic 16A), then the interaction energy is reduced by that factor to  $-2.1$  kJ mol $^{-1}$ .

**Self-test 16B.1** Repeat the calculation for bulk water as the medium.

Answer:  $-0.96$  kJ mol $^{-1}$

## 16B.2 The interactions of dipoles

Most of the discussion in this and the following sections is based on the Coulombic potential energy of interaction between two charges (eqn 16B.1). This expression can be adapted to find the potential energy of a point charge and a dipole and extend it to the interaction between two dipoles.

### (a) Charge–dipole interactions

A **point dipole** is a dipole in which the separation between the charges is much smaller than the distance at which the dipole is being observed ( $l \ll r$ ). We show in the following *Justification* that the potential energy of interaction between a point dipole with a dipole moment of magnitude  $\mu_1 = Q_1 l$ , and the point charge  $Q_2$  in the arrangement shown in 1 is

$$V = -\frac{\mu_1 Q_2}{4\pi\epsilon_0 r^2} \quad \text{Energy of interaction between a point dipole and a point charge} \quad (16B.2)$$

**Figure 16B.1** There are two contributions to the diminishing field of an electric dipole with distance (here seen from the side). The potentials of the charges decrease (shown here by a fading intensity) and the two charges appear to merge, so their combined effect approaches zero more rapidly than by the distance effect alone.

With  $\mu_1$  in coulomb metres,  $Q_2$  in coulombs, and  $r$  in metres,  $V$  is obtained in joules (and in the orientation shown in 1 is negative, representing a net attraction). The potential energy rises towards zero (the value at infinite separation of the charge and the dipole) more rapidly (as  $1/r^2$ ) than that between two point charges (which varies as  $1/r$ ) because, from the viewpoint of the point charge, the partial charges of the dipole seem to merge and cancel as the distance  $r$  increases (Fig. 16B.1).

#### Justification 16B.1 The interaction between a point charge and a point dipole

The sum of the potential energies of repulsion between like charges and attraction between opposite charges in the orientation shown in 1 is

$$V = \frac{1}{4\pi\epsilon_0} \left( -\frac{Q_1 Q_2}{r - \frac{1}{2}l} + \frac{Q_1 Q_2}{r + \frac{1}{2}l} \right) = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \left( -\frac{1}{1-x} + \frac{1}{1+x} \right)$$

where  $x = l/2r$ . Because  $l \ll r$  for a point dipole, this expression can be simplified by expanding the terms in  $x$  by using (*Mathematical background 1*)

$$\frac{1}{1+x} = 1 - x + x^2 - \dots \quad \frac{1}{1-x} = 1 + x + x^2 + \dots$$

and retaining only the leading surviving term:

$$V = \frac{Q_1 Q_2}{4\pi\epsilon_0 r} \{ -(1+x+\dots) + (1-x+\dots) \} \approx -\frac{2x Q_1 Q_2}{4\pi\epsilon_0 r} = -\frac{Q_1 Q_2 l}{4\pi\epsilon_0 r^2}$$

With  $\mu_1 = Q_1 l$ , this expression becomes eqn 16B.2. The equation should be multiplied by  $\cos \theta$  when the point charge lies at an angle  $\theta$  to the axis of the dipole.

**Brief illustration 16B.2** The energy of interaction of a point charge and a point dipole

Consider a  $\text{Li}^+$  ion and a water molecule ( $\mu = 1.85 \text{ D}$ ) separated by  $1.0 \text{ nm}$ , with the point charge on the ion and the dipole of the molecule arranged as in 1. The energy of interaction is given by eqn 16B.2 as

$$V = -\frac{\overbrace{(1.602 \times 10^{-19} \text{ C})}^{Q_{\text{Li}^+}} \times \overbrace{(1.85 \times 3.336 \times 10^{-30} \text{ C m})}^{\mu_{\text{H}_2\text{O}}}}{4\pi \times \underbrace{(8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^{-2} \text{ m}^{-1})}_{\epsilon_0} \times \underbrace{(1.0 \times 10^{-9} \text{ m})^2}_r}$$

$$= -8.9 \times 10^{-21} \text{ J}$$

This energy corresponds to  $-5.4 \text{ kJ mol}^{-1}$ .

**Self-test 16B.2** Consider the arrangement in 1 and calculate the molar energy required to reverse the direction of the water molecule when it is at  $300 \text{ pm}$  from the  $\text{Li}^+$  ion.

Answer:  $119 \text{ kJ mol}^{-1}$

**(b) Dipole–dipole interactions**

We show in the following *Justification* that the preceding discussion can be extended to the interaction of two dipoles arranged as in 2. The result is

$$V = -\frac{\mu_1 \mu_2}{2\pi \epsilon_0 r^3} \quad \text{Arrangement as in 2} \quad \text{Energy of interaction between two dipoles} \quad (16B.3)$$

This interaction energy approaches zero more rapidly (as  $1/r^3$ ) than for the previous case: now both interacting entities appear neutral to each other at large separations.

**Justification 16B.2** The interaction energy of two dipoles

To calculate the potential energy of interaction of two dipoles separated by  $r$  in the arrangement shown in 2 we proceed in exactly the same way as in *Justification* 16B.1, but now the total interaction energy is the sum of four pairwise terms, two attractions between opposite charges, which contribute negative terms to the potential energy, and two repulsions between like charges, which contribute positive terms.

The sum of the four contributions is

$$V = \frac{1}{4\pi \epsilon_0} \left( -\frac{Q_1 Q_2}{r+l} + \frac{Q_1 Q_2}{r} + \frac{Q_1 Q_2}{r} - \frac{Q_1 Q_2}{r-l} \right)$$

$$= -\frac{Q_1 Q_2}{4\pi \epsilon_0 r} \left( \frac{1}{1+x} - 2 + \frac{1}{1-x} \right)$$

with  $x = l/r$ . As before, provided  $l \ll r$  we can expand the two terms in  $x$  and retain only the first surviving term, which is equal to  $2x^2$ . This step results in the expression

$$V = -\frac{2x^2 Q_1 Q_2}{4\pi \epsilon_0 r}$$

Therefore, because  $\mu_1 = Q_1 l$  and  $\mu_2 = Q_2 l$ , the potential energy of interaction in the alignment shown in 2 is given by eqn 16B.3.

The preceding *Justification* represents only one possible orientation of two dipoles. More generally, the potential energy of interaction between two polar molecules is a complicated function of their relative orientation. When the two dipoles are parallel and arranged as in 3, the potential energy is simply

$$V = \frac{\mu_1 \mu_2 f(\theta)}{4\pi \epsilon_0 r^3} \quad f(\theta) = 1 - 3 \cos^2 \theta \quad \text{Energy of interaction between two fixed parallel dipoles} \quad (16B.4)$$

**Brief illustration 16B.3** The dipolar interaction

We can use eqn 16B.4 to calculate the molar potential energy of the dipolar interaction between two amide groups. Supposing that the groups are separated by  $3.0 \text{ nm}$  with  $\theta = 180^\circ$  (so that  $\cos \theta = -1$  and  $1 - 3 \cos^2 \theta = -2$ ), we take  $\mu_1 = \mu_2 = 2.7 \text{ D}$ , corresponding to  $9.1 \times 10^{-30} \text{ C m}$ , and find

$$V = \frac{\overbrace{(9.1 \times 10^{-30} \text{ C m})^2}^{\mu_1 \mu_2} \times \overbrace{(-2)}^{1 - 3 \cos^2 \theta}}{4\pi \times \underbrace{(8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1})}_{\epsilon_0} \times \underbrace{(3.0 \times 10^{-9} \text{ m})^3}_{r^3}}$$

$$= \frac{(9.1 \times 10^{-30})^2 \times (-2)}{4\pi \times (8.854 \times 10^{-12}) \times (3.0 \times 10^{-9})^3} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1} \text{ m}^3$$

$$= -5.5 \times 10^{-23} \text{ J}$$

This value corresponds to  $-33 \text{ J mol}^{-1}$ . Note that this energy is considerably less than that between two partial charges at the same separation (see *Brief illustration 16B.1*).

**Self-test 16B.3** Repeat the calculation for an amide group and a water molecule separated by 3.5 nm with  $\theta=90^\circ$ , in a medium with relative permittivity of 3.5.

Answer:  $-2.1 \text{ J mol}^{-1}$

Equation 16B.4 applies to polar molecules in a fixed, parallel, orientation in a solid. In a fluid of freely rotating molecules, the interaction between dipoles averages to zero because  $f(\theta)$  changes sign as the orientation changes, and its average value is zero. Physically, the like partial charges of two freely rotating molecules are close together as much as the two opposite partial charges, and the repulsion of the former is cancelled by the attraction of the latter. Mathematically, this result arises from the fact that, as we show in the following *Justification*, the average of the function  $1 - 3 \cos^2 \theta$  is zero.

### Justification 16B.3 The dipolar interaction between two freely rotating molecules

Consider the unit sphere shown in Fig. 16B.2. The average value of  $f(\theta) = 1 - 3 \cos^2 \theta$  is the sum of its values in each of the infinitesimal regions on the surface of the sphere (that is, the integral of the function over the surface) divided by the surface area of the sphere (which is equal to  $4\pi$ ).

**Figure 16B.2** A unit sphere showing the area element  $\sin \theta \, d\theta \, d\phi$ .

With the area element in spherical polar coordinates as  $\sin \theta \, d\theta \, d\phi$ ,  $\theta$  ranging from 0 to  $\pi$ , and  $\phi$  ranging from 0 to  $2\pi$ , the average value  $\langle f(\theta) \rangle$  of  $f(\theta)$  is

$$\begin{aligned} \langle f(\theta) \rangle &= \frac{1}{4\pi} \int_0^{2\pi} \int_0^\pi (1 - 3\cos^2 \theta) \sin \theta \, d\theta \, d\phi \\ &= \frac{1}{4\pi} \int_0^{2\pi} d\phi \int_0^\pi (1 - 3\cos^2 \theta) \sin \theta \, d\theta \\ &= \frac{1}{2} \int_0^\pi (1 - 3\cos^2 \theta) \sin \theta \, d\theta \end{aligned}$$

The integral is calculated as follows:

$$\begin{aligned} \int_0^\pi (1 - 3\cos^2 \theta) \sin \theta \, d\theta &= \int_0^\pi \sin \theta \, d\theta - 3 \int_0^\pi \cos^2 \theta \sin \theta \, d\theta \\ &\stackrel{\text{Integrals T.1 and A.1}}{=} -\cos \theta \Big|_0^\pi - 3 \left( -\frac{1}{3} \cos^3 \theta \Big|_0^\pi \right) \\ &= \underbrace{+2}_{+2} + \underbrace{-2}_{-2} = 0 \end{aligned}$$

It follows that  $\langle f(\theta) \rangle = 0$ , and, from eqn 16B.6, that the dipolar interaction between two freely rotating molecules vanishes when averaged over a sphere.

The average interaction energy of two *freely* rotating dipoles is zero. However, because their mutual potential energy depends on their relative orientation, the molecules do not in fact rotate completely freely, even in a gas. In fact, the lower energy orientations are marginally favoured, so there is a nonzero average interaction between polar molecules. We show in the following *Justification* that the average potential energy of two rotating molecules that are separated by a distance  $r$  is

$$\langle V \rangle = -\frac{C}{r^6} \quad C = \frac{2\mu_1^2 \mu_2^2}{3(4\pi\epsilon_0)^2 kT} \quad \text{Average potential energy of two rotating polar molecules} \quad (16B.5)$$

This expression describes the **Keesom interaction**, and is the first of the contributions to the van der Waals interaction (when that is taken to be a  $1/r^6$  interaction).

### Justification 16B.4 The Keesom interaction

The detailed calculation of the Keesom interaction energy is quite complicated, but the form of the final answer can be constructed quite simply. First, we note that the average interaction energy of two polar molecules rotating at a fixed separation  $r$  is given by

$$\langle V \rangle = \frac{\mu_1 \mu_2 \langle f(\theta) \rangle}{4\pi\epsilon_0 r^3}$$

where  $\langle f(\theta) \rangle$  now includes a weighting factor in the averaging that is equal to the probability that a particular orientation will be adopted. This probability is given by the Boltzmann distribution,  $p \propto e^{-E/kT}$ , with  $E$  interpreted as the potential energy of interaction of the two dipoles in that orientation. That is,

$$p \propto e^{-V/kT} \quad V = \frac{\mu_1 \mu_2 f(\theta)}{4\pi\epsilon_0 r^3}$$

When the potential energy of interaction of the two dipoles is very small compared with the energy of thermal motion, we can use  $V \ll kT$ , expand the exponential function in  $p$ , and retain only the first two terms:

$$p \propto 1 - V/kT + \dots$$

We now write the weighted average of  $f(\theta)$  as

$$\langle f(\theta) \rangle = \frac{\int_0^\pi f(\theta) p d\theta}{\int_0^\pi d\theta} = \frac{1}{\pi} \int_0^\pi f(\theta) p d\theta = \frac{1}{\pi} \int_0^\pi f(\theta) (1 - V/kT) d\theta + \dots$$

It follows that

$$\begin{aligned} \langle f(\theta) \rangle &= \frac{1}{\pi} \int_0^\pi f(\theta) p d\theta - \frac{1}{\pi} \int_0^\pi f(\theta) (V/kT) d\theta + \dots \\ &= \frac{1}{\pi} \int_0^\pi f(\theta) p d\theta - \frac{1}{\pi} \int_0^\pi \frac{\mu_1^2 \mu_2^2}{(4\pi\epsilon_0)^2 kTr^6} f(\theta)^2 d\theta + \dots \\ &= \overbrace{\frac{1}{\pi} \int_0^\pi f(\theta) p d\theta}^{\langle f(\theta) \rangle_0} - \frac{\mu_1^2 \mu_2^2}{(4\pi\epsilon_0)^2 kTr^6} \overbrace{\left( \int_0^\pi \frac{1}{\pi} f(\theta)^2 d\theta \right)}^{\langle f(\theta)^2 \rangle_0} + \dots \\ &= \langle f(\theta) \rangle_0 - \frac{\mu_1^2 \mu_2^2}{(4\pi\epsilon_0)^2 kTr^6} \langle f(\theta)^2 \rangle_0 + \dots \end{aligned}$$

where  $\langle \dots \rangle_0$  denotes an unweighted spherical average. The spherical average of  $f(\theta)$  is zero (as in *Justification 16B.3*), so the first term in the expression for  $\langle f(\theta) \rangle$  vanishes. However, the average value of  $f(\theta)^2$  is nonzero because  $f(\theta)^2$  is positive at all orientations, so we can write

$$\langle V \rangle = - \frac{\mu_1^2 \mu_2^2 \langle f(\theta)^2 \rangle_0}{(4\pi\epsilon_0)^2 kTr^6}$$

The average value  $\langle f(\theta)^2 \rangle_0$  turns out to be  $\frac{2}{3}$  when the calculation is carried through in detail. The final result is that quoted in eqn 16B.5.

The important features of eqn 16B.5 are

- The negative sign shows that the average interaction is attractive.
- The dependence of the average interaction energy on the inverse sixth power of the separation identifies it as a van der Waals interaction.
- The inverse dependence on the temperature reflects the way that the greater thermal motion overcomes the mutual orientating effects of the dipoles at higher temperatures.
- The inverse sixth power arises from the inverse third power of the interaction potential energy that is weighted by the energy in the Boltzmann term, which is also proportional to the inverse third power of the separation.

Physical interpretation

#### Brief illustration 16B.4 The Keesom interaction

Suppose a water molecule ( $\mu_1 = 1.85$  D) can rotate 1.0 nm from an amide group ( $\mu_2 = 2.7$  D). The average energy of their interaction at 25 °C (298 K) is

$$\begin{aligned} \langle V \rangle &= - \frac{2 \times \overbrace{(1.85 \times 3.336 \times 10^{-30} \text{ C m})^2}^{\mu_1} \times \overbrace{(2.7 \times 3.336 \times 10^{-30} \text{ C m})^2}^{\mu_2}}{3 \times \underbrace{(1.710 \times 10^{-43} \text{ J}^{-1} \text{ C}^4 \text{ m}^{-2} \text{ K}^{-1})}_{(4\pi\epsilon_0)^2 k} \times \underbrace{(298 \text{ K})}_T \times \underbrace{(1.0 \times 10^{-9} \text{ m})^6}_r} \\ &= -4.0 \times 10^{-23} \text{ J} \end{aligned}$$

This interaction energy corresponds (after multiplication by Avogadro's constant) to  $-24 \text{ J mol}^{-1}$ , and it is much smaller than the energies involved in the making and breaking of chemical bonds.

**Self-test 16B.4** Calculate the average interaction energy for pairs of molecules in the gas phase with  $\mu = 1$  D when the separation is 0.5 nm at 298 K. Compare this energy with the average molar kinetic energy of the molecules.

$$\text{Answer: } \langle V \rangle = -0.07 \text{ kJ mol}^{-1} \ll \frac{3}{2} RT = 3.7 \text{ kJ mol}^{-1}$$

Table 16B.1 summarizes the various expressions for the interaction of charges and dipoles. It is quite easy to extend the formulas given there to obtain expressions for the energy of interaction of higher multipoles (electric multipoles are described in Topic 16A). The feature to remember is that the interaction energy falls off more rapidly the higher the order of the multipole. For the interaction of an  $n$ -pole with an  $m$ -pole, the potential energy varies with distance as

$$V \propto \frac{1}{r^{n+m-1}} \quad \text{Energy of interaction between multipoles} \quad (16B.6)$$

The reason for the even steeper decrease with distance is the same as before: the array of charges appears to blend together into neutrality more rapidly with distance the higher the number of individual charges that contribute to the multipole. Note that a given molecule may have a charge distribution that corresponds to a superposition of several different multipoles, and

Table 16B.1 Interaction potential energies

Interaction type	Distance dependence of potential energy	Typical energy/ (kJ mol <sup>-1</sup> )	Comment
Ion-ion	$1/r$	250	Only between ions
Hydrogen bond		20	Occurs in X-H...Y, where X, Y = N, O, or F
Ion-dipole	$1/r^2$	15	
Dipole-dipole	$1/r^3$	2	Between stationary polar molecules
	$1/r^6$	0.3	Between rotating polar molecules
London (dispersion)	$1/r^6$	2	Between all types of molecules and ions

**Figure 16B.3** (a) A polar molecule (full arrow) can induce a dipole (outline arrow) in a nonpolar molecule, and (b) the orientation of the latter follows that of the former, so the interaction does not average to zero.

in such cases the energy of interaction is the sum of terms given by eqn 16B.6.

### (c) Dipole–induced dipole interactions

A polar molecule can induce a dipole in a neighbouring polarizable molecule (Fig. 16B.3). The induced dipole interacts with the permanent dipole of the first molecule, and the two are attracted together. The average interaction energy when the separation of the centres of the molecules is  $r$  is

$$V = -\frac{C}{r^6} \quad C = \frac{\mu_1^2 \alpha'_2}{4\pi\epsilon_0} \quad \text{Potential energy of a polar molecule and a polarizable molecule} \quad (16B.7)$$

where  $\alpha'_2$  is the polarizability volume (Topic 16A) of molecule 2 and  $\mu_1$  is the magnitude of the permanent dipole moment of molecule 1. Note that the  $C$  in this expression is different from the  $C$  in eqn 16B.5 and other expressions below: we are using the same symbol in  $C/r^6$  to emphasize the similarity of form of each expression.

The dipole–induced dipole interaction energy is independent of the temperature because thermal motion has no effect on the averaging process. Moreover, like the dipole–dipole interaction, the potential energy depends on  $1/r^6$ : this distance dependence stems from the  $1/r^3$  dependence of the field (and hence the magnitude of the induced dipole) and the  $1/r^3$  dependence of the potential energy of interaction between the permanent and induced dipoles.

#### Brief illustration 16B.5 The dipole–induced dipole interaction

For a molecule with  $\mu = 1.0 \text{ D}$  ( $3.3 \times 10^{-30} \text{ C m}$ , such as HCl) separated by  $0.30 \text{ nm}$  from a molecule of polarizability volume  $\alpha' = 10 \times 10^{-30} \text{ m}^3$  (such as benzene, Table 16A.1), the average interaction energy is

$$V = -\frac{(3.3 \times 10^{-30} \text{ C m})^2 \times (10 \times 10^{-30} \text{ m}^3)}{4\pi \times (8.854 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}) \times (3.0 \times 10^{-10} \text{ m})^6} \\ = -1.4 \times 10^{-21} \text{ J}$$

which, upon multiplication by Avogadro's constant, corresponds to  $-0.83 \text{ kJ mol}^{-1}$ .

**Self-test 16B.5** Calculate the average interaction energy, in units of joules per mole ( $\text{J mol}^{-1}$ ), between a water molecule and a benzene molecule separated by  $1.0 \text{ nm}$ .

Answer:  $-2.1 \text{ J mol}^{-1}$

### (d) Induced dipole–induced dipole interactions

Nonpolar molecules (including closed-shell atoms, such as Ar) attract one another even though neither has a permanent dipole moment. The abundant evidence for the existence of interactions between them is the formation of condensed phases of non-polar substances, such as the condensation of hydrogen or argon to a liquid at low temperatures and the fact that benzene is a liquid at normal temperatures.

The interaction between nonpolar molecules arises from the transient dipoles that all molecules possess as a result of fluctuations in the instantaneous positions of electrons. To appreciate the origin of the interaction, suppose that the electrons in one molecule flicker into an arrangement that gives the molecule an instantaneous dipole moment  $\mu_1^*$ . This dipole generates an electric field that polarizes the other molecule, and induces in that molecule an instantaneous dipole moment  $\mu_2^*$ . The two dipoles attract each other and the potential energy of the pair is lowered. Although the first molecule will go on to change the size and direction of its instantaneous dipole, the electron distribution of the second molecule will follow; that is, the two dipoles are correlated in direction (Fig. 16B.4). Because of this correlation, the attraction between the two instantaneous dipoles does not average to zero, and gives rise to an induced dipole–induced dipole interaction. This interaction is called either the **dispersion interaction** or the **London interaction** (for Fritz London, who first described it).

The strength of the dispersion interaction depends on the polarizability of the first molecule because the instantaneous dipole moment of magnitude  $\mu_1^*$  depends on the looseness of the control that the nuclear charge exercises over the outer electrons. The strength of the interaction also depends on the polarizability of the second molecule, for that polarizability determines how readily a dipole can be induced by another

**Figure 16B.4** (a) In the dispersion interaction, an instantaneous dipole on one molecule induces a dipole on another molecule, and the two dipoles then interact to lower the energy. (b) The two instantaneous dipoles are correlated, and although they occur in different orientations at different instants, the interaction does not average to zero.

molecule. The actual calculation of the dispersion interaction is quite involved, but a reasonable approximation to the interaction energy is given by the **London formula**:

$$V = -\frac{C}{r^6} \quad C = \frac{3}{2} \alpha'_1 \alpha'_2 \frac{I_1 I_2}{I_1 + I_2} \quad \text{London formula} \quad (16B.8)$$

where  $I_1$  and  $I_2$  are the ionization energies of the two molecules (Table 9B.2). This interaction energy is also proportional to the inverse sixth power of the separation of the molecules, which identifies it as a third contribution to the van der Waals interaction. The dispersion interaction generally dominates all the interactions between molecules other than hydrogen bonds.

#### Brief illustration 16B.6 The London interaction

For two  $\text{CH}_4$  molecules separated by 0.30 nm, we can use eqn 16B.9 with  $\alpha' = 2.6 \times 10^{-30} \text{ m}^3$  and  $I \approx 700 \text{ kJ mol}^{-1}$  and obtain

$$\begin{aligned} V &= -\frac{\frac{3}{2} \times (2.6 \times 10^{-30} \text{ m}^3)^2}{(0.30 \times 10^{-9} \text{ m})^6} \times \frac{(7.00 \times 10^5 \text{ J mol}^{-1})^2}{2 \times (7.00 \times 10^5 \text{ J mol}^{-1})} \\ &= -4.9 \text{ kJ mol}^{-1} \end{aligned}$$

A very approximate check on this figure is the enthalpy of vaporization of methane, which is  $8.2 \text{ kJ mol}^{-1}$ . However, this comparison is questionable, partly because the enthalpy of vaporization is a many-body quantity and partly because the long-distance assumption breaks down.

**Self-test 16B.6** Estimate the energy of the London interaction for two He atoms separated by 1.0 nm.

Answer:  $-0.071 \text{ J mol}^{-1}$

## 16B.3 Hydrogen bonding

The interactions described so far are universal in the sense that they are possessed by all molecules independent of their specific identity. However, there is a type of interaction possessed by molecules that have a particular constitution. A **hydrogen bond** is an attractive interaction between two species that arises from a link of the form  $\text{A-H} \cdots \text{B}$ , where A and B are highly electronegative elements and B possesses a lone pair of electrons. Hydrogen bonding is conventionally regarded as being limited to N, O, and F but, if B is an anionic species (such as  $\text{Cl}^-$ ), it may also participate in hydrogen bonding. There is no strict cut-off for an ability to participate in hydrogen bonding, but N, O, and F participate most effectively.

The formation of a hydrogen bond can be regarded either as the approach between a partial positive charge of H and a partial negative charge of B or as a particular example of delocalized molecular orbital formation in which A, H, and B each supply one atomic orbital from which three molecular orbitals are constructed (Fig. 16B.5). Experimental evidence and

**Figure 16B.5** The molecular orbital interpretation of the formation of an  $\text{A-H} \cdots \text{B}$  hydrogen bond. From the three A, H, and B orbitals, three molecular orbitals can be formed (their relative contributions are represented by the sizes of the spheres). Only the two lower energy orbitals are occupied, and there may therefore be a net lowering of energy compared with the separate AH and B species.

theoretical arguments have been presented in favour of both views and the matter has not yet been resolved. The electrostatic interaction model can be understood readily in terms of the discussion in Section 16B.1. Here we develop the molecular orbital model.

Thus, if the  $\text{A-H}$  bond is regarded as formed from the overlap of an orbital on A,  $\chi_A$ , and a hydrogen 1s orbital,  $\chi_H$ , and the lone pair on B occupies an orbital on B,  $\chi_B$ , then, when the two molecules are close together, we can build three molecular orbitals from the three basis orbitals:

$$\psi = c_1 \chi_A + c_2 \chi_H + c_3 \chi_B$$

One of the molecular orbitals is bonding, one almost nonbonding, and the third anti-bonding. These three orbitals need to accommodate four electrons (two from the original  $\text{A-H}$  bond and two from the lone pair of B), so two enter the bonding orbital and two enter the nonbonding orbital. Because the anti-bonding orbital remains empty, the net effect—depending on the precise energy of the almost nonbonding orbital—may be a lowering of energy.

In practice, the strength of the bond is found to be about  $20 \text{ kJ mol}^{-1}$  (there are two hydrogen bonds per molecule in liquid water, and its standard enthalpy of vaporization, from Table 2C.2, is  $44 \text{ kJ mol}^{-1}$ ). Because the bonding depends on orbital overlap, it is virtually a contact-like interaction that is turned on when AH touches B and is zero as soon as the contact is broken. If hydrogen bonding is present, it dominates the other intermolecular interactions. The properties of liquid and solid water, for example, are dominated by the hydrogen bonding between  $\text{H}_2\text{O}$  molecules. The structure of DNA and hence the transmission of genetic information is crucially dependent on the strength of hydrogen bonds between base pairs. The structural evidence for hydrogen bonding comes from noting that the internuclear distance between formally non-bonded atoms

is less than expected on the basis of their van der Waals radii, which suggests that a dominating attractive interaction is present. For example, the O–O distance in O–H···O is expected to be 280 pm on the basis of van der Waals radii, but is found to be 270 pm in typical compounds. Moreover, the H···O distance is expected to be 260 pm but is found to be only 170 pm.

Hydrogen bonds may be either symmetric or non-symmetric. In a symmetric hydrogen bond, the H atom lies midway between the two other atoms. This arrangement is rare, but occurs in F–H···F<sup>−</sup>, where both bond lengths are 120 pm. More common is the non-symmetric arrangement, where the A–H bond is shorter than the H···B bond. Simple electrostatic arguments, treating A–H···B as an array of point charges (partial negative charges on A and B, partial positive on H) suggest that the lowest energy is achieved when the bond is linear, because then the two partial negative charges are furthest apart. The experimental evidence from structural studies supports a linear or near-linear arrangement.

#### Brief illustration 16B.7 The hydrogen bond

A common hydrogen bond is that formed between O–H groups and O atoms, as in liquid water and ice. In Problem 16B.6, you are invited to use the electrostatic model to calculate the dependence of the potential energy of interaction on the OOH angle, denoted  $\theta$  in 4, and the results are plotted in Fig. 16B.6. We see that the strength of bonding is greatest at  $\theta=0$  when the OHO atoms lie in a straight line; the molar potential energy is then  $-19\text{ kJ mol}^{-1}$ .

**Figure 16B.6** The variation of the energy of interaction (according to the electrostatic model) of a hydrogen bond as the angle between the O–H and :O groups is changed.

**Self-test 16B.7** Use Fig. 16B.6 to explore the dependence of the interaction energy on angle: at what angle does the interaction energy become negative?

Answer: Only  $\pm 12^\circ$ , so that the energy is negative (and the interaction is attractive) only when the atoms are close to a linear arrangement

## 16B.4 The hydrophobic interaction

Nonpolar molecules do dissolve slightly in polar solvents, but strong interactions between solute and solvent are not possible and as a result it is found that each individual solute molecule is surrounded by a solvent cage (Fig. 16B.7). To understand the consequences of this effect, consider the thermodynamics of transfer of a nonpolar hydrocarbon solute from a nonpolar solvent to water, a polar solvent. Experiments indicate that the process is endergonic ( $\Delta_{\text{transfer}}G > 0$ ), as expected on the basis of the increase in polarity of the solvent, but exothermic ( $\Delta_{\text{transfer}}H < 0$ ). Therefore, it is a large decrease in the entropy of the system ( $\Delta_{\text{transfer}}S < 0$ ) that accounts for the positive Gibbs energy of transfer. For example, the process

has  $\Delta_{\text{transfer}}G = +12\text{ kJ mol}^{-1}$ ,  $\Delta_{\text{transfer}}H = -10\text{ kJ mol}^{-1}$ , and  $\Delta_{\text{transfer}}S = -75\text{ J K}^{-1}\text{ mol}^{-1}$  at 298 K. Substances characterized by a positive Gibbs energy of transfer from a nonpolar to a polar solvent are called **hydrophobic**.

It is possible to quantify the hydrophobicity of a small molecular group R by defining the **hydrophobicity constant**,  $\pi$ , as

$$\pi = \log \frac{S}{S_0} \quad \text{Definition Hydrophobicity constant (16B.9)}$$

**Figure 16B.7** When a hydrocarbon molecule is surrounded by water, the H<sub>2</sub>O molecules form a cage. As a result of this acquisition of structure, the entropy of the water decreases, so the dispersal of the hydrocarbon into the water is entropy-opposed; its coalescence is entropy-favoured.

where  $S$  is the ratio of the molar solubility of the compound R–A in octanol, a nonpolar solvent, to that in water, and  $S_0$  is the ratio of the molar solubility of the compound H–A in octanol to that in water. Therefore, positive values of  $\pi$  indicate hydrophobicity and negative values of  $\pi$  indicate hydrophilicity, the thermodynamic preference for water as a solvent. It is observed experimentally that the  $\pi$  values of most groups do not depend on the nature of A. However, measurements do suggest group additivity of  $\pi$  values, as the following data show:

R	CH <sub>3</sub>	CH <sub>3</sub> CH <sub>2</sub>	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>2</sub>	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>3</sub>	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>4</sub>
$\pi$	0.5	1.0	1.5	2.0	2.5

Thus, acyclic saturated hydrocarbons become more hydrophobic as the carbon chain length increases. This trend can be rationalized by  $\Delta_{\text{transfer}}H$  becoming more positive and  $\Delta_{\text{transfer}}S$  more negative as the number of carbon atoms in the chain increases.

At the molecular level, formation of a solvent cage around a hydrophobic molecule involves the formation of new hydrogen bonds among solvent molecules. This process is exothermic and accounts for the negative values of  $\Delta_{\text{transfer}}H$ . On the other hand, the increase in order associated with formation of a very large number of small solvent cages decreases the entropy of the system and accounts for the negative values of  $\Delta_{\text{transfer}}S$ . However, when many solute molecules cluster together, fewer (albeit larger) cages are required and more solvent molecules are free to move. The net effect of formation of large clusters of hydrophobic molecules is then a decrease in the organization of the solvent and therefore a net *increase* in entropy of the system. This increase in entropy of the solvent is large enough to render spontaneous the association of hydrophobic molecules in a polar solvent.

The increase in entropy that results from fewer structural demands on the solvent placed by the clustering of nonpolar molecules is the origin of the **hydrophobic interaction**, which tends to stabilize aggregation of hydrophobic groups in micelles and biopolymers (Topic 17C). The hydrophobic interaction is an example of an ordering process that is driven by a tendency toward greater disorder of the solvent.

## 16B.5 The total interaction

Here we consider molecules that are unable to participate in hydrogen bond formation. The total attractive interaction energy between rotating molecules is then the sum of the dipole–dipole, dipole–induced dipole, and dispersion interactions. Only the dispersion interaction contributes if both molecules are nonpolar. In a fluid phase, all three contributions to the potential energy vary as the inverse sixth power of the separation of the molecules, so we may write

$$V = -\frac{C_6}{r^6} \quad (16B.10)$$

where  $C_6$  is a coefficient that depends on the identity of the molecules.

Although attractive interactions between molecules are often expressed as in eqn 16B.10 we must remember that this equation has only limited validity. First, we have taken into account only dipolar interactions of various kinds, for they have the longest range and are dominant if the average separation of the molecules is large. However, in a complete treatment we should also consider quadrupolar and higher-order multipole interactions, particularly if the molecules do not have permanent dipole moments. Secondly, the expressions have been derived by assuming that the molecules can rotate reasonably freely. That is not the case in most solids, and in rigid media the dipole–dipole interaction is proportional to  $1/r^3$  (as in eqn 16B.3) because the Boltzmann averaging procedure is irrelevant when the molecules are trapped into a fixed orientation.

A different kind of limitation is that eqn 16B.10 relates to the interactions of pairs of molecules. There is no reason to suppose that the energy of interaction of three (or more) molecules is the sum of the pairwise interaction energies alone. The total dispersion energy of three closed-shell atoms, for instance, is given approximately by the **Axilrod–Teller formula**:

$$V = -\frac{C_6}{r_{AB}^6} - \frac{C_6}{r_{BC}^6} - \frac{C_6}{r_{CA}^6} + \frac{C'}{(r_{AB}r_{BC}r_{CA})^3} \quad \text{Axilrod–Teller formula} \quad (16B.11a)$$

where

$$C' = a(3 \cos \theta_A \cos \theta_B \cos \theta_C + 1) \quad (16B.11b)$$

The parameter  $a$  is approximately equal to  $\frac{3}{4}\alpha' C_6$ ; the angles  $\theta$  are the internal angles of the triangle formed by the three atoms (5). The term in  $C'$  (which represents the non-additivity of the pairwise interactions) is negative for a linear arrangement of atoms (so that arrangement is stabilized) and positive for an equilateral triangular cluster (so that arrangement is destabilized). It is found that the three-body term contributes about 10 per cent of the total interaction energy in liquid argon.

When molecules are squeezed together, the nuclear and electronic repulsions begin to dominate the attractive forces. The repulsions increase steeply with decreasing separation in a way that can be deduced only by very extensive, complicated

**Figure 16B.8** The general form of an intermolecular potential energy curve (the graph of the potential energy of two closed shell species as the distance between them is changed). The attractive (negative) contribution has a long range, but the repulsive (positive) interaction increases more sharply once the molecules come into contact.

molecular structure calculations of the kind described in Topic 10E (Fig. 16B.8).

In many cases, however, progress can be made by using a greatly simplified representation of the potential energy, where the details are ignored and the general features expressed by a few adjustable parameters. One such approximation is the **hard-sphere potential energy**, in which it is assumed that the potential energy rises abruptly to infinity as soon as the particles come within a separation  $d$ :

$$V = \infty \text{ for } r \leq d \quad V = 0 \text{ for } r > d \quad \text{Hard-sphere potential energy} \quad (16B.12)$$

This very simple expression for the potential energy is surprisingly useful for assessing a number of properties. Another widely used approximation is the **Mie potential energy**:

$$V = \frac{C_n}{r^n} - \frac{C_m}{r^m} \quad \text{Mie potential energy} \quad (16B.13)$$

with  $n > m$ . The first term represents repulsions and the second term attractions. The **Lennard-Jones potential energy** is a special case of the Mie potential energy with  $n=12$  and  $m=6$  (Fig. 16B.9); it is often written in the form

$$V = 4\epsilon \left\{ \left( \frac{r_0}{r} \right)^{12} - \left( \frac{r_0}{r} \right)^6 \right\} \quad \text{Lennard-Jones potential energy} \quad (16B.14)$$

The two parameters are  $\epsilon$ , the depth of the well (not to be confused with the symbol of the permittivity of a medium used in Section 16B.1), and  $r_0$ , the separation at which  $V=0$  (Table 16B.2).

Although the Lennard-Jones potential energy has been used in many calculations, there is plenty of evidence to show that

**Figure 16B.9** The Lennard-Jones potential energy is another approximation to the true intermolecular potential energy curves. It models the attractive component by a contribution that is proportional to  $1/r^6$  and the repulsive component by a contribution that is proportional to  $1/r^{12}$ . Specifically, these choices result in the Lennard-Jones (12,6) potential energy. Although there are good theoretical reasons for the former, there is plenty of evidence to show that  $1/r^{12}$  is only a very poor approximation to the repulsive part of the curve.

**Table 16B.2\*** Lennard-Jones parameters for the (12,6) potential

	$\epsilon/(\text{kJ mol}^{-1})$	$r_0/\text{pm}$
Ar	128	342
Br <sub>2</sub>	536	427
C <sub>6</sub> H <sub>6</sub>	454	527
Cl <sub>2</sub>	368	412
H <sub>2</sub>	34	297
He	11	258
Xe	236	406

\* More values are given in the *Resource section*.

$1/r^{12}$  is a very poor representation of the repulsive potential energy, and that an exponential form,  $e^{-r/r_0}$ , is greatly superior. An exponential function is more faithful to the exponential decay of atomic wavefunctions at large distances, and hence to the overlap that is responsible for repulsion. The potential energy with an exponential repulsive term and a  $1/r^6$  attractive term is known as an **exp-6 potential energy**. These expressions for the potential energy can be used to calculate the virial coefficients of gases, as explained in Topic 1C, and through them various properties of real gases, such as the Joule–Thomson coefficient (Topic 2D). They are also used to model the structures of condensed fluids.

With the advent of **atomic force microscopy** (AFM), in which the force between a molecular sized probe and a surface is monitored (Topic 22A), it has become possible to measure directly the forces acting between molecules. The force,  $F$ , is the

negative slope of the potential energy, so for the Lennard-Jones potential energy between individual molecules we write

$$F = -\frac{dV}{dr} = \frac{24\epsilon}{r_0} \left\{ 2 \left( \frac{r_0}{r} \right)^{13} - \left( \frac{r_0}{r} \right)^7 \right\} \quad (16B.15)$$

### Example 16B.1 Calculating an intermolecular force from the Lennard-Jones potential energy

Use the expression for the Lennard-Jones potential energy to estimate the greatest net attractive force between two  $\text{N}_2$  molecules.

**Method** The magnitude of the force is greatest at the distance  $r$  at which  $dF/dr=0$ . Therefore differentiate eqn 16B.15 with respect to  $r$ , set the resulting expression to zero, and solve for  $r$ . Finally, use the value of  $r$  in eqn 16B.15 to calculate the corresponding value of  $F$ .

**Answer** Because  $dx^n/dx = nx^{n-1}$ , the derivative of  $F$  with respect to  $r$  is

$$\frac{dF}{dr} = \frac{24\epsilon}{r_0} \left\{ 2 \left( -\frac{13r_0^{13}}{r^{14}} \right) - \left( -\frac{7r_0^7}{r^8} \right) \right\} = 24\epsilon r_0^6 \left\{ \frac{7}{r^8} - \frac{26r_0^6}{r^{14}} \right\}$$

It follows that  $dF/dr=0$  when

$$\frac{7}{r^8} - \frac{26r_0^6}{r^{14}} = 0 \quad \text{or} \quad 7r^6 - 26r_0^6 = 0$$

or

$$r = \left( \frac{26}{7} \right)^{1/6} r_0 = 1.244r_0$$

At this separation the force is

$$F = \frac{24\epsilon}{r_0} \left\{ 2 \left( \frac{r_0}{1.244r_0} \right)^{13} - \left( \frac{r_0}{1.244r_0} \right)^7 \right\} = -\frac{2.396\epsilon}{r_0}$$

From Table 16B.2,  $\epsilon = 1.268 \times 10^{-21} \text{ J}$  and  $r_0 = 3.919 \times 10^{-10} \text{ m}$ . It follows that

$$F = -\frac{2.396 \times (1.268 \times 10^{-21} \text{ J})}{3.919 \times 10^{-10} \text{ m}} \stackrel{1\text{N}=1\text{Jm}^{-1}}{=} -7.752 \times 10^{-12} \text{ N}$$

That is, the magnitude of the force is about 8 pN.

**Self-test 16B.8** At what separation  $r_e$  does the minimum of the potential energy curve occur for a Lennard-Jones potential?

Answer:  $r_e = 2^{1/6}r_0$

## Checklist of concepts

- 1. A **van der Waals interaction** between closed-shell molecules is inversely proportional to the sixth power of their separation.
- 2. The following molecular interactions are important: **charge–charge**, **charge–dipole**, **dipole–dipole**, **dipole–induced dipole**, **dispersion (London)**, **hydrogen bonding**, and the **hydrophobic interaction**.
- 3. A **hydrogen bond** is an interaction of the form  $\text{X–H}\cdots\text{Y}$ , where X and Y are typically N, O, or F.
- 4. The **hydrophobic interaction** fosters clustering of non-polar molecules in polar solvents.
- 5. The **Lennard-Jones potential energy function** is a model of the total intermolecular potential energy.

## Checklist of equations

Property	Equation	Comment	Equation number
Potential energy of interaction between two point charges in a medium	$V = Q_1Q_2/4\pi\epsilon r$	The relative permittivity of the medium is $\epsilon_r = \epsilon/\epsilon_0$	16B.1

### ► Why do you need to know this material?

Many chemical reactions, including those in biological cells and chemical reactors, occur in liquids, so you need to understand the structure of liquids, how molecular interactions foster condensation of a gas into a liquid, the thermodynamic properties of liquids, and how liquid surfaces are formed.

### ► What is the key idea?

The attractions between molecules are responsible for the condensation of gases into liquids at low temperatures.

### ► What do you need to know already?

You need to understand the nature of molecular interactions (Topic 16B), the concepts of Helmholtz and Gibbs energies (Topic 3C), and the Boltzmann distribution (Topic 15A).

At low enough temperatures the molecules of a gas have insufficient kinetic energy to escape from each other's attraction and they stick together. But although molecules attract each other when they are a few diameters apart, as soon as they come into contact they repel each other. This repulsion is responsible for the fact that liquids and solids have a definite bulk and do not collapse to an infinitesimal point. The molecules are held together by molecular interactions, but their kinetic energies are comparable to their potential energies. As a result, although the molecules of a liquid are not free to escape completely from the bulk, the whole structure is very mobile and we can speak only of the *average* relative locations of molecules. In this Topic we build on those concepts and add thermodynamic arguments to describe the surface of a liquid and the condensation of a gas into a liquid.

## 16C.1 Molecular interactions in liquids

The starting point for the discussion of solids is the well-ordered structure of a perfect crystal, which is discussed in Topic 18A. The starting point for the discussion of gases is the completely disordered distribution of the molecules of a perfect gas (Topic 1A). Liquids lie between these two extremes. We see that the structural and thermodynamic properties of liquids depend on the nature of intermolecular interactions and that an equation of state can be built in a similar way to that just demonstrated for real gases.

### (a) The radial distribution function

The average relative locations of the particles of a liquid are expressed in terms of the **radial distribution function**,  $g(r)$ . This function is defined so that  $\mathcal{N}g(r)r^2dr$ , where  $\mathcal{N}$  is the number density of molecules ( $\mathcal{N}=N/V$ ), is the probability that a molecule will be found in the range  $dr$  at a distance  $r$  from another molecule. In a perfect crystal,  $g(r)$  is a periodic array of sharp spikes, representing the certainty (in the absence of defects and thermal motion) that molecules (or ions) lie at definite locations. This regularity continues out to the edges of the crystal, so we say that crystals have **long-range order**. When the crystal melts, the long-range order is lost and, wherever we look at long distances from a given molecule, there is equal probability of finding a second molecule. Close to the first molecule, though, the nearest neighbours might

still adopt approximately their original relative positions and, even if they are displaced by newcomers, the new particles might adopt their vacated positions. It is still possible to detect a sphere of nearest neighbours at a distance  $r_1$ , and perhaps beyond them a sphere of next-nearest neighbours at  $r_2$ . The existence of this **short-range order** means that the radial distribution function can be expected to oscillate at short distances, with a peak at  $r_1$ , a smaller peak at  $r_2$ , and perhaps some more structure beyond that.

The radial distribution function of the oxygen atoms in liquid water is shown in Fig. 16C.1. Closer analysis shows that any given  $\text{H}_2\text{O}$  molecule is surrounded by other molecules at the corners of a tetrahedron. The form of  $g(r)$  at  $100^\circ\text{C}$  shows that the intermolecular interactions (in this case, principally by hydrogen bonds) are strong enough to affect the local structure right up to the boiling point. Raman spectra indicate that in liquid water most molecules participate in either three or four hydrogen bonds. Infrared spectra show that about 90 per cent of hydrogen bonds are intact at the melting point of ice, falling to about 20 per cent at the boiling point.

The formal expression for the radial distribution function for molecules 1 and 2 in a fluid consisting of  $N$  particles is the somewhat fearsome equation

$$g(r) = \frac{N(N-1) \iint \dots \int e^{-\beta V_N} d\tau_3 d\tau_4 \dots d\tau_N}{N^2 \iint \dots \int e^{-\beta V_N} d\tau_1 d\tau_2 \dots d\tau_N} \quad \text{Radial distribution function} \quad (16C.1)$$

where  $\beta = 1/kT$  and  $V_N$  is the  $N$ -particle potential energy. Although fearsome, this expression is nothing more than the Boltzmann distribution for the relative locations of two molecules in a field provided by all the other molecules in the system.

**Figure 16C.1** The radial distribution function of the oxygen atoms in liquid water at three temperatures. Note the expansion as the temperature is raised. (Based on A.H. Narten, M.D. Danford, and H.A. Levy, *Discuss. Faraday Soc.* **43**, 97 (1967).)

## (b) The calculation of $g(r)$

Because the radial distribution function can be calculated by making assumptions about the intermolecular interactions, it can be used to test theories of liquid structure. However, even a fluid of hard spheres without attractive interactions (a collection of ball-bearings in a container) gives a function that oscillates near the origin (Fig. 16C.2), and one of the factors influencing, and sometimes dominating, the structure of a liquid is the geometrical problem of stacking together reasonably hard spheres. Indeed, the radial distribution function of a liquid of hard spheres shows more pronounced oscillations at a given temperature than that of any other type of liquid. The attractive part of the potential modifies this basic structure, but sometimes only quite weakly. One of the reasons behind the difficulty of describing liquids theoretically is the similar importance of both the attractive and repulsive (hard core) components of the potential.

There are several ways of building the intermolecular potential into the calculation of  $g(r)$ . Numerical methods take a box of about  $10^3$  particles (the number increases as computers grow more powerful), and the rest of the liquid is simulated by surrounding the box with replications of the original box (Fig. 16C.3). Then, whenever a particle leaves the box through one of its faces, its image arrives through the opposite face. When calculating the interactions of a molecule in a box, it interacts with all the molecules in the box and all the periodic replications of those molecules and itself in the other boxes.

In the **Monte Carlo method**, the particles in the box are moved through small but otherwise random distances, and the change in total potential energy of the  $N$  particles in the box,  $\Delta V_N$ , is calculated. Whether or not this new configuration is accepted is then judged from the following rules:

- If the potential energy is not greater than before the change, then the configuration is accepted.

If the potential energy is greater than before the change, then it is necessary to check if the new configuration is reasonable and

**Figure 16C.2** The radial distribution function for a simulation of a liquid using impenetrable hard spheres (ball bearings).

**Figure 16C.3** In a two-dimensional simulation of a liquid that uses periodic boundary conditions, when one particle leaves the cell its mirror image enters through the opposite face.

can exist in equilibrium with configurations of lower potential energy at a given temperature. To make progress, we use the result that, at equilibrium, the ratio of populations of two states with energy separation  $\Delta V_N$  is  $e^{-\Delta V_N/kT}$ . Because we are testing the viability of a configuration with a higher potential energy than the previous configuration in the calculation,  $\Delta V_N > 0$  and the exponential factor varies between 0 and 1. In the Monte Carlo method, the second rule, therefore, is:

- The exponential factor is compared with a random number between 0 and 1; if the factor is larger than the random number, then the configuration is accepted; if the factor is not larger, the configuration is rejected.

The configurations generated with Monte Carlo calculations can be used to construct  $g(r)$  simply by counting the number of pairs of particles with a separation  $r$  and averaging the result over the whole collection of configurations.

In the **molecular dynamics** approach, the history of an initial arrangement is followed by calculating the trajectories of all the particles under the influence of the intermolecular potentials and the forces they exert. The calculation gives a series of snapshots of the liquid, and  $g(r)$  can be calculated as before. The temperature of the system is inferred by computing the mean kinetic energy of the particles and using the equipartition result (*Foundations B*) that

$$\langle \frac{1}{2} m v_q^2 \rangle = \frac{1}{2} kT \quad (16C.2)$$

for each coordinate  $q$ .

#### Brief illustration 16C.1 The radial distribution function

A simple pair distribution function has the form

$$g(r) = 1 + \cos\left(\frac{4r}{r_0} - 4\right) e^{-(r/r_0 - 1)}$$

**Figure 16C.4** An example of a radial distribution function for two particles with an interaction energy given by the Lennard-Jones potential energy function.

for  $r \geq r_0$  and  $g(r) = 0$  for  $r < r_0$ . Here the parameter  $r_0$  is the separation at which the Lennard-Jones potential energy function (eqn 16B.13;  $V = 4\epsilon\{(r_0/r)^{1/2} - (r_0/r)^6\}$ ) is equal to zero. The function  $g(r)$  is plotted in Fig. 16C.4, and we see that it resembles the form shown in Fig. 16C.2.

**Self-test 16C.1** Use mathematical software to plot the function  $v_2(r) = r(dV/dr)$ . The significance of this function will become apparent soon.

Answer: See Fig. 16C.5.

### (c) The thermodynamic properties of liquids

Once  $g(r)$  is known it can be used to calculate the thermodynamic properties of liquids. For example, the contribution of the pairwise additive intermolecular potential,  $V_2$ , to the internal energy is given by the integral

$$U_{\text{interaction}}(T) = \frac{2\pi N^2}{V} \int_0^\infty g(r) V_2 r^2 dr \quad (16C.3)$$

Contribution of pairwise interactions to the internal energy

That is,  $U_{\text{interaction}}$  is essentially the average two-particle potential energy weighted by  $g(r)r^2 dr$ , which is the probability that the pair of particles have a separation between  $r$  and  $r + dr$ . Likewise, the contribution that pairwise interactions make to the pressure is

$$\frac{pV}{nRT} = 1 - \frac{2\pi N}{3kTV} \int_0^\infty g(r) v_2 r^2 dr \quad v_2 = r \frac{dV_2}{dr} \quad (16C.4a)$$

The quantity  $v_2$  is called the **virial** (hence the term ‘virial equation of state’). The dependence of  $v_2$  on  $r$  is shown for a simple form of  $g(r)$  in Fig. 16C.5. To understand the physical content of this expression, we rewrite it as

$$p = \frac{nRT}{V} - \frac{2\pi}{3} \left(\frac{N}{V}\right)^2 \int_0^\infty g(r) v_2 r^2 dr \quad \text{Pressure in terms of } g(r) \quad (16C.4b)$$

Figure 16C.5 The virial  $v_2(r)$  associated with the Lennard-Jones potential energy function.

and then note that

- The first term on the right is the **kinetic pressure**, the contribution to the pressure from the impact of the molecules in free flight.
- The second term is essentially the internal pressure,  $\pi_T = (\partial U / \partial V)_T$  (Topic 2D), representing the contribution to the pressure from the intermolecular forces.

Physical interpretation

To see the connection to the internal pressure, we should recognize  $-dV_2/dr$  (in  $v_2$ ) as the force required to move two molecules apart, and therefore  $-r(dV_2/dr)$  as the work required to separate the molecules through a distance  $r$ . The second term is therefore the average of this work over the range of pairwise separations in the liquid as represented by the probability of finding two molecules at separations between  $r$  and  $r+dr$ , which is  $g(r)r^2dr$ . In brief, the integral, when multiplied by the square of the number density, is the change in internal energy of the system as it expands, and therefore is equal to the internal pressure.

## 16C.2 The liquid–vapour interface

We turn our attention to the physical boundary between phases, such as the surface where solid is in contact with liquid or liquid is in contact with its vapour. In this Topic we concentrate on the liquid–vapour interface, which is interesting because it is so mobile. Topic 22A deals with solid surfaces.

### (a) Surface tension

Liquids tend to adopt shapes that minimize their surface area, for then the maximum number of molecules is in the bulk and hence surrounded by and interacting with neighbours. Droplets of liquids therefore tend to be spherical, because a

Table 16C.1\* Surface tensions of liquids at 293 K,  $\gamma/(\text{mN m}^{-1})$

	$\gamma/(\text{mN m}^{-1})$
Benzene	28.88
Mercury	472
Methanol	22.6
Water	72.75

\* More values are given in the *Resource section*. Note that  $1 \text{ N m}^{-1} = 1 \text{ J m}^{-2}$ .

sphere is the shape with the smallest surface-to-volume ratio. However, there may be other forces present that compete against the tendency to form this ideal shape, and in particular gravity may flatten spheres into puddles or oceans.

Surface effects may be expressed in the language of Helmholtz and Gibbs energies (Topic 3C). The link between these quantities and the surface area is the work needed to change the area by a given amount, and the fact that  $dA$  and  $dG$  are equal (under different conditions) to the work done in changing the energy of a system. The work needed to change the surface area,  $\sigma$ , of a sample by an infinitesimal amount  $d\sigma$  is proportional to  $d\sigma$ , and we write

$$dw = \gamma d\sigma \quad \text{Definition Surface tension} \quad (16C.5)$$

The constant of proportionality,  $\gamma$  is called the **surface tension**; its dimensions are energy/area and its units are typically joules per metre squared ( $\text{J m}^{-2}$ ). However, as in Table 16C.1, values of  $\gamma$  are usually reported in newtons per metre (because  $1 \text{ J} = 1 \text{ N m}$ , it follows that  $1 \text{ J m}^{-2} = 1 \text{ N m}^{-1}$ ). The work of surface formation at constant volume and temperature can be identified with the change in the Helmholtz energy, and we can write

$$dA = \gamma d\sigma \quad (16C.6)$$

Because the Helmholtz energy decreases ( $dA < 0$ ) if the surface area decreases ( $d\sigma < 0$ ), surfaces have a natural tendency to contract. This is a more formal way of expressing what we have already described.

### Example 16C.1 Using the surface tension

Calculate the work needed to raise a wire of length  $l$  and to stretch the surface of a liquid through a height  $h$  in the arrangement shown in Fig. 16C.6. Disregard gravitational potential energy.

**Method** According to eqn 16C.5, the work required to create a surface of area  $\sigma$  given that the surface tension does not vary as the surface is formed is  $w = \gamma\sigma$ . Therefore, all we need do is to calculate the surface area of the two-sided rectangle formed as the frame is withdrawn from the liquid.

**Figure 16C.6** The model used for calculating the work of forming a liquid film when a wire of length  $l$  is raised and pulls the surface with it through a height  $h$ .

**Answer** When the wire of length  $l$  is raised through a height  $h$  it increases the area of the liquid by twice the area of the rectangle (because there is a surface on each side). The total increase is therefore  $2lh$  and the work done is  $2\gamma lh$ .

The expression  $2\gamma lh$  can be expressed as force  $\times$  distance by writing it as  $2\gamma l \times h$ , and identifying  $\gamma l$  as the opposing force on the wire of length  $l$ . This interpretation is why  $\gamma$  is called a tension and why its units are often chosen to be newtons per metre (so  $\gamma$  is a force in newtons).

**Self-test 16C.2** Calculate the work of creating a spherical cavity of radius  $r$  in a liquid of surface tension  $\gamma$ .

Answer:  $4\pi r^2\gamma$

## (b) Curved surfaces

The minimization of the surface area of a liquid may result in the formation of a curved surface. A **bubble** is a region in which vapour (and possibly air too) is trapped by a thin film; a **cavity** is a vapour-filled hole in a liquid. What are widely called ‘bubbles’ in liquids are therefore strictly cavities. True bubbles have two surfaces (one on each side of the film); cavities have only one. The treatments of both are similar, but a factor of 2 is required for bubbles to take into account the doubled surface area. A **droplet** is a small volume of liquid at equilibrium surrounded by its vapour (and possibly also air).

The pressure on the concave side of an interface,  $p_{\text{in}}$ , is always greater than the pressure on the convex side,  $p_{\text{out}}$ . This relation is expressed by the **Laplace equation**, which is derived in the following *Justification*:

$$p_{\text{in}} = p_{\text{out}} + \frac{2\gamma}{r} \quad \text{Laplace equation} \quad (16C.7)$$

### Justification 16C.1 The Laplace equation

The cavities in a liquid are at equilibrium when the tendency for their surface area to decrease is balanced by the

rise of internal pressure which would then result. When the pressure inside a cavity is  $p_{\text{in}}$  and its radius is  $r$ , the outward force is

$$\text{pressure} \times \text{area} = 4\pi r^2 p_{\text{in}}$$

The force inwards arises from the external pressure and the surface tension. The former has magnitude  $4\pi r^2 p_{\text{out}}$ . The latter is calculated as follows. The change in surface area when the radius of a sphere changes from  $r$  to  $r + dr$  is

$$d\sigma = 4\pi(r + dr)^2 - 4\pi r^2 = 8\pi r dr$$

(The second-order infinitesimal,  $(dr)^2$ , is ignored.) The work done when the surface is stretched by this amount is therefore

$$dw = 8\pi\gamma r dr$$

As force  $\times$  distance is work, the force opposing stretching through a distance  $dr$  when the radius is  $r$  is

$$F = 8\pi\gamma r$$

The total inward force is therefore  $4\pi r^2 p_{\text{out}} + 8\pi\gamma r$ . At equilibrium, the outward and inward forces are balanced, so we can write

$$4\pi r^2 p_{\text{in}} = 4\pi r^2 p_{\text{out}} + 8\pi\gamma r$$

which rearranges into eqn 16C.7.

The Laplace equation shows that the difference in pressure decreases to zero as the radius of curvature becomes infinite (when the surface is flat, Fig. 16C.7). Small cavities have small radii of curvature, so the pressure difference across their surface is quite large.

**Figure 16C.7** The dependence of the pressure inside a curved surface on the radius of the surface, for two different values of the surface tension.

**Brief illustration 16C.2** The Laplace equation

The pressure differential of water across the surface of a spherical droplet of radius 200 nm at 20 °C is

$$p_{\text{in}} - p_{\text{out}} = \frac{2 \times \overbrace{(72.75 \times 10^{-3} \text{ N m}^{-1})}^{\gamma_{\text{water at 20 } ^\circ\text{C}}}}{\underbrace{2.00 \times 10^{-7} \text{ m}}_r} = 7.28 \times 10^5 \text{ N m}^{-2} = 728 \text{ kPa}$$

**Self-test 16C.3** Calculate the pressure differential of ethanol across the surface of a spherical droplet of radius 220 nm at 20 °C. The surface tension of ethanol at that temperature is 22.39 mN m<sup>-1</sup>.

Answer: 204 kPa

**(c) Capillary action**

The tendency of liquids to rise up capillary tubes (tubes of narrow bore; the name comes from the Latin word for ‘hair’), which is called **capillary action**, is a consequence of surface tension. Consider what happens when a glass capillary tube is first immersed in water or any liquid that has a tendency to adhere to the walls. The energy is lowest when a thin film covers as much of the glass as possible. As this film creeps up the inside wall it has the effect of curving the surface of the liquid inside the tube. This curvature implies that the pressure just beneath the curving meniscus is less than the atmospheric pressure by approximately  $2\gamma/r$ , where  $r$  is the radius of the tube and we assume a hemispherical surface. The pressure immediately under the flat surface outside the tube is  $p$ , the atmospheric pressure; but inside the tube under the curved surface it is only  $p - 2\gamma/r$ . The excess external pressure presses the liquid up the tube until hydrostatic equilibrium (equal pressures at equal depths) has been reached (Fig. 16C.8).

To calculate the height to which the liquid rises, we note that the pressure exerted by a column of liquid of mass density  $\rho$  and height  $h$  is

$$p = \rho gh \quad (16C.8)$$

This hydrostatic pressure matches the pressure difference  $2\gamma/r$  at equilibrium. Therefore, the height of the column at equilibrium is obtained by equating  $2\gamma/r$  and  $\rho gh$ , which gives

$$h = \frac{2\gamma}{\rho gr} \quad (16C.9)$$

This simple expression provides a reasonably accurate way of measuring the surface tension of liquids. Surface tension decreases with increasing temperature (Fig. 16C.9).

**Figure 16C.8** When a capillary tube is first stood in a liquid, the latter climbs up the walls, so curving the surface. The pressure just under the meniscus is less than that arising from the atmosphere by  $2\gamma/r$ . The pressure is equal at equal heights throughout the liquid provided the hydrostatic pressure (which is equal to  $\rho gh$ ) cancels the pressure difference arising from the curvature.

**Figure 16C.9** The variation of the surface tension of water with temperature.

**Brief illustration 16C.3** Capillary action

If water at 25 °C rises through 7.36 cm in a capillary of radius 0.20 mm, its surface tension at that temperature is

$$\begin{aligned} \gamma &= \frac{1}{2} \rho g h r \\ &= \frac{1}{2} \times (997.1 \text{ kg m}^{-3}) \times (9.81 \text{ m s}^{-2}) \times (7.36 \times 10^{-2} \text{ m}) \\ &\quad \times (2.0 \times 10^{-4} \text{ m}) \\ &\stackrel{1 \text{ kg m s}^{-2} = 1 \text{ N}}{=} 72 \text{ mN m}^{-1} \end{aligned}$$

**Self-test 16C.4** Calculate the surface tension of water at 30 °C given that at that temperature water climbs to a height of 9.11 cm in a clean glass capillary tube of internal radius 0.320 mm. The density of water at 30 °C is 0.9956 g cm<sup>-3</sup>.

Answer: 142 mN m<sup>-1</sup>

Figure 16C.10 The balance of forces that results in a contact angle,  $\theta_c$ .

When the adhesive forces between the liquid and the material of the capillary wall are weaker than the cohesive forces within the liquid (as for mercury in glass), the liquid in the tube retracts from the walls. This retraction curves the surface with the concave, high pressure side downwards. To equalize the pressure at the same depth throughout the liquid the surface must fall to compensate for the heightened pressure arising from its curvature. This compensation results in a capillary depression.

In many cases there is a nonzero angle between the edge of the meniscus and the wall. If this contact angle is  $\theta_c$ , then eqn 16C.9 should be modified by multiplying the right-hand side by  $\cos \theta_c$ . The origin of the contact angle can be traced to the balance of forces at the line of contact between the liquid and the solid (Fig. 16C.10). If the solid–gas, solid–liquid, and liquid–gas surface tensions (essentially the energy needed to create unit area of each of the interfaces) are denoted  $\gamma_{sg}$ ,  $\gamma_{sl}$ , and  $\gamma_{lg}$ , respectively, then the vertical forces are in balance if

$$\gamma_{sg} = \gamma_{sl} + \gamma_{lg} \cos \theta_c \quad (16C.10)$$

This expression solves to

$$\cos \theta_c = \frac{\gamma_{sg} - \gamma_{sl}}{\gamma_{lg}} \quad (16C.11)$$

If we note that the superficial work of adhesion of the liquid to the solid (the work of adhesion divided by the area of contact) is

$$w_{ad} = \gamma_{sg} + \gamma_{lg} - \gamma_{sl} \quad (16C.12)$$

eqn 16C.11 can be written

$$\cos \theta_c = \frac{w_{ad}}{\gamma_{lg}} - 1 \quad \text{Contact angle} \quad (16C.13)$$

We now see that:

- The liquid ‘wets’ (spreads over) the surface, corresponding to  $0 < \theta_c < 90^\circ$ , when  $1 < w_{ad}/\gamma_{lg} < 2$  (Fig. 16C.11).
- The liquid does not wet the surface, corresponding to  $90^\circ < \theta_c < 180^\circ$ , when  $0 < w_{ad}/\gamma_{lg} < 1$ .

Physical interpretation

Figure 16C.11 The variation of contact angle (shown by the semaphore-like object) as the ratio  $w_{ad}/\gamma_{lg}$  changes.

For mercury in contact with glass,  $\theta_c = 140^\circ$ , which corresponds to  $w_{ad}/\gamma_{lg} = 0.23$ , indicating a relatively low work of adhesion of the mercury to glass on account of the strong cohesive forces within mercury.

### 16C.3 Surface films

The compositions of surface layers have been investigated by the simple but technically elegant procedure of slicing thin layers off the surfaces of solutions and analysing their compositions. The physical properties of surface films have also been investigated. Surface films one molecule thick are called **monolayers**. When a monolayer has been transferred to a solid support, it is called a **Langmuir–Blodgett film**, after Irving Langmuir and Katherine Blodgett, who developed experimental techniques for studying them.

#### (a) Surface pressure

The principal apparatus used for the study of surface monolayers is a **surface film balance** (Fig. 16C.12). This device consists of a shallow trough and a barrier that can be moved along the surface of the liquid in the trough, and hence compress any monolayer on the surface. The **surface pressure**,  $\pi$ , the difference between the surface tension of the pure solvent and the solution ( $\pi = \gamma^* - \gamma$ ) is measured by using a torsion wire attached to a strip of mica that rests on the surface and pressing against one edge of the monolayer. The parts of the apparatus that are in touch with liquids are coated in polytetrafluoroethene to eliminate effects arising from the liquid–solid interface. In an actual experiment, a small amount (about 0.01 mg) of the surfactant under investigation is dissolved in a volatile solvent and then poured on to the surface of the water; the compression barrier is then moved across the surface and the surface pressure exerted on the mica bar is monitored.

**Figure 16C.12** A schematic diagram of the apparatus used to measure the surface pressure and other characteristics of a surface film. The surfactant is spread on the surface of the liquid in the trough, and then compressed horizontally by moving the compression barrier towards the mica float. The latter is connected to a torsion wire, so the difference in force on either side of the float can be monitored.

Some typical results are shown in Fig. 16C.13. One parameter obtained from the isotherms is the area occupied by the molecules when the monolayer is closely packed. This quantity is obtained from the extrapolation of the steepest part of the isotherm to the horizontal axis. As can be seen from the illustration, even though stearic acid (1) and isostearic acid (2) are chemically very similar (they differ only in the location of a methyl group at the end of a long hydrocarbon chain), they occupy significantly different areas in the monolayer. Neither, though, occupies as much area as the tri-*p*-cresyl phosphate molecule (3), which is like a wide bush rather than a lanky tree.

1 Stearic acid,  $C_{17}H_{35}COOH$

2 Isostearic acid,  $C_{17}H_{35}COOH$

3 Tri-*p*-cresylphosphate

The second feature to note from Fig. 16C.13 is that the tri-*p*-cresyl phosphate isotherm is much less steep than the stearic acid isotherms. This difference indicates that the tri-*p*-cresyl

**Figure 16C.13** The variation of surface pressure with the area occupied by each surfactant molecule. The collapse pressures are indicated by the horizontal lines.

phosphate film is more compressible than the stearic acid films, which is consistent with their different molecular structures.

A third feature of the isotherms is the **collapse pressure**, the highest surface pressure. When the monolayer is compressed beyond the point represented by the collapse pressure, the monolayer buckles and collapses into a film several molecules thick. As can be seen from the isotherms in Fig. 16C.13, stearic acid has a high collapse pressure, but that of tri-*p*-cresyl phosphate is significantly smaller, indicating a much weaker film.

### (b) The thermodynamics of surface layers

A **surfactant** is a species that is active at the interface between two phases, such as at the interface between hydrophilic and hydrophobic phases. A surfactant accumulates at the interface, and modifies its surface tension and hence the surface pressure. To establish the relation between the concentration of surfactant at a surface and the change in surface tension it brings about, we consider two phases  $\alpha$  and  $\beta$  in contact and suppose that the system consists of several components  $J$ , each one present in an overall amount  $n_j$ . If the components were distributed uniformly through the two phases right up to the interface, which is taken to be a plane of surface area  $\sigma$ , the total Gibbs energy,  $G$ , would be the sum of the Gibbs energies of both phases,  $G = G(\alpha) + G(\beta)$ . However, the components are not uniformly distributed because one may accumulate at the interface. As a result, the sum of the two Gibbs energies differs from  $G$  by an amount called the **surface Gibbs energy**,  $G(\sigma)$ :

$$G(\sigma) = G - \{G(\alpha) + G(\beta)\} \quad \text{Definition} \quad \text{Surface Gibbs energy} \quad (16C.14)$$

Similarly, if it is supposed that the concentration of a species  $J$  is uniform right up to the interface, then from its volume we would conclude that it contains an amount  $n_j(\alpha)$  of  $J$  in phase  $\alpha$  and an amount  $n_j(\beta)$  in phase  $\beta$ . However, because a species may

accumulate at the interface, the total amount of J differs from the sum of these two amounts by  $n_j(\sigma) = n_j - \{n_j(\alpha) + n_j(\beta)\}$ . This difference is expressed in terms of the **surface excess**,  $\Gamma_j$ :

$$\Gamma_j = \frac{n_j(\sigma)}{\sigma} \quad \text{Definition Surface excess} \quad (16C.15)$$

The surface excess may be either positive (an accumulation of J at the interface) or negative (a deficiency there).

The relation between the change in surface tension and the composition of a surface (as expressed by the surface excess) was derived by Gibbs. In the following *Justification* we derive the **Gibbs isotherm**, between the changes in the chemical potentials of the substances present in the interface and the change in surface tension:

$$d\gamma = -\sum_j \Gamma_j d\mu_j \quad \text{Gibbs isotherm} \quad (16C.16)$$

### Justification 16C.2 The Gibbs isotherm

A general change in  $G$  is brought about by changes in  $T$ ,  $p$ , and the  $n_j$ :

$$dG = -SdT + Vdp + \gamma d\sigma + \sum_j \mu_j dn_j$$

When this relation is applied to  $G$ ,  $G(\alpha)$ , and  $G(\beta)$  we find

$$dG(\sigma) = -S(\sigma)dT + \gamma d\sigma + \sum_j \mu_j dn_j(\sigma)$$

because at equilibrium the chemical potential of each component is the same in every phase,  $\mu_j(\alpha) = \mu_j(\beta) = \mu_j(\sigma)$ . Just as in the discussion of partial molar quantities (Chapter 5), the last equation integrates at constant temperature to

$$G(\sigma) = \gamma\sigma + \sum_j \mu_j n_j(\sigma)$$

We are seeking a connection between the change of surface tension  $d\gamma$  and the change of composition at the interface. Therefore, we use the argument that in Topic 5A led to the Gibbs–Duhem equation (eqn 5A.12b), but this time we compare the expression

$$dG(\sigma) = \gamma d\sigma + \sum_j \mu_j dn_j(\sigma)$$

(which is valid at constant temperature) with the expression for the same quantity but derived from the preceding equation:

$$dG(\sigma) = \gamma d\sigma + \sigma d\gamma + \sum_j \mu_j dn_j(\sigma) + \sum_j n_j(\sigma) d\mu_j$$

The comparison implies that, at constant temperature,

$$\sigma d\gamma + \sum_j n_j(\sigma) d\mu_j = 0$$

Division by  $\sigma$  then gives eqn 16C.16.

Now consider a simplified model of the interface in which the ‘oil’ and ‘water’ phases are separated by a geometrically flat surface. This approximation implies that only the surfactant, S, accumulates at the surface, and hence that  $\Gamma_{\text{oil}}$  and  $\Gamma_{\text{water}}$  are both zero. Then the Gibbs isotherm equation becomes

$$d\gamma = -\Gamma_s d\mu_s \quad (16C.17)$$

For dilute solutions,

$$d\mu_s = RT \ln c \quad (16C.18)$$

where  $c$  is the molar concentration of the surfactant. It follows that

$$d\gamma = -RT\Gamma_s \frac{dc}{c}$$

at constant temperature, or

$$\left(\frac{\partial \gamma}{\partial c}\right)_T = -\frac{RT\Gamma_s}{c} \quad \text{Dependence of the surface tension on surfactant concentration} \quad (16C.19)$$

If the surfactant accumulates at the interface, its surface excess is positive and eqn 16C.19 implies that  $(\partial \gamma / \partial c)_T < 0$ . That is, the surface tension decreases when a solute accumulates at a surface. Conversely, if the concentration dependence of  $\gamma$  is known, then the surface excess may be predicted and used to infer the area occupied by each surfactant molecule on the surface.

### Example 16C.2 Calculating the surface excess

Calculate the surface excess of 1-aminobutanoic acid in a  $0.10 \text{ mol dm}^{-3}$  aqueous solution at  $20^\circ\text{C}$  given that  $d\gamma/d(\ln c) = -40 \mu\text{N m}^{-1}$ . Convert the answer to the number of molecules per square metre.

**Method** Use the relation  $d(\ln x) = (1/x)dx$  to convert eqn 16C.19 into an expression for  $\partial \gamma / \partial (\ln c)$ , then rearrange it to obtain an expression for the surface excess  $\Gamma_s$ . Multiplying the surface excess by Avogadro’s constant gives the number of molecules per square metre.

**Answer** Because  $d(\ln c) = (1/c)dc$  and  $dc = cd(\ln c)$ , eqn 16C.19 may be written as

$$\left(\frac{\partial \gamma}{\partial (\ln c)}\right)_T = -RT\Gamma_s$$

It follows that

$$\begin{aligned}\Gamma_s &= \frac{1}{RT} \left( \frac{\partial \gamma}{\partial (\ln c)} \right)_T \\ &= \frac{1}{(8.314 \text{ J K}^{-1} \text{ mol}^{-1}) \times (293 \text{ K})} \times (-4.0 \times 10^{-5} \text{ N m}^{-1}) \\ &= 1.6 \times 10^{-8} \text{ mol m}^{-2}\end{aligned}$$

The number of molecules per square metre,  $\mathcal{N}$ , is

$$\begin{aligned}\mathcal{N} &= N_A \Gamma_s = (6.02 \times 10^{23} \text{ mol}^{-1}) \times (1.6 \times 10^{-8} \text{ mol m}^{-2}) \\ &= 9.6 \times 10^{15} \text{ m}^{-2}\end{aligned}$$

**Self-test 16C.5** Use the result from *Example 16C.2* to calculate the area occupied by a molecule.

Answer:  $1.0 \times 10^2 \text{ nm}^2$

## 16C.4 Condensation

We now bring together concepts from this Topic and Topic 4B to explain the condensation of a gas to a liquid. We saw in Topic 4B that the vapour pressure of a liquid depends on the pressure applied to the liquid. Because curving a surface gives rise to a pressure differential of  $2\gamma/r$ , we can expect the vapour pressure above a curved surface to be different from that above a flat surface. By substituting this value of the pressure difference into eqn 4B.3 ( $p = p^* e^{V_m \Delta p / RT}$ , where  $p^*$  is the vapour pressure when the pressure difference is zero) we obtain the **Kelvin equation** for the vapour pressure of a liquid when it is dispersed as droplets of radius  $r$ :

$$p = p^* e^{2\gamma V_m / rRT} \quad \text{Kelvin equation} \quad (16C.20)$$

The analogous expression for the vapour pressure inside a cavity can be written at once. The pressure of the liquid outside the cavity is less than the pressure inside, so the only change is in the sign of the exponent in the last expression. For droplets of water of radius  $1 \mu\text{m}$  and  $1 \text{ nm}$  the ratios  $p/p^*$  at  $25^\circ\text{C}$  are about 1.001 and 3, respectively. The second figure, although quite large, is unreliable because at that radius the droplet is less than

about 10 molecules in diameter and the basis of the calculation is suspect. The first figure shows that the effect is usually small; nevertheless it may have important consequences.

Consider the formation of a cloud. Warm, moist air rises into the cooler regions higher in the atmosphere. At some altitude the temperature is so low that the vapour becomes thermodynamically unstable with respect to the liquid and we expect it to condense into a cloud of liquid droplets. The initial step can be imagined as a swarm of water molecules congregating into a microscopic droplet. Because the initial droplet is so small, it has an enhanced vapour pressure. Therefore, instead of growing it evaporates. This effect stabilizes the vapour because an initial tendency to condense is overcome by a heightened tendency to evaporate. The vapour phase is then said to be **supersaturated**. It is thermodynamically unstable with respect to the liquid but not unstable with respect to the small droplets that need to form before the bulk liquid phase can appear, so the formation of the latter by a simple, direct mechanism is hindered.

Clouds do form, so there must be a mechanism. Two processes are responsible. The first is that a sufficiently large number of molecules might congregate into a droplet so big that the enhanced evaporative effect is unimportant. The chance of one of these **spontaneous nucleation centres** forming is low, and in rain formation it is not a dominant mechanism. The more important process depends on the presence of minute dust particles or other kinds of foreign matter. These **nucleate** the condensation (that is, provide centres at which it can occur) by providing surfaces to which the water molecules can attach.

Liquids may be **superheated** above their boiling temperatures and **supercooled** below their freezing temperatures. In each case the thermodynamically stable phase is not achieved on account of the kinetic stabilization that occurs in the absence of nucleation centres. For example, superheating occurs because the vapour pressure inside a cavity is artificially low, so any cavity that does form tends to collapse. This instability is encountered when an unstirred beaker of water is heated, for its temperature may be raised above its boiling point. Violent bumping often ensues as spontaneous nucleation leads to bubbles big enough to survive. To ensure smooth boiling at the true boiling temperature, nucleation centres, such as small pieces of sharp-edged glass or bubbles (cavities) of air, should be introduced.

## Checklist of concepts

- 1. The **radial distribution function**,  $g(r)$ , is a probability density in the sense that  $g(r)dr$  is the probability that a molecule will be found in the range  $dr$  at a distance  $r$  from another molecule.
- 2. The radial distribution function may be calculated with **Monte Carlo** and **molecular dynamics** techniques.
- 3. The internal energy and pressure of a fluid may be expressed in terms of the radial distribution function.
- 4. Liquids tend to adopt shapes that minimize their surface area.
- 5. The minimization of surface area results in the formation of bubbles, cavities, and droplets.

- 6. **Capillary action** is the tendency of liquids to rise up narrow tubes.
- 7. The **surface pressure** is the difference between the surface tension of the pure solvent and the solution.
- 8. The **collapse pressure** is the highest surface pressure that a surface film can sustain.
- 9. A **surfactant** modifies the surface tension and surface pressure.
- 10. **Nucleation** provides surfaces to which molecules can attach and thereby induce **condensation**.

## Checklist of equations

Property	Equation	Comment	Equation number
Radial distribution function	$g(r_{12}) = A/B,$ $A = N(N-1) \iint \dots \int e^{-\beta V_N} d\tau_3 d\tau_4 \dots d\tau_N,$ $B = \mathcal{N}^2 \iint \dots \int e^{-\beta V_N} d\tau_1 d\tau_2 \dots d\tau_N$		16C.1
Contribution of interactions to the internal energy	$U_{\text{interaction}}(T) = (2\pi N^2/V) \int_0^\infty g(r) V_2 r^2 dr$	$V_2$ is the intermolecular potential energy	16C.3
Pressure in terms of $g(r)$	$p = nRT/V - (2\pi/3)(N/V)^2 \int_0^\infty g(r) v_2 r^2 dr$		16C.4b
Laplace equation	$p_{\text{in}} = p_{\text{out}} + 2\gamma/r$	$\gamma$ is the surface tension	16C.7
Contact angle	$\cos \theta_c = (w_{\text{ad}}/\gamma_{\text{lg}}) - 1$		16C.13
Surface Gibbs energy	$G(\sigma) = G - \{G(\alpha) + G(\beta)\}$	Definition	16C.14
Excess energy	$\Gamma_j = n_j(\sigma)/\sigma$	Definition	16C.15
Gibbs isotherm	$d\gamma = -\sum_j \Gamma_j d\mu_j$		16C.16
Dependence of the surface tension on surfactant concentration	$(\partial\gamma/\partial c)_T = -RT\Gamma_j/c$		16C.19
Kelvin equation	$p = p^* e^{2\gamma V_m/rRT}$		16C.20

# CHAPTER 16 Molecular interactions

## TOPIC 16A Electric properties of molecules

### Discussion questions

**16A.1** Explain how the permanent dipole moment and the polarizability of a molecule arise.

**16A.2** Explain why the polarizability of a molecule decreases at high frequencies.

**16A.3** Describe the experimental procedures available for determining the electric dipole moment of a molecule.

### Exercises

**16A.1(a)** Which of the following molecules may be polar:  $\text{ClF}_3$ ,  $\text{O}_3$ ,  $\text{H}_2\text{O}_2$ ?

**16A.1(b)** Which of the following molecules may be polar:  $\text{SO}_3$ ,  $\text{XeF}_4$ ,  $\text{SF}_4$ ?

**16A.2(a)** Calculate the resultant of two dipole moments of magnitude 1.5 D and 0.80 D that make an angle of  $109.5^\circ$  to each other.

**16A.2(b)** Calculate the resultant of two dipole moments of magnitude 2.5 D and 0.50 D that make an angle of  $120^\circ$  to each other.

**16A.3(a)** Calculate the magnitude and direction of the dipole moment of the following arrangement of charges in the  $xy$ -plane:  $3e$  at  $(0,0)$ ,  $-e$  at  $(0.32 \text{ nm}, 0)$ , and  $-2e$  at an angle of  $20^\circ$  from the  $x$ -axis and a distance of 0.23 nm from the origin.

**16A.3(b)** Calculate the magnitude and direction of the dipole moment of the following arrangement of charges in the  $xy$ -plane:  $4e$  at  $(0, 0)$ ,  $-2e$  at  $(162 \text{ pm}, 0)$ , and  $-2e$  at an angle of  $30^\circ$  from the  $x$ -axis and a distance of 143 pm from the origin.

**16A.4(a)** The molar polarization of fluorobenzene vapour varies linearly with  $T^{-1}$ , and is  $70.62 \text{ cm}^3 \text{ mol}^{-1}$  at 351.0 K and  $62.47 \text{ cm}^3 \text{ mol}^{-1}$  at 423.2 K. Calculate the polarizability and dipole moment of the molecule.

**16A.4(b)** The molar polarization of the vapour of a compound was found to vary linearly with  $T^{-1}$ , and is  $75.74 \text{ cm}^3 \text{ mol}^{-1}$  at 320.0 K and  $71.43 \text{ cm}^3 \text{ mol}^{-1}$  at 421.7 K. Calculate the polarizability and dipole moment of the molecule.

**16A.5(a)** At  $0^\circ\text{C}$ , the molar polarization of liquid chlorine trifluoride is  $27.18 \text{ cm}^3 \text{ mol}^{-1}$  and its density is  $1.89 \text{ g cm}^{-3}$ . Calculate the relative permittivity of the liquid.

**16A.5(b)** At  $0^\circ\text{C}$ , the molar polarization of a liquid is  $32.16 \text{ cm}^3 \text{ mol}^{-1}$  and its density is  $1.92 \text{ g cm}^{-3}$ . Calculate the relative permittivity of the liquid. Take  $M = 85.0 \text{ g mol}^{-1}$ .

**16A.6(a)** The refractive index of  $\text{CH}_2\text{I}_2$  is 1.732 for 656 nm light. Its density at  $20^\circ\text{C}$  is  $3.32 \text{ g cm}^{-3}$ . Calculate the polarizability of the molecule at this wavelength.

**16A.6(b)** The refractive index of a compound is 1.622 for 643 nm light. Its density at  $20^\circ\text{C}$  is  $2.99 \text{ g cm}^{-3}$ . Calculate the polarizability of the molecule at this wavelength. Take  $M = 65.5 \text{ g mol}^{-1}$ .

**16A.7(a)** The polarizability volume of  $\text{H}_2\text{O}$  at optical frequencies is  $1.5 \times 10^{-24} \text{ cm}^3$ : estimate the refractive index of water. The experimental value is 1.33; what may be the origin of the discrepancy?

**16A.7(b)** The polarizability volume of a liquid of molar mass  $72.3 \text{ g mol}^{-1}$  and density  $865 \text{ kg m}^{-3}$  at optical frequencies is  $2.2 \times 10^{-30} \text{ m}^3$ : estimate the refractive index of the liquid.

**16A.8(a)** The dipole moment of chlorobenzene is 1.57 D and its polarizability volume is  $1.23 \times 10^{-23} \text{ cm}^3$ . Estimate its relative permittivity at  $25^\circ\text{C}$ , when its density is  $1.173 \text{ g cm}^{-3}$ .

**16A.8(b)** The dipole moment of bromobenzene is  $5.17 \times 10^{-30} \text{ C m}$  and its polarizability volume is approximately  $1.5 \times 10^{-19} \text{ m}^3$ . Estimate its relative permittivity at  $25^\circ\text{C}$ , when its density is  $1491 \text{ kg m}^{-3}$ .

### Problems

**16A.1** The electric dipole moment of toluene (methylbenzene) is 0.4 D. Estimate the dipole moments of the three xylenes (dimethylbenzene). About which answer can you be sure?

**16A.2** Plot the magnitude of the electric dipole moment of hydrogen peroxide as the  $\text{H}-\text{O}-\text{O}-\text{H}$  (azimuthal) angle  $\phi$  changes from 0 to  $2\pi$ . Use the dimensions shown in 1.

**16A.3** Acetic acid vapour contains a proportion of planar, hydrogen bonded dimers (2). The apparent dipole moment of molecules in pure gaseous acetic

acid has a magnitude that increases with increasing temperature. Suggest an interpretation of this observation.

**16A.4\*** D.D. Nelson et al. (*Science* 238, 1670 (1987)) examined several weakly bound gas-phase complexes of ammonia in search of examples in which the H atoms in  $\text{NH}_3$  formed hydrogen bonds, but found none. For example, they found that the complex of  $\text{NH}_3$  and  $\text{CO}_2$  has the carbon atom nearest the nitrogen (299 pm away): the  $\text{CO}_2$  molecule is at right angles to the C-N 'bond'.

\* These problems were supplied by Charles Trapp and Carmen Giunta

**16B.2(a)** Calculate the potential energy of the interaction between two linear quadrupoles when they are collinear and their centres are separated by a distance  $r$ .

**16B.2(b)** Calculate the potential energy of the interaction between two linear quadrupoles when they are parallel and separated by a distance  $r$ .

**16B.3(a)** Estimate the energy of the dispersion interaction (use the London formula) for two He atoms separated by 1.0 nm. Relevant data can be found in the *Resource section*.

## Problems

**16B.1** An  $\text{H}_2\text{O}$  molecule is aligned by an external electric field of strength  $1.0 \text{ kV m}^{-1}$  and an Ar atom ( $\alpha' = 1.66 \times 10^{-30} \text{ m}^3$ ) is brought up slowly from one side. At what separation is it energetically favourable for the  $\text{H}_2\text{O}$  molecule to flip over and point towards the approaching Ar atom?

**16B.2** Suppose an  $\text{H}_2\text{O}$  molecule ( $\mu = 1.85 \text{ D}$ ) approaches an anion. What is the favourable orientation of the molecule? Calculate the electric field (in volts per metre) experienced by the anion when the water dipole is (a) 1.0 nm, (b) 0.3 nm, (c) 30 nm from the ion.

**16B.3** Phenylalanine (Phe, 4) is a naturally occurring amino acid. What is the energy of interaction between its phenyl group and the electric dipole moment of a neighbouring peptide group? Take the distance between the groups as 4.0 nm and treat the phenyl group as a benzene molecule. The dipole moment of the peptide group is  $\mu = 2.7 \text{ D}$  and the polarizability volume of benzene is  $\alpha' = 1.04 \times 10^{-29} \text{ m}^3$ .

4 Phenylalanine

**16B.4** Now consider the London interaction between the phenyl groups of two Phe residues (see Problem 16B.3). (a) Estimate the potential energy of interaction between two such rings (treated as benzene molecules) separated by 4.0 nm. For the ionization energy, use  $I = 5.0 \text{ eV}$ . (b) Given that force is the negative slope of the potential, calculate the distance-dependence of the force acting between two non-bonded groups of atoms, such as the phenyl groups of Phe, in a polypeptide chain that can have a London dispersion interaction with each other. What is the separation at which the force between the phenyl groups (treated as benzene molecules) of two Phe residues is zero? (*Hint*: Calculate the slope by considering the potential energy at  $r$  and  $r + \delta r$ , with  $\delta r \ll r$ ,

**16B.3(b)** Estimate the energy of the dispersion interaction (use the London formula) for two Ar atoms separated by 1.0 nm. Relevant data can be found in the *Resource section*.

**16B.4(a)** How much energy (in  $\text{kJ mol}^{-1}$ ) is required to break the hydrogen bond in a vacuum ( $\epsilon_r = 1$ )? Use the electrostatic model of the hydrogen bond.

**16B.4(b)** How much energy (in  $\text{kJ mol}^{-1}$ ) is required to break the hydrogen bond in water ( $\epsilon_r \approx 80.0$ )? Use the electrostatic model of the hydrogen bond.

and evaluating  $\{V(r + \delta r) - V(r)\}/\delta r$ . At the end of the calculation, let  $\delta r$  become vanishingly small.)

**16B.5** Given that  $F = -dV/dr$ , calculate the distance dependence of the force acting between two non-bonded groups of atoms in a polymer chain that have a London dispersion interaction with each other.

**16B.6** Consider the arrangement shown in 5 for a system consisting of an O–H group and an O atom, and then use the electrostatic model of the hydrogen bond to calculate the dependence of the molar potential energy of interaction on the angle  $\theta$ .

**16B.7** Suppose you distrusted the Lennard-Jones (12,6) potential for assessing a particular polypeptide conformation, and replaced the repulsive term by an exponential function of the form  $e^{-r/r_0}$ . (a) Sketch the form of the potential energy and locate the distance at which it is a minimum. (b) Identify the distance at which the exponential-6 potential is a minimum.

**16B.8** The *cohesive energy density*,  $\mathcal{U}$ , is defined as  $U/V$ , where  $U$  is the mean potential energy of attraction within the sample and  $V$  its volume. Show that  $\mathcal{U} = \frac{1}{2} \mathcal{N} \int V(R) d\tau$  where  $\mathcal{N}$  is the number density of the molecules and  $V(R)$  is their attractive potential energy and where the integration ranges from  $d$  to infinity and over all angles. Go on to show that the cohesive energy density of a uniform distribution of molecules that interact by a van der Waals attraction of the form  $-C_6/R^6$  is equal to  $(2\pi/3)(N_A^2/d^3 M^2)\rho^2 C_6$ , where  $\rho$  is the mass density of the solid sample and  $M$  is the molar mass of the molecules.

## TOPIC 16C Liquids

### Discussion question

**16C.1** Describe the process of condensation.

### Exercises

**16C.1(a)** Calculate the vapour pressure of a spherical droplet of water of radius 10 nm at  $20^\circ\text{C}$ . The vapour pressure of bulk water at that temperature is  $2.3 \text{ kPa}$  and its density is  $0.9982 \text{ g cm}^{-3}$ .

**16C.1(b)** Calculate the vapour pressure of a spherical droplet of water of radius  $20.0 \text{ nm}$  at  $35.0^\circ\text{C}$ . The vapour pressure of bulk water at that temperature is  $5.623 \text{ kPa}$  and its density is  $994.0 \text{ kg m}^{-3}$ .

**16C.2(a)** The contact angle for water on clean glass is close to zero. Calculate the surface tension of water at  $20^\circ\text{C}$  given that at that temperature water climbs to a height of  $4.96 \text{ cm}$  in a clean glass capillary tube of internal radius  $0.300 \text{ mm}$ . The density of water at  $20^\circ\text{C}$  is  $998.2 \text{ kg m}^{-3}$ .

**16C.2(b)** The contact angle for water on clean glass is close to zero. Calculate the surface tension of water at  $30^\circ\text{C}$  given that at that temperature water

climbs to a height of 9.11 cm in a clean glass capillary tube of internal diameter 0.320 mm. The density of water at 30 °C is 0.9956 g cm<sup>-3</sup>.

**16C.3(a)** Calculate the pressure differential of water across the surface of a spherical droplet of radius 200 nm at 20 °C.

## Problem

**16C.1** The surface tensions of a series of aqueous solutions of a surfactant A were measured at 20 °C, with the following results:

[A]/(mol dm <sup>-3</sup> )	0	0.10	0.20	0.30	0.40	0.50
$\gamma$ /(mN m <sup>-1</sup> )	72.8	70.2	67.7	65.1	62.8	59.8

## Integrated activities

**16.1** Show that the mean interaction energy of  $N$  atoms of diameter  $d$  interacting with a potential energy of the form  $C_6/R^6$  is given by  $U = -2N^2C_6/3Vd^3$ , where  $V$  is the volume in which the molecules are confined and all effects of clustering are ignored. Hence, find a connection between the van der Waals parameter  $a$  and  $C_6$ , from  $n^2a/V^2 = (\partial U/\partial V)_T$ .

**16.2\*** F. Luo et al. (*J. Chem. Phys.* **98**, 3564 (1993)) reported experimental observation of the He<sub>2</sub> complex, a species which had escaped detection for a long time. The fact that the observation required temperatures in the neighbourhood of 1 mK is consistent with computational studies which suggest that  $hc\bar{D}_e$  for He<sub>2</sub> is about  $1.51 \times 10^{-23}$  J,  $hc\bar{D}_0$  about  $2 \times 10^{-26}$  J, and  $R$  about 297 pm. (a) Determine the Lennard-Jones parameters  $r_0$ , and  $a$  and plot the Lennard-Jones potential for He–He interactions. (b) Plot the Morse potential given that  $a = 5.79 \times 10^{10}$  m<sup>-1</sup>.

**16.3** Molecular orbital calculations may be used to predict structures of intermolecular complexes. Hydrogen bonds between purine and pyrimidine bases are responsible for the double helix structure of DNA (see Topic 17A). Consider methyladenine (6, with R=CH<sub>3</sub>) and methylthymine (7, with R=CH<sub>3</sub>) as models of two bases that can form hydrogen bonds in DNA. (a) Using molecular modelling software and the computational method of your choice, calculate the atomic charges of all atoms in methyladenine and methylthymine. (b) Based on your tabulation of atomic charges, identify the atoms in methyladenine and methylthymine that are likely to participate in hydrogen bonds. (c) Draw all possible adenine–thymine pairs that can be linked by hydrogen bonds, keeping in mind that linear arrangements of the A–H···B fragments are preferred in DNA. For this step, you may want to use your molecular modelling software to align the molecules properly. (d) Consult Topic 17A and determine which of the pairs that you drew in part (c) occur naturally in DNA molecules. (e) Repeat parts (a)–(d) for cytosine and guanine, which also form base pairs in DNA (see Topic 17A for the structures of these bases).

**16.4** Molecular orbital calculations may be used to predict the dipole moments of molecules. (a) Using molecular modelling software and the computational method of your choice, calculate the dipole moment of the peptide link, modelled as a *trans*-*N*-methylacetamide (8). Plot the energy of interaction between these dipoles against the angle  $\theta$  for  $r = 3.0$  nm (see eqn 16B.4). (b) Compare the maximum value of the dipole–dipole interaction energy from

**16C.3(b)** Calculate the pressure differential of ethanol across the surface of a spherical droplet of radius 220 nm at 20 °C. The surface tension of ethanol at that temperature is 22.39 mN m<sup>-1</sup>.

Calculate the surface excess concentration.

part (a) to 20 kJ mol<sup>-1</sup>, a typical value for the energy of a hydrogen bonding interaction in biological systems.

**8** *trans*-*N*-methylacetamide

**16.5** This problem gives a simple example of a quantitative structure–activity relation (QSAR). The binding of nonpolar groups of amino acid to hydrophobic sites in the interior of proteins is governed largely by hydrophobic interactions. (a) Consider a family of hydrocarbons R–H. The hydrophobicity constants,  $\pi$ , for R=CH<sub>3</sub>, CH<sub>2</sub>CH<sub>3</sub>, (CH<sub>2</sub>)<sub>2</sub>CH<sub>3</sub>, (CH<sub>2</sub>)<sub>3</sub>CH<sub>3</sub>, and (CH<sub>2</sub>)<sub>4</sub>CH<sub>3</sub> are, respectively, 0.5, 1.0, 1.5, 2.0, and 2.5. Use these data to predict the  $\pi$  value for (CH<sub>2</sub>)<sub>6</sub>CH<sub>3</sub>. (b) The equilibrium constants  $K_1$  for the dissociation of inhibitors (9) from the enzyme chymotrypsin were measured for different substituents R:

R	CH <sub>3</sub> CO	CN	NO <sub>2</sub>	CH <sub>3</sub>	Cl
$\pi$	-0.20	-0.025	0.33	0.5	0.9
log $K_1$	-1.73	-1.90	-2.43	-2.55	-3.40

Plot log  $K_1$  against  $\pi$ . Does the plot suggest a linear relationship? If so, what are the slope and intercept to the log  $K_1$  axis of the line that best fits the data? (c) Predict the value of  $K_1$  for the case R=H.

**9**

**16.6** Derivatives of the compound TIBO (10) inhibit the enzyme reverse transcriptase, which catalyses the conversion of retroviral RNA to DNA. A QSAR analysis of the activity  $A$  of a number of TIBO derivatives suggests the following equation:

$$\log A = b_0 + b_1S + b_2W$$

where  $S$  is a parameter related to the drug's solubility in water and  $W$  is a parameter related to the width of the first atom in a substituent X shown in 10. (a) Use the following data to determine the values of  $b_0$ ,  $b_1$ , and  $b_2$ . *Hint:* The QSAR equation relates one dependent variable, log  $A$ , to two independent variables,  $S$  and  $W$ . To fit the data, you must use the mathematical procedure of

multiple regression, which can be performed with mathematical software or an electronic spreadsheet.

X	H	Cl	SCH <sub>3</sub>	OCH <sub>3</sub>	CN	CHO	Br	CH <sub>3</sub>	CCH
log A	7.36	8.37	8.3	7.47	7.25	6.73	8.52	7.87	7.53
S	3.53	4.24	4.09	3.45	2.96	2.89	4.39	4.03	3.80
W	1.00	1.80	1.70	1.35	1.60	1.60	1.95	1.60	1.60

(b) What should be the value of *W* for a drug with *S*=4.84 and log *A*=7.60?

10

# CHAPTER 17

## Macromolecules and self-assembly

Macromolecules are built from covalently linked components. They are everywhere, inside us and outside us. Some are natural: they include polysaccharides (such as cellulose), polypeptides (such as protein enzymes), and polynucleotides (such as deoxyribonucleic acid, DNA). Others are synthetic (such as nylon and polystyrene). Molecules both large and small may also gather together in a process called 'self-assembly' and give rise to aggregates that to some extent behave like macromolecules. One example is the assembly of the protein actin into filaments in muscle tissue. In this chapter we examine the structures and properties of macromolecules and aggregates.

### 17A The structures of macromolecules

Macromolecules adopt shapes that are governed by the molecular interactions described in Topic 16B. The overall shape of a protein, for instance, is maintained by van der Waals interactions, hydrogen bonding, and the hydrophobic effect. In this Topic we consider a range of structures, beginning with a structureless 'random coil', partially structured coils, and then the structurally precise proteins and nucleic acids.

### 17B Properties of macromolecules

Natural macromolecules differ in certain respects from synthetic macromolecules, particularly in their composition and the resulting structure, but the two share a number of common properties. In this Topic we concentrate on mechanical, thermal, and electrical properties.

### 17C Self-assembly

Atoms, small molecules, and macromolecules can form large aggregates, sometimes by processes involving self-assembly, that are held together by one or more of the molecular interactions described in Topic 16B. In this Topic we explore 'colloids', 'micelles', and biological membranes, which are assemblies with some of the typical properties of molecules but also with their own characteristic features. We also consider examples in which the controlled design of new materials with enhanced properties is informed by understanding of the principles underlying self-assembly.

### 17D Determination of size and shape

Macromolecules, whether natural or synthetic, and aggregates need to be characterized in terms of their molar mass, their size, and their shape. This Topic considers how these features are determined experimentally.

### What is the impact of this material?

The impact of this material is immense as it underlies the discussion of biological phenomena and the properties of many modern materials. However, the applications are embedded in the development of the concepts and are not found on the web site.

### ► Why do you need to know this material?

Macromolecules give rise to special problems that include the investigation and description of their shapes and the determination of their sizes. You need to know how to describe the structural features of macromolecules in order to understand their physical and chemical properties.

### ► What is the key idea?

The structure of a macromolecule takes on different meanings at the different levels at which the arrangement of the chain or network of its building blocks is considered.

### ► What do you need to know already?

You need to be familiar with statistical arguments (Topic 15A). The discussion of the shapes of biological macromolecules depends on an understanding of the nonbonding interactions that act between molecules (Topic 16B).

**Macromolecules** are very large molecules assembled from smaller molecules biosynthetically in organisms, by chemists in the laboratory, or in an industrial reactor. Naturally occurring macromolecules include polysaccharides such as cellulose, polypeptides such as protein enzymes, and polynucleotides such as deoxyribonucleic acid (DNA). Synthetic macromolecules include **polymers** such as nylon and polystyrene that are manufactured by stringing together and in some cases cross-linking smaller units known as **monomers** (Fig. 17A.1).

## 17A.1 The different levels of structure

The concept of the 'structure' of a macromolecule takes on different meanings at the different levels at which we think about the arrangement of the chain or network of monomers. The **primary structure** of a macromolecule is the sequence of small molecular residues making up the polymer. The residues may form either a chain, as in polyethylene, or a more complex network in which cross-links connect different chains, as in cross-linked polyacrylamide. In a synthetic polymer, virtually all the residues are identical and it is sufficient to name the monomer used in the synthesis. Thus, the repeating unit of polyethylene and its derivatives is  $-\text{CHXCH}_2-$ , and the primary structure of the chain is specified by denoting it as  $-(\text{CHXCH}_2)_n-$ .

The concept of primary structure ceases to be trivial in the case of synthetic copolymers and biological macromolecules, for in general these substances are chains formed from different

Figure 17A.1 Three varieties of polymer: (a) a simple linear polymer, (b) a cross-linked polymer, and (c) one variety of copolymer.

molecules. For example, proteins are **polypeptides** formed from different amino acids (about twenty occur naturally) strung together by the **peptide link**,  $-\text{CONH}-$ . The determination of the primary structure is then a highly complex problem of chemical analysis called **sequencing**. The **degradation** of a polymer is a disruption of its primary structure, when the chain breaks into shorter components.

The term **conformation** refers to the spatial arrangement of the different parts of a chain, and one conformation can be changed into another by rotating one part of a chain around a bond. The conformation of a macromolecule is relevant at three levels of structure. The **secondary structure** of a macromolecule is the (often local) spatial arrangement of a chain. The secondary structure of a molecule of polyethylene in a good solvent is typically a random coil in the absence of a solvent polyethylene forms crystals consisting of stacked sheets with a hairpin-like bend about every 100 monomer units, presumably because for that number of monomers the intermolecular (in this case *intramolecular*) potential energy is sufficient to overcome thermal disordering. The secondary structure of a protein is a highly organized arrangement determined largely by hydrogen bonds, and taking the form of random coils, helices (Fig. 17A.2a), or sheets in various segments of the molecule.

The **tertiary structure** is the overall three-dimensional structure of a macromolecule. For instance, the hypothetical protein shown in Fig. 17A.2b has helical regions connected by short random-coil sections. The helices interact to form a compact tertiary structure. Denaturation may also occur at this level, with tertiary structure lost but secondary structure largely retained.

The **quaternary structure** of a macromolecule is the manner in which large molecules are formed by the aggregation of others. Figure 17A.3 shows how four molecular subunits, each with a specific tertiary structure, aggregate. Quaternary structure can be very important in biology. For example, the oxygen-transport protein haemoglobin consists of four myoglobin-like subunits that work cooperatively to take up and release  $\text{O}_2$ .

**Figure 17A.2** (a) A polymer adopts a highly organized helical conformation, an example of a secondary structure. The helix is represented as a cylinder. (b) Several helical segments connected by short random coils pack together, providing an example of tertiary structure.

**Figure 17A.3** Several subunits with specific tertiary structures pack together, providing an example of quaternary structure.

## 17A.2 Random coils

The most likely conformation of a chain of identical units not capable of forming hydrogen bonds or any other type of specific bond is a **random coil**. Polyethylene is a simple example. The random coil model is a helpful starting point for estimating the orders of magnitude of the hydrodynamic properties of polymers and denatured proteins in solution.

The simplest model of a random coil is a **freely-jointed chain**, in which any bond is free to make any angle with respect to the preceding one (Fig. 17A.4). We assume that the residues occupy zero volume, so different parts of the chain can occupy the same region of space. The model is obviously an oversimplification because a bond is actually constrained to a cone of angles around a direction defined by its neighbour (Fig. 17A.5) and real chains are self-avoiding in the sense that distant parts of the same chain cannot fold back and occupy the same space.

In a hypothetical one-dimensional freely jointed chain all the residues lie in a straight line, and the angle between neighbours is either  $0^\circ$  or  $180^\circ$ . The residues in a three-dimensional freely jointed chain are not restricted to lie in a line or a plane.

**Figure 17A.4** A freely-jointed chain is like a three-dimensional random walk, each step being in an arbitrary direction but of the same length.

Figure 17A.5 A better description is obtained by fixing the bond angle (for example, at the tetrahedral angle) and allowing free rotation about a bond direction.

### (a) Measures of size

As shown in the following *Justification*, the probability,  $P$ , that the ends of a long one-dimensional freely jointed chain composed of  $N$  units of length  $l$  (and therefore of total length  $Nl$ ) are a distance  $nl$  apart is

$$P = \left( \frac{2}{\pi N} \right)^{1/2} e^{-n^2/2N} \quad \text{One-dimensional random coil} \quad \text{Probability distribution} \quad (17A.1)$$

This function is plotted in Fig. 17A.6.

Figure 17A.6 The probability distribution for the separation of the ends of a one-dimensional random coil. The separation of the ends is  $Nl$ , where  $l$  is the bond length.

#### Brief illustration 17A.1 One-dimensional random coils

Suppose that  $N = 1000$  and  $l = 150$  pm, then the probability that the ends of a one-dimensional random coil are  $nl = 3.00$  nm apart is given by eqn 17A.1 by setting  $n = (3.00 \times 10^3 \text{ pm}) / (150 \text{ pm}) = 20.0$ :

$$P = \left( \frac{2}{\pi \times 1000} \right)^{1/2} e^{-20.0^2 / (2 \times 1000)} = 0.0207$$

meaning that there is a 1 in 48 chance of being found there.

**Self-test 17A.1** What is the probability that the ends of a polyethylene chain of molar mass  $85 \text{ kg mol}^{-1}$  are 10 nm apart when the polymer is treated as a one-dimensional freely jointed chain?

Answer:  $9.8 \times 10^{-3}$

#### Justification 17A.1 One-dimensional random coils

Consider a one-dimensional freely jointed polymer. We can specify its conformation by stating the number of bonds pointing to the right ( $N_R$ ) and the number pointing to the left ( $N_L$ ). The distance between the ends of the chain is  $(N_R - N_L)l$ , where  $l$  is the length of an individual bond. We write  $n = N_R - N_L$  and the total number of bonds as  $N = N_R + N_L$ . Later in the calculation we use  $N_R = \frac{1}{2}(N + n)$  and  $N_L = \frac{1}{2}(N - n)$ .

The probability,  $P$ , that the end-to-end separation of a randomly selected polymer is  $nl$  is

$$P = \frac{\text{number of polymers with end-to-end distance } nl}{\text{total number of possible conformations}}$$

Each of the  $N$  bonds of the polymer may in principle lie to the left or the right, so the total number of possible conformations is  $2^N$ . The total number of ways,  $W$ , of forming a chain of  $N$  bonds with the end-to-end distance  $nl$  is the number of ways of having  $N_R$  right-pointing bonds, the rest being left-pointing bonds. Therefore, to calculate  $W$  we need to determine the number of ways of achieving  $N_R$  right-pointing bonds given a total of  $N$  bonds. This is the same problem as selecting  $N_R$  objects from a collection of  $N$  objects (see Topic 15A), and is

$$W = \frac{N!}{N_R!(N - N_R)!} = \frac{N!}{N_R!N_L!} = \frac{N!}{\left\{ \frac{1}{2}(N + n) \right\}! \left\{ \frac{1}{2}(N - n) \right\}!}$$

It now follows that

$$P = \frac{W}{2^N} = \frac{N!}{\left\{ \frac{1}{2}(N + n) \right\}! \left\{ \frac{1}{2}(N - n) \right\}! 2^N}$$

When the chain is compact in the sense that  $n \ll N$ , it is more convenient to evaluate  $\ln P$ : the factorials are then large and we can use Stirling's approximation (Topic 15A) in the form

$$\ln x! \approx \ln(2\pi)^{1/2} + \left(x + \frac{1}{2}\right) \ln x - x$$

The result, after quite a lot of algebra (see Problem 17A.7), is

$$\ln P \approx \ln \left( \frac{2}{\pi N} \right)^{1/2} - \frac{1}{2}(N + n + 1) \ln(1 + \nu) - \frac{1}{2}(N - n + 1) \ln(1 - \nu)$$

where  $v = n/N$ . For a compact coil ( $v \ll 1$ ) we use the approximation  $\ln(1 \pm v) \approx \pm v - \frac{1}{2}v^2$  and so obtain

$$\ln P \approx \ln \left( \frac{2}{\pi N} \right)^{1/2} - \frac{1}{2} N v^2$$

which rearranges into eqn 17A.1.

To confirm that the total probability of the chain ends being at any separation is 1, we integrate  $P$  over all values of  $n$ . However, because  $n$  can change only in steps of 2, the integration step size is  $\frac{1}{2}dn$ , not  $dn$  itself. Then (with  $N$  allowed to become infinite),

$$\sum_{n=-N}^N P \rightarrow \int_{-\infty}^{\infty} P(n) \left( \frac{1}{2} dn \right) = \frac{1}{2} \left( \frac{2}{\pi N} \right)^{1/2} \int_{-\infty}^{\infty} e^{-n^2/2N} dn \stackrel{\text{Integral G.1}}{=} 1$$

We show in the following *Justification* that eqn 17A.1 can be used to calculate the probability that the ends of a long three-dimensional freely jointed chain lie in the range  $r$  to  $r+dr$ . We write this probability as  $f(r)dr$ , where

$$f(r) = 4\pi \left( \frac{a}{\pi^{1/2}} \right)^3 r^2 e^{-a^2 r^2} \quad \begin{array}{l} \text{Three-} \\ \text{dimensional} \\ \text{random coil} \end{array} \quad \begin{array}{l} \text{Probability} \\ \text{distribution} \end{array} \quad (17A.2)$$

$$a = \left( \frac{3}{2Nl^2} \right)^{1/2}$$

For a narrow range of distances  $\delta r$ , the probability density can be treated as a constant and the probability calculated from  $f(r)\delta r$ . An alternative interpretation of this expression is to regard each coil in a sample as ceaselessly writhing from one conformation to another; then  $f(r)dr$  is the probability that at any instant the chain will be found with the separation of its ends between  $r$  and  $r+dr$ .

### Justification 17A.2 Three-dimensional random coils

The formation of a three-dimensional random coil can be regarded as the outcome of a three-dimensional random walk, in which each bond of length  $l$  represents a step of length  $l$  taken in a random direction. The length of the step can be expressed in terms of its projections on each of three orthogonal axes as  $l^2 = l_x^2 + l_y^2 + l_z^2$ . The average values of  $l_x^2$ ,  $l_y^2$ , and  $l_z^2$  are all the same in a spherically symmetric environment, so the average length of a step in the  $x$ -direction (or any of the other two directions) can be obtained by writing  $l^2 = 3\langle l_x^2 \rangle$ , and is  $x = \langle l_x^2 \rangle^{1/2} = l/3^{1/2}$ . The probability that the random walk will end up at a distance  $x$  from the origin is given by eqn 17A.1 with  $n = x/(l/3^{1/2}) = 3^{1/2}x/l$ :

$$P(x) = \left( \frac{2}{\pi N} \right)^{1/2} e^{-3x^2/2Nl^2}$$

If  $x$  is regarded as continuously variable, we need to replace this probability by a probability density  $f(x)$  such that  $f(x)dx$  is the probability that the ends of the chain will be found between  $x$  and  $x+dx$ . Because  $dx = 2(l/3^{1/2})dn$  (for the factor 2, see the remark at the end of *Justification* 17A.1),  $dn = (3^{1/2}/2l)dx$ , so

$$f(x) = \frac{1}{2l} \left( \frac{6}{\pi N} \right)^{1/2} e^{-3x^2/2Nl^2}$$

Because the probabilities of making steps along all three coordinates are independent, the probability of finding the ends of the chain in a region of volume  $dV = dx dy dz$  at a distance  $r$  is the product of these densities:

$$f(x, y, z)dV = f(x)f(y)f(z)dx dy dz = \frac{1}{8l^3} \left( \frac{6}{\pi N} \right)^{3/2} e^{-3r^2/2Nl^2} dV$$

The volume of a spherical shell at a distance  $r$  is  $4\pi r^2$ , so the total probability of finding the ends at a separation between  $r$  and  $r+dr$ , regardless of orientation, is

$$f(r)dr = \frac{4\pi}{8l^3} \left( \frac{6}{\pi N} \right)^{3/2} r^2 e^{-3r^2/2Nl^2} dr$$

from which  $f(r)$  can be identified (in blue), as in eqn 17A.2.

In some coils, the ends may be far apart whereas in others their separation is small. Here and elsewhere we are ignoring the fact that the chain cannot be longer than  $Nl$ . Although eqn 17A.2 gives a nonzero probability for  $r > Nl$ , the values are so small that the errors in pretending that  $r$  can range up to infinity are negligible.

### Brief illustration 17A.2 Three-dimensional random coils

Consider the chain described in *Brief illustration* 17A.1, with  $N = 1000$  and  $l = 150$  pm. If the coil is three dimensional, we set

$$a = \left( \frac{3}{2 \times 1000 \times (150 \text{ pm})^2} \right)^{1/2} = 2.58 \dots \times 10^{-4} \text{ pm}^{-1}$$

Then the probability density at  $r = 3.00$  nm is given by eqn 17A.2 as

$$f(3.00 \text{ nm}) = 4\pi \times \left( \frac{2.58 \dots \times 10^{-4} \text{ pm}^{-1}}{\pi^{1/2}} \right)^3 \times (3.00 \times 10^3 \text{ pm})^2 \times e^{-(2.58 \dots \times 10^{-4} \text{ pm}^{-1})^2 (3.00 \times 10^3 \text{ pm})^2} = 1.92 \times 10^{-4} \text{ pm}^{-1}$$

The probability that the ends will be found in a narrow range of width  $\delta r = 10.0$  pm at 3.00 nm (regardless of direction) is therefore

$$f(3.00 \text{ nm})\delta r = (1.92 \times 10^{-4} \text{ pm}^{-1}) \times (10.0 \text{ pm}) = 1.92 \times 10^{-3}$$

or about 1 in 5200.

**Self-test 17A.2** What is the probability that the ends of a polyethylene chain of molar mass  $85 \text{ kg mol}^{-1}$  are between 15.0 nm and 15.1 nm apart when the polymer is treated as a three-dimensional freely jointed chain?

Answer:  $5.9 \times 10^{-3}$

There are several measures of the geometrical size of a random coil. The **contour length**,  $R_c$ , is the length of the macromolecule measured along its backbone from atom to atom. For a polymer of  $N$  monomer units each of length  $l$ , the contour length is

$$R_c = Nl \quad \text{Random coil} \quad \text{Contour length} \quad (17A.3)$$

The **root-mean-square separation**,  $R_{\text{rms}}$ , is a measure of the average separation of the ends of a random coil: it is the square root of the mean value of  $R^2$ . To determine its value we note that the vector joining the two ends of the chain is the vector sum of the vectors joining neighbouring monomers:  $\mathbf{R} = \sum_{i=1}^N \mathbf{r}_i$  (Fig. 17A.7). The mean square separation of the ends of the chain is therefore

$$\langle R^2 \rangle = \langle \mathbf{R} \cdot \mathbf{R} \rangle = \sum_{i,j} \langle \mathbf{r}_i \cdot \mathbf{r}_j \rangle = \sum_i \langle r_i^2 \rangle + \sum_{i \neq j} \langle \mathbf{r}_i \cdot \mathbf{r}_j \rangle$$

When  $N$  is large (which we assume throughout) the second sum (in blue) vanishes because the individual vectors all lie in random directions. The remaining sum is equal to  $Nl^2$  as all bond lengths are the same (and equal to  $l$ ); so, after taking square roots to obtain  $R_{\text{rms}} = \langle R^2 \rangle^{1/2}$ , we conclude that

$$R_{\text{rms}} = N^{1/2}l \quad \text{Random coil} \quad \text{Root-mean-square separation} \quad (17A.4)$$

We see that, as the number of monomer units increases, the root-mean-square separation of its end increases as  $N^{1/2}$  (Fig. 17A.8), and consequently its volume increases as  $N^{3/2}$ . The result must be multiplied by a factor when the chain is not freely jointed (see next section).

Another convenient measure of size is the **radius of gyration**,  $R_g$ , which is the radius of a hollow sphere that has the

**Figure 17A.7** A schematic illustration of the calculation of the root-mean-square separation of the ends of a random coil.

**Figure 17A.8** The variation of the root-mean-square separation of the ends of a three-dimensional random coil,  $R_{\text{rms}}$ , with the number of monomers.

same moment of inertia (and therefore rotational characteristics) as the actual molecule of the same mass. We show in the following *Justification* that

$$R_g = N^{1/2}l \quad \text{One-dimensional random coil} \quad \text{Radius of gyration} \quad (17A.5)$$

A similar calculation for a three-dimensional random coil gives

$$R_g = \left(\frac{N}{6}\right)^{1/2} l \quad \text{Three-dimensional random coil} \quad \text{Radius of gyration} \quad (17A.6)$$

The radius of gyration is smaller in this case because the extra dimensions enable the coil to be more compact. The radius of gyration may also be calculated for other geometries. For example, a solid uniform sphere of radius  $R$  has  $R_g = (\frac{3}{5})^{1/2}R$ , and a long thin uniform rod of length  $l$  has  $R_g = l/(12)^{1/2}$  for rotation about an axis perpendicular to the long axis. A solid sphere with the same radius and mass as a random coil has a greater radius of gyration as it is entirely dense throughout.

### Brief illustration 17A.3 Measures of size of a random coil

With a powerful microscope it is possible to see that a long piece of DNA is flexible and writhes as if it were a random coil. However, small segments of the macromolecule resist bending, so it is more appropriate to visualize DNA as a freely jointed chain with  $N$  and  $l$  as the number and length, respectively, of these rigid units. The length  $l$  of a rigid unit is approximately 45 nm. It follows that for a piece of DNA with  $N=200$ , we estimate (by using  $10^3 \text{ nm} = 1 \mu\text{m}$ )

$$\text{From eqn 17A.3: } R_c = 200 \times 45 \text{ nm} = 9.0 \mu\text{m}$$

$$\text{From eqn 17A.4: } R_{\text{rms}} = (200)^{1/2} \times 45 \text{ nm} = 0.64 \mu\text{m}$$

$$\text{From eqn 17A.6: } R_g = \left(\frac{200}{6}\right)^{1/2} \times 45 \text{ nm} = 0.26 \mu\text{m}$$

**Self-test 17A.3** Calculate the contour and root-mean-square lengths of a polymer chain modelled as a random coil with  $N=1000$  and  $l=150$  pm.

Answer:  $R_c=150$  nm,  $R_{\text{rms}}=4.74$  nm

### Justification 17A.3 The radius of gyration

For a one-dimensional random coil with  $N+1$  identical monomers (and therefore  $N$  bonds) each of mass  $m$ , the moment of inertia around the centre of the chain (which is also at the first monomer, because steps occur in equal numbers to left and right) is

$$I = \sum_{i=0}^N m_i r_i^2 = m \sum_{i=0}^N r_i^2$$

This moment of inertia is set equal to  $m_{\text{tot}} R_g^2$ , where  $m_{\text{tot}}$  is the total mass of the polymer,  $m_{\text{tot}}=(N+1)m$ . Therefore, after averaging over all conformations,

$$R_g^2 = \frac{1}{N+1} \sum_{i=0}^N \langle r_i^2 \rangle$$

For a linear random chain,  $\langle r_i^2 \rangle = Nl^2$ , and as there are  $N+1$  such terms in the sum, we find

$$R_g^2 = Nl^2$$

Equation 17A.5 then follows after taking the square root of each side.

The random coil model ignores the role of the solvent: a poor solvent will tend to cause the coil to tighten so that solute-solvent contacts are minimized; a good solvent does the opposite. Therefore, calculations based on this model are better regarded as lower bounds to the dimensions for a polymer in a good solvent and as an upper bound for a polymer in a poor solvent. The model is most reliable for a polymer in a bulk solid sample, where the coil is likely to have its natural dimensions.

### (b) Constrained chains

The freely jointed chain model is improved by removing the freedom of bond angles to take any value. For long chains, we can simply take groups of neighbouring bonds and consider the direction of their resultant. Although each successive individual bond is constrained to a single cone of angle  $\theta$  relative to its neighbour, the resultant of several bonds lies in a random direction. By concentrating on such groups rather than individuals, it turns out that for long chains the expressions for the root-mean-square separation and the radius of gyration given above should be multiplied by

$$F = \left( \frac{1 - \cos \theta}{1 + \cos \theta} \right)^{1/2} \quad (17A.7)$$

For tetrahedral bonds, for which  $\cos \theta = \frac{1}{3}$  (that is,  $\theta = 109.5^\circ$ ),  $F = 2^{1/2}$ . Therefore:

$$R_{\text{rms}} = (2N)^{1/2} l \quad R_g = \left( \frac{N}{3} \right)^{1/2} l \quad \text{Dimensions of a tetrahedrally constrained chain} \quad (17A.8)$$

The model of a randomly coiled molecule is still an approximation, even after the bond angles have been restricted, because it does not take into account the impossibility of two or more atoms occupying the same place. Such self-avoidance tends to swell the coil, so (in the absence of solvent effects) it is better to regard  $R_{\text{rms}}$  and  $R_g$  as lower bounds to the actual values.

### (c) Partly rigid coils

An important measure of the flexibility of a chain is the **persistence length**,  $l_p$ , a measure of the length over which the direction of the first monomer–monomer direction is sustained. If the chain is a rigid rod, then the persistence length is the same as the contour length. For a freely-jointed random coil, the persistence length is just the length of the monomer–monomer bond. Therefore, the persistence length can be regarded as a measure of the stiffness of the chain. In general, the persistence length of a chain of identical monomers of length  $l$  is defined as the average value of the projection of the end-to-end vector on the first bond of the chain (Fig. 17A.9):

$$l_p = \left\langle \frac{\mathbf{r}_1}{l} \cdot \mathbf{R} \right\rangle = \frac{1}{l} \sum_{i=1}^{N-1} \langle \mathbf{r}_1 \cdot \mathbf{r}_i \rangle \quad \text{Definition Persistence length} \quad (17A.9)$$

(The sum ends at  $N-1$  because the last atom is atom  $N$  and the last bond is from atom  $N-1$  to atom  $N$ .) Experimental values of persistence lengths are as follows:

poly(glycine)	poly(L-alanine)	poly(L-proline)
0.6 nm	2 nm	22 nm

These values suggest that the stiffness of the chain increases from left to right along the series.

The mean square distance between the ends of a chain that has a persistence length greater than the monomer length can be expected to be greater than for a random coil because the partial rigidity of the coil does not let it roll up so tightly. We show in the following *Justification* that

$$R_{\text{rms}} = N^{1/2} l F \quad \text{where } F = \left( \frac{2l_p}{l} - 1 \right)^{1/2} \quad (17A.10)$$

For a random coil,  $l_p = l$ , so  $R_{\text{rms}} = N^{1/2} l$ , as we have already found. For  $l_p > l$ ,  $F > 1$ , so the coil has swollen, as we anticipated.

**Figure 17A.9** The persistence length is defined as the average value of the projection of the end-to-end vector on the first bond of the chain.

#### Justification 17A.4 Partly rigid coils

In each of the following steps we use  $N \rightarrow \infty$  when necessary. We start from

$$\langle R^2 \rangle = \sum_i \langle r_i^2 \rangle + \sum_{i \neq j} \langle r_i \cdot r_j \rangle$$

The first term on the right is  $Nl^2$  regardless of the rigidity of the coil. The second term can be written as follows:

$$\sum_{i \neq j} \langle r_i \cdot r_j \rangle = 2 \sum_{i=2}^N \langle r_1 \cdot r_i \rangle + 2 \sum_{i=3}^N \langle r_2 \cdot r_i \rangle + \dots$$

There are  $N-1$  such terms, and provided we allow  $N$  to become infinite, all the sums on the right have the same value, so

$$\sum_{i \neq j} \langle r_i \cdot r_j \rangle = 2(N-1) \sum_{i=2}^N \langle r_1 \cdot r_i \rangle \approx 2N \sum_{i=2}^N \langle r_1 \cdot r_i \rangle$$

The final (blue) sum on the right is close to being the square of the persistence length. Specifically, from eqn 17A.9,

$$\sum_{j=2}^N \langle r_1 \cdot r_j \rangle = \sum_{j=1}^N \langle r_1 \cdot r_j \rangle - \langle r_1^2 \rangle = ll_p - l^2$$

Now we bring the three pieces of the calculation together:

$$\langle R^2 \rangle = Nl^2 + 2N(ll_p - l^2) = 2Nll_p - Nl^2$$

which, on taking the square root of both sides, is eqn 17A.10.

#### Example 17A.1 Calculating the root-mean-square separation of a partly rigid coil

By what percentage does the root-mean-square separation of the ends of a polymer chain with  $N=1000$  increase or decrease when the persistence length changes from  $l$  (the bond length) to 2.5 per cent of the contour length?

**Method** When  $l_p = l$ , the chain is a random coil. From eqn 17A.4, write the root-mean-square separation of the ends of the chain in the random coil limit as  $R_{\text{rms, random coil}} = N^{1/2}l$ . Then it follows from eqn 17A.10 that the root-mean-square separation of the ends of the chain,  $R_{\text{rms}}$ , of the partly rigid coil with persistence length  $l_p$  is

$$R_{\text{rms}} = R_{\text{rms, random coil}} \left( \frac{2l_p}{l} - 1 \right)^{1/2}$$

From eqn 17A.3, we write  $R_c = Nl$  and we are given that  $l_p = 0.025R_c$ , which can therefore be interpreted as  $0.025Nl$ . From these expressions, calculate the fractional change in the root-mean-square separation,  $(R_{\text{rms}} - R_{\text{rms, random coil}}) / R_{\text{rms, random coil}}$ , and express the result as a percentage.

**Answer** We write the fractional change in the root-mean-square separation as

$$\begin{aligned} \frac{R_{\text{rms}} - R_{\text{rms, random coil}}}{R_{\text{rms, random coil}}} &= \frac{R_{\text{rms}}}{R_{\text{rms, random coil}}} - 1 \\ &= \left( \frac{2l_p}{l} - 1 \right)^{1/2} - 1 \\ &= \left( \frac{2 \times 0.025Nl}{l} - 1 \right)^{1/2} - 1 \\ &= (0.050N - 1)^{1/2} - 1 \end{aligned}$$

With  $N=1000$ , the fractional change is 6.00, so the root-mean-square separation increases by 600 per cent.

**Self-test 17A.4** Calculate the fractional change in the volume of the same coil.

Answer: 340

## 17A.3 Biological macromolecules

A protein is a polypeptide composed of linked  $\alpha$ -amino acids,  $\text{NH}_2\text{CHR}\text{COOH}$ , where R is one of about 20 groups. For a protein to function correctly, it needs to have the correct conformation. For example, an enzyme has its greatest catalytic efficiency only when it is in a specific conformation. The amino acid sequence of a protein contains the necessary information to create the active conformation of the protein as it is formed. However, the prediction of the observed conformation from the primary structure, the so-called *protein folding problem*, is extraordinarily difficult and is still the focus of much research. The other class of biological macromolecules we consider are the nucleic acids, which are key components of the mechanism of storage and transfer of genetic information in biological cells. Deoxyribonucleic acid (DNA) contains the instructions for protein synthesis, which is carried out by different forms of ribonucleic acid (RNA).

**(a) Proteins**

The origin of the secondary structures of proteins is found in the rules formulated by Linus Pauling and Robert Corey in 1951 that seek to identify the principal contributions to the lowering of energy of the molecule by focusing on the role of hydrogen bonds and the peptide link,  $-\text{CONH}-$ . The latter can act both as a donor of the H atom (the NH part of the link) and as an acceptor (the CO part). The **Corey–Pauling rules** are as follows (Fig. 17A.10):

1. The four atoms of the peptide link lie in a relatively rigid plane.

The planarity of the link is due to delocalization of  $\pi$  electrons over the O, C, and N atoms and the maintenance of maximum overlap of their p orbitals.

2. The N, H, and O atoms of a hydrogen bond lie in a straight line (with displacements of H tolerated up to not more than  $30^\circ$  from the N–O direction).
3. All NH and CO groups of the peptide links are engaged in hydrogen bonding.

The rules are satisfied by two structures. One, in which hydrogen bonding between peptide links leads to a helical structure, is a *helix*, which can be arranged as either a right- or a left-handed screw. The other, in which hydrogen bonding between peptide links leads to a planar structure, is a *sheet*; this form is the secondary structure of the protein fibroin, the constituent of silk.

Because the planar peptide link is relatively rigid, the geometry of a polypeptide chain can be specified by the two angles that two neighbouring planar peptide links make to each other. Figure 17A.11 shows the two angles  $\phi$  and  $\psi$  commonly used to specify this relative orientation. The sign convention is that a positive angle means that the front atom must be rotated clockwise to bring it into an eclipsed position relative to the rear atom. For an all-*trans* form of the chain, all  $\phi$  and  $\psi$  are  $180^\circ$ . A helix is obtained when all the  $\phi$  are equal and when all the

**Figure 17A.10** The dimensions that characterize the peptide link. The C–NH–CO–C atoms define a plane (the C–N bond has partial double-bond character), but there is rotational freedom around the C–CO and N–C bonds.

**Figure 17A.11** The definition of the torsional angles  $\psi$  and  $\phi$  between two peptide units. In this case (an  $\alpha$ -L-polypeptide) the chain has been drawn in its all-*trans* form, with  $\psi = \phi = 180^\circ$ .

$\psi$  are equal. For a right-handed helix, an  $\alpha$  helix (Fig. 17A.12), all  $\phi = 57^\circ$  and all  $\psi = -47^\circ$ . For a left-handed helix, both angles are positive. The torsional contribution to the total potential energy is

$$V_{\text{torsion}} = A(1 + \cos 3\phi) + B(1 + \cos 3\psi) \quad (17A.11)$$

in which  $A$  and  $B$  are constants of the order of  $1 \text{ kJ mol}^{-1}$ . Because only two angles are needed to specify the conformation of a helix, and they range from  $-180^\circ$  to  $+180^\circ$ , the torsional potential energy of the entire molecule can be represented on a **Ramachandran plot**, a contour diagram in which one axis represents  $\phi$  and the other represents  $\psi$ .

Figure 17A.13 shows the Ramachandran plots for the helical form of polypeptide chains formed from the non-chiral amino acid glycine ( $R = \text{H}$ ) and the chiral amino acid L-alanine ( $R = \text{CH}_3$ ). The glycine map is symmetrical, with minima of equal depth at  $\phi = -80^\circ$ ,  $\psi = +90^\circ$  and at  $\phi = +80^\circ$ ,  $\psi = -90^\circ$ . In contrast, the map for L-alanine is unsymmetrical, and there are three distinct low-energy conformations (marked I, II, III). The minima of regions I and II lie close to the angles typical of

**Figure 17A.12** The polypeptide  $\alpha$  helix, with poly-L-glycine as an example. There are 3.6 residues per turn, and a translation along the helix of 150 pm per residue, giving a pitch of 540 pm. The diameter (ignoring side chains) is about 600 pm.

**Figure 17A.13** Contour plots of potential energy against the angles  $\psi$  and  $\phi$ , also known as a Ramachandran diagram, for (a) a glycyl residue of a polypeptide chain and (b) an alanyl residue. The glycyl diagram is symmetrical, but that for alanyl is unsymmetrical and the global minimum corresponds to an  $\alpha$ -helix. (T. Hovmoller et al., *Acta Cryst.* **D58**, 768 (2002).)

right- and left-handed helices, but the former has a lower minimum. This result is consistent with the observation that polypeptides of the naturally occurring L-amino acids tend to form right-handed helices.

A  $\beta$ -sheet (also called the  $\beta$ -pleated sheet) is formed by hydrogen bonding between two extended polypeptide chains (large absolute values of the torsion angles  $\phi$  and  $\psi$ ). In an **antiparallel  $\beta$ -sheet** (Fig. 17A.14a),  $\phi = 139^\circ$ ,  $\psi = 113^\circ$ , and the N—H $\cdots$ O atoms of the hydrogen bonds form a straight line. This arrangement is a consequence of the antiparallel arrangement of the chains: every N—H bond on one chain is aligned with a C—O bond from another chain. Antiparallel  $\beta$ -sheets are very common in proteins. In a **parallel  $\beta$ -sheet** (Fig. 17A.14b),  $\phi = 119^\circ$ ,  $\psi = 113^\circ$ , and the N—H $\cdots$ O atoms of the hydrogen bonds are not perfectly aligned. This arrangement is a result of the parallel arrangement of the chains: each N—H bond on one chain is aligned with a N—H bond of another chain and, as a result, each

**Figure 17A.14** The two types of  $\beta$ -sheets: (a) antiparallel ( $\phi = -139^\circ$ ,  $\psi = 113^\circ$ ), in which the N—H—O atoms of the hydrogen bonds form a straight-line; (b) parallel ( $\phi = -119^\circ$ ,  $\psi = 113^\circ$ ) in which the N—H—O atoms of the hydrogen bonds are not perfectly aligned.

C—O bond of one chain is aligned with a C—O bond of another chain. These structures are not common in proteins.

Covalent and non-covalent interactions may cause polypeptide chains with well-defined secondary structures to fold into tertiary structures. Although the rules that govern protein folding are still being elucidated, a few general conclusions may be drawn from X-ray diffraction studies of water-soluble natural proteins and synthetic polypeptides. In an aqueous environment, the chains fold in such a way as to place nonpolar R groups in the interior (which is often not very accessible to solvent) and charged R groups on the surface (in direct contact with the polar solvent). Other factors that promote the folding of proteins include covalent disulfide (—S—S—) links, Coulombic interactions between ions (which depend on the degree of protonation of groups and therefore on the pH), van der Waals interactions, and hydrophobic interactions (Topic 16B). The clustering of nonpolar, hydrophobic, amino acids into the interior of a protein is driven primarily by hydrophobic interactions.

## (b) Nucleic acids

Both DNA and RNA are *polynucleotides* (1), in which base-sugar-phosphate units are linked by phosphodiester bonds. In RNA the sugar is  $\beta$ -D-ribose and in DNA it is  $\beta$ -D-2-deoxyribose (as shown in 1). The most common bases are adenine (A, 2), cytosine (C, 3), guanine (G, 4), thymine (T, found in DNA only, 5), and uracil (U, found in RNA only, 6). At physiological pH, each phosphate group of the chain carries a negative charge and the bases are deprotonated and neutral. This charge distribution leads to two important properties. One is that the polynucleotide chain is a **polyelectrolyte**, a macromolecule with many different charged sites, with a large and negative overall surface charge. The second is that the bases can interact by hydrogen bonding, as shown for A—T (7) and C—G base pairs (8). The secondary and tertiary structures of DNA and RNA arise primarily from the pattern of this hydrogen bonding between bases of one or more chains.

In DNA, two polynucleotide chains wind around each other to form a double helix (Fig. 17A.15). The chains are held together by links involving A–T and C–G base pairs that lie

**Figure 17A.15** The DNA double helix, in which two polynucleotide chains are linked together by hydrogen bonds between adenine (A) and thymine (T) and between cytosine (C) and guanine (G).

parallel to each other and perpendicular to the axis of the helix. The structure is stabilized further by interactions between the planar  $\pi$  systems of the bases. In B-DNA, the most common form of DNA found in biological cells, the helix is right-handed with a diameter of 2.0 nm and a pitch of 3.4 nm.

## Checklist of concepts

- 1. The **primary structure** of a macromolecule is the sequence of small molecular residues making up the polymer.
- 2. The **secondary structure** is the spatial arrangement of a chain of residues.
- 3. The **tertiary structure** is the overall three-dimensional structure of a macromolecule.
- 4. The **quaternary structure** is the manner in which large molecules are formed by the aggregation of others.
- 5. In a **freely jointed chain** any bond in a polymer is free to make any angle with respect to the preceding one.
- 6. The freely jointed chain model is improved by removing the freedom of bond angles to take any value.
- 7. The least structured conformation of a macromolecule is a **random coil**, which can be modelled as a freely jointed chain.
- 8. The secondary structure of a protein is the spatial arrangement of the polypeptide chain and includes **helices** and the  **$\beta$ -sheet**.
- 9. Helical and sheet-like polypeptide chains are folded into a tertiary structure by bonding influences between the residues of the chain.
- 10. Some proteins have a quaternary structure as aggregates of two or more polypeptide chains.
- 11. In DNA, two polynucleotide chains held together by hydrogen bonded base pairs wind around each other to form a double helix.
- 12. In RNA, single chains fold into complex structures by formation of specific base pairs.

## Checklist of equations

Property	Equation	Comment	Equation number
Probability distribution	$P = (2/\pi N)^{1/2} e^{-n^2/2N}$	One-dimensional random coil	17A.1
	$f(r) = 4\pi(a/\pi^{1/2})^3 r^2 e^{-a^2 r^2}$ $a = (\frac{3}{2} N l^2)^{1/2}$	Three-dimensional random coil	17A.2
Contour length of a random coil	$R_c = Nl$		17A.3

Property	Equation	Comment	Equation number

### ► Why do you need to know this material?

Macromolecules are important in modern technology. They are also building blocks of biological cells. To understand why this is so, you need to explore the characteristic physical properties of macromolecules.

### ► What is the key idea?

The unique properties of macromolecules are related to their unique structural features.

### ► What do you need to know already?

You need to be familiar with the structural features of macromolecules (Topic 17A), particularly the properties of a random coil. You also need to be familiar with the statistical interpretation of entropy (Topic 15E) and the concept of internal energy (Topic 2A).

Macromolecules have special physical properties that arise from details of their structures. In this Topic we explore the physical mechanical, thermal, and electrical properties of synthetic and biological macromolecules.

## 17B.1 Mechanical properties

Significant insight into the consequences of stretching and contracting a polymer can be obtained on the basis of the freely jointed chain as a model (Topic 17A).

### (a) Conformational entropy

The random coil is the least structured conformation of a polymer chain and corresponds to the state of greatest entropy. Any stretching of the coil introduces order and reduces the entropy. Conversely, the formation of a random coil from a more extended form is a spontaneous process (provided enthalpy contributions do not interfere). As shown in the following *Justification*, we can use the same model to deduce that the change in **conformational entropy**, the statistical entropy arising from the arrangement of bonds, when a one-dimensional chain containing  $N$  bonds of length  $l$  is stretched or compressed by  $nl$  is

$$\Delta S = -\frac{1}{2}kN \ln\{(1+\nu)^{1+\nu}(1-\nu)^{1-\nu}\} \quad \begin{array}{l} \text{Random} \\ \text{coil} \end{array} \quad \begin{array}{l} \text{Conformational} \\ \text{entropy} \end{array} \quad (17B.1)$$
$$\nu = n/N$$

This function is plotted in Fig. 17B.1, and we see that minimum extension corresponds to maximum entropy.

#### Brief illustration 17B.1 Conformational entropy

Suppose that  $N=1000$  and  $l=150$  pm. The change in entropy when the (one-dimensional) random coil is stretched through 1.5 nm (corresponding to  $n=10$  and  $\nu=1/100$ ) is

$$\Delta S = -\frac{1}{2}k \times (1000) \times \left( \ln \left\{ \left( 1 + \frac{1}{100} \right)^{1+(1/100)} \left( 1 - \frac{1}{100} \right)^{1-(1/100)} \right\} \right)$$
$$= -0.050k$$

Because  $R=N_A k$ , the change in molar entropy is  $\Delta S_m = -0.050R$ , or  $-0.42 \text{ J K}^{-1} \text{ mol}^{-1}$ .

**Self-test 17B.1** What is the change in conformational entropy when the same random coil is stretched from fully coiled by 10 per cent?

Answer:  $-0.042 \text{ J K}^{-1} \text{ mol}^{-1}$

#### Justification 17B.1 The conformational entropy of a freely jointed chain

The conformational entropy of the chain is given by the Boltzmann formula,  $S=k \ln \mathcal{W}$  (eqn 15E.7). In the present case, we identify  $\mathcal{W}$  with the number of ways of achieving a coil with a given extension, the  $W$  calculated in eqn 17A.2:

$$W = \frac{N!}{\left\{\frac{1}{2}(N+n)\right\}! \left\{\frac{1}{2}(N-n)\right\}!}$$

Therefore,

$$S/k = \ln N! - \ln \left\{\frac{1}{2}(N+n)\right\}! - \ln \left\{\frac{1}{2}(N-n)\right\}!$$

Because the factorials are large (except for large extensions), we can use Stirling's approximation (Topic 15A,  $\ln x! \approx (x + \frac{1}{2}) \ln x - x + \frac{1}{2} \ln 2\pi$ ) to obtain

$$S/k = \ln(2\pi)^{1/2} + (N+1) \ln 2 - \left(N + \frac{1}{2}\right) \ln N - \frac{1}{2} \ln \left\{ (N+n)^{N+n+1} (N-n)^{N-n+1} \right\}$$

We have seen that the most probable conformation of a one-dimensional chain is the one with the ends close together ( $n=0$ ). This conformation also corresponds to maximum entropy, as may be confirmed by differentiation. Therefore, the maximum entropy is

$$S/k = \ln(2\pi)^{1/2} + (N+1) \ln 2 + \frac{1}{2} \ln N$$

The change in entropy when the chain is stretched or compressed by  $nl$  is therefore the difference of these two quantities, and the resulting expression, after some algebraic manipulation, is eqn 17B.1.

**Figure 17B.1** The change in molar entropy of a perfect elastomer as its extension changes;  $\nu=1$  corresponds to complete extension;  $\nu=0$ , the conformation of highest entropy, corresponds to a random coil.

## (b) Elastomers

The fundamental concepts for the discussion of the mechanical properties of solids are stress and strain. The **stress** on an object is the applied force divided by the area to which it is applied. The **strain** is the resulting distortion of the sample. The general field of the relations between stress and strain is called **rheology**.

**Figure 17B.2** A typical stress–strain curve.

The stress–strain curve in Fig. 17B.2 shows how a material responds to stress. The region of **elastic deformation** is where the strain is proportional to the stress and is reversible: when the stress is removed, the sample returns to its initial shape. As we see in more detail in Topic 18C, the slope of the stress–strain curve in this region is ‘Young’s modulus’,  $E$ , for the material. At the **yield point**, the reversible, linear deformation gives way to **plastic deformation**, where the strain is no longer linearly proportional to the stress and the initial shape of the sample is not recovered when the stress is removed. Thermosetting plastics have only a very short elastic range; thermoplastics typically (but not universally) have a long plastic range. An **elastomer** is specifically a polymer with a long elastic range. They typically have numerous cross-links (such as the sulfur links in vulcanized rubber) that pull them back into their original shape when the stress is removed.

Although practical elastomers are typically extensively cross-linked, even a freely jointed chain behaves as an elastomer for small extensions. It is a model of a **perfect elastomer**, a polymer in which the internal energy is independent of the extension. In the following *Justification* we also see that the restoring force,  $F$ , of a one-dimensional random coil when the chain is stretched or compressed by  $nl$  is

$$F = \frac{kT}{2l} \ln \frac{1+\nu}{1-\nu} \quad \nu = n/N \quad \begin{array}{l} \text{One-} \\ \text{dimensional} \\ \text{random coil} \end{array} \quad \begin{array}{l} \text{Restoring} \\ \text{force} \end{array} \quad (17B.2a)$$

where  $N$  is the total number of bonds each of length  $l$ . This function is plotted in Fig. 17B.3. At low extensions, when  $\nu \ll 1$  we can use  $\ln(1+x) = x - \frac{1}{2}x^2 + \dots$  and find (retaining only linear terms) that

$$F \approx \frac{\nu kT}{l} = \frac{nkT}{Nl} \quad \begin{array}{l} \text{One-dimensional} \\ \text{random coil, small} \\ \text{extensions} \end{array} \quad \begin{array}{l} \text{Restoring} \\ \text{force} \end{array} \quad (17B.2b)$$

That is, for small displacements the sample obeys Hooke’s law: the restoring force is proportional to the displacement (which is proportional to  $n$ ). For small displacements, therefore, the whole coil shakes with simple harmonic motion. When this equation is rearranged to

**Figure 17B.3** The restoring force,  $F$ , of a one-dimensional perfect elastomer. For small strains,  $F$  is linearly proportional to the extension, corresponding to Hooke's law.

$$nl = \left( \frac{Nl^2}{kT} \right) F \quad (17B.2c)$$

we see that for small displacements, the strain, as measured by the extension  $nl$ , is proportional to the applied force, as is characteristic of the elastic deformation region of an elastomer.

#### Brief illustration 17B.2 The restoring force

Consider a polymer chain with  $N=5000$  and  $l=0.15$  nm. If the ends of the chain are moved apart by 1.5 nm, then  $n=(1.5 \text{ nm})/(0.15 \text{ nm})=10$  and  $v=n/N=10/5000=2.0 \times 10^{-3}$ . Because  $v \ll 1$ , the restoring force at 293 K is given by eqn 17B.2b as

$$F = \frac{10 \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (293 \text{ K})}{5000 \times (1.5 \times 10^{-10} \text{ m})} = 5.4 \times 10^{-14} \text{ N}$$

or 54 fN.

**Self-test 17B.2** Repeat the calculation for  $N=6.0 \times 10^3$  and a displacement of 2.0 nm at 298 K.

Answer: 61 fN

#### Justification 17B.2 Hooke's law

The work done on an elastomer when it is extended through a distance  $dx$  is  $Fdx$ , where  $F$  is the restoring force. The change in internal energy is therefore

$$dU = TdS + Fdx$$

It follows that

$$\left( \frac{\partial U}{\partial x} \right)_T = T \left( \frac{\partial S}{\partial x} \right)_T + F$$

In a perfect elastomer, as in a perfect gas, the internal energy is independent of the dimensions (at constant temperature), so  $(\partial U/\partial x)_T = 0$ . The restoring force is therefore

$$F = -T \left( \frac{\partial S}{\partial x} \right)_T$$

If now we substitute eqn 17B.1 into this expression, we obtain

$$F = -\frac{T}{l} \left( \frac{\partial S}{\partial n} \right)_T = \frac{T}{Nl} \left( \frac{\partial S}{\partial v} \right)_T = \frac{kT}{2l} \ln \left( \frac{1+v}{1-v} \right)$$

as in eqn 17B.2a.

## 17B.2 Thermal properties

The crystallinity of synthetic polymers can be destroyed by thermal motion at sufficiently high temperatures. This change in crystallinity may be thought of as a kind of intramolecular melting from a crystalline solid to a more fluid random coil. Polymer melting also occurs at a specific **melting temperature**,  $T_m$ , which increases with the strength and number of intermolecular interactions in the material. Thus, polyethylene, which has chains that interact only weakly in the solid, has  $T_m=414$  K and nylon-66 fibre, in which there are strong hydrogen bonds between chains, has  $T_m=530$  K. High melting temperatures are desirable in most practical applications involving fibres and plastics.

All synthetic polymers undergo a transition from a state of high to low chain mobility at the **glass transition temperature**,  $T_g$ . To visualize the glass transition, we consider what happens to an elastomer as we lower its temperature. There is sufficient energy available at normal temperatures for limited bond rotation to occur and the flexible chains writhe. At lower temperatures, the amplitudes of the writhing motion decrease until a specific temperature,  $T_g$ , is reached at which motion is frozen completely and the sample forms a glass. Glass transition temperatures well below 300 K are desirable in elastomers that are to be used at normal temperatures. Both the glass transition temperature and the melting temperature of a polymer may be measured by calorimetric methods. Because the motion of the segments of a polymer chain increase at the glass transition temperature,  $T_g$  may also be determined from a plot of the specific volume of a polymer (the reciprocal of its mass density) against temperature (Fig. 17B.4).

Proteins and nucleic acids are relatively unstable towards chemical and thermal **denaturation**, the loss of structure. Thermal denaturation is similar to the melting of synthetic polymers. Denaturation is a **cooperative process** in the sense that the biopolymer becomes increasingly more susceptible to denaturation once the process begins. This cooperativity is observed as a sharp step in a plot of fraction of unfolded polymer against temperature. The melting temperature,  $T_m$ , is the temperature at which the fraction of denatured polymer is 0.5

**Figure 17B.4** The variation of specific volume with temperature of a synthetic polymer. The glass transition temperature,  $T_g$ , is at the point of intersection of extrapolations of the two linear parts of the curve.

(Fig. 17B.5). For example,  $T_m = 320$  K for ribonuclease  $T_1$  (an enzyme that cleaves RNA in the cell), which is not far above the temperature at which the enzyme must operate (close to body temperature, 310 K). More surprisingly, the Gibbs energy for the denaturation of ribonuclease  $T_1$  at pH=7.0 and 298 K is only  $19.5 \text{ kJ mol}^{-1}$ , which is comparable to the energy required to break a single hydrogen bond (about  $20 \text{ kJ mol}^{-1}$ ). The stability of a protein does not increase in a simple way with the number of hydrogen bonding interactions. While the reasons for the low stability of proteins are not known, the answer probably lies in a delicate balance of the intra- and intermolecular interactions that allow a protein to fold into its active conformation, and the role of the aqueous environment. By contrast, the melting temperature of DNA can be predicted with reasonable accuracy by examining its structure, as we see in the following *Example*.

**Figure 17B.5** A protein unfolds as the temperature of the sample increases. The sharp step in the plot of fraction of unfolded protein against temperature indicated that the transition is cooperative. The melting temperature,  $T_m$ , is the temperature at which the fraction of unfolded polymer is 0.5.

### Example 17B.1 Predicting the melting temperature of DNA

The melting temperature of a DNA molecule (in the sense of the temperature at which it undergoes denaturation) can be determined by calorimetric methods. The following data were obtained in  $0.010 \text{ M Na}_3\text{PO}_4(\text{aq})$  for a series of DNA molecules with varying base pair composition, with  $f$  the fraction of G–C base pairs:

$f$	0.375	0.509	0.589	0.688	0.750
$T_m/\text{K}$	339	344	348	351	354

Estimate the melting temperature of a DNA molecule containing 40.0 per cent G–C base pairs.

**Method** Look for a quantitative relationship between the melting temperature and the composition of DNA. Begin by plotting  $T_m$  against fraction of G–C base pairs and examining the shape of the curve. If visual inspection of the plot suggests a linear relationship, then the melting point at any composition can be predicted from the equation of the straight line that fits the data.

**Answer** Figure 17B.6 shows that  $T_m$  varies linearly with the fraction of G–C base pairs, at least in this range of composition. The equation of the line that fits the data is

$$T_m/\text{K} = 325 + 39.7f$$

It follows that  $T_m = 341$  K for 40.0 per cent G–C base pairs (at  $f = 0.400$ ). The thermal stability of DNA increases with the number of C–G base pairs in the sequence because each G–C base pair has three hydrogen bonds, whereas each T–A base pair has only two (Topic 17A). More energy, and therefore a higher temperature, is required to unravel a double helix that

**Figure 17B.6** Data for *Example 17B.1* showing the variation of the melting temperature of DNA molecules with the fraction of G–C base pairs. All the samples also contain  $1.0 \times 10^{-2} \text{ mol dm}^{-3} \text{ Na}_3\text{PO}_4$ .

has a higher proportion of hydrogen bonding interactions per base pair.

*A note on good practice* In this example we do not have a good theory to guide us in the choice of a mathematical model to describe the behaviour of the system over a wide range of conditions. We are limited to finding a purely empirical relation—in this case a simple first-order polynomial equation—that fits the available data. It follows that we should not attempt to predict the property of a system that falls outside the narrow range of the data used to generate the fit because the mathematical model may have to be enhanced (for example, by using higher-order polynomial equations) to describe the system over a wider range of conditions. In the present case, we should not attempt to predict the  $T_m$  of DNA molecules outside the range  $0.375 < f < 0.750$ .

**Self-test 17B.3** The following calorimetric data were obtained in solutions containing 0.15 M NaCl(aq) for the same series of DNA molecules studied in *Example 17B.1*. Estimate the melting temperature of a DNA molecule containing 40.0 per cent G–C base pairs under these conditions.

$f$	0.375	0.509	0.589	0.688	0.750
$T_m/\text{K}$	359	364	368	371	374

Answer: 360 K

### 17B.3 Electrical properties

Most of the macromolecules and self-assembled structures considered in this chapter are insulators, or very poor electrical conductors. However, a variety of newly developed macromolecular materials have electrical conductivities that rival those of silicon-based semiconductors and even metallic conductors. We examine one example in detail: **conducting polymers**, in which extensively conjugated double bonds permit electron

**Figure 17B.7** The mechanism of migration of a partially localized cation radical, or polaron, in polyacetylene.

conduction along the polymer chain. The 2000 Nobel Prize in chemistry was awarded to A.J. Heeger, A.G. MacDiarmid, and H. Shirakawa for their pioneering work in the synthesis and characterization of conducting polymers.

One example of a conducting polymer is polyacetylene (polyethyne, Fig. 17B.7). Whereas the delocalized  $\pi$  bonds do suggest that electrons can move up and down the chain, the electrical conductivity of polyacetylene increases significantly when it is partially oxidized by  $\text{I}_2$  and other strong oxidants. The product is a **polaron**, a partially localized cation radical that travels virtually (by exchanging its identity with a neighbour) through the chain, as shown in Fig. 17B.7. Further oxidation of the polymer forms either **bipolarons**, a di-cation that moves virtually (in a similar way) as a unit through the chain, or **solitons**, two separate cation radicals that move independently. Polarons and solitons contribute to the mechanism of charge conduction in polyacetylene.

Conducting polymers are slightly better electrical conductors than silicon semiconductors but are far worse than metallic conductors. They are currently used in a number of devices, such as electrodes in batteries, electrolytic capacitors, and sensors. Recent studies of photon emission by conducting polymers may lead to new technologies for light-emitting diodes and flat-panel displays. Conducting polymers also show promise as molecular wires that can be incorporated into nanometre-sized electronic devices.

## Checklist of concepts

1. The **elastic properties** of a material are summarized by a stress–strain curve.
2. A **perfect elastomer** is a polymer for which the internal energy is independent of the extension.
3. The disruption of long-range order in a polymer occurs at a **melting temperature**.
4. Synthetic polymers undergo a transition from a state of high to low chain mobility at the **glass transition temperature**.
5. The **melting temperature**,  $T_m$ , of a protein or nucleic acid is the temperature at which the fraction of denatured polymer is 0.5.
6. In **conducting polymers** conjugated double bonds permit electron conduction along the chain.

### ► Why do you need to know this material?

Aggregates of small and large molecules form the basis of many technologies (such as detergents and nanotechnology) and are abundant in biological cells. To see why this is the case, you need to understand their structures and properties.

### ► What is the key idea?

Colloids, micelles, and biological membranes form spontaneously by self-assembly of molecules or macromolecules and are held together by molecular interactions.

### ► What do you need to know already?

You need to be familiar with molecular interactions (Topic 16B), the formation of liquids (Topic 16C), and interactions between ions (Topic 5F).

**Self-assembly** is the spontaneous formation of complex structures of molecules or macromolecules that are held together by molecular interactions, such as Coulombic, dispersion, hydrogen bonding, or hydrophobic interactions. Examples

of self-assembly include the formation of liquid crystals, of protein quaternary structures from two or more polypeptide chains (Topic 17A), and (by implication) of a DNA double helix from two polynucleotide chains (Topic 17A). Here we concentrate on the specific properties of additional self-assembled systems, including some that are becoming important in the development of nanotechnology.

## 17C.1 Colloids

A **colloid**, or **disperse phase**, is a dispersion of small particles of one material in another that does not settle out under gravity. In this context, ‘small’ means that one dimension at least is smaller than about 500 nm in diameter (about the wavelength of visible light). Many colloids are suspensions of nanoparticles (particles of diameter up to about 100 nm). In general, colloidal particles are aggregates of numerous atoms or molecules, but are commonly but not universally too small to be seen with an ordinary optical microscope. They pass through most filter papers, but can be detected by light-scattering and sedimentation (Topic 17D).

### (a) Classification and preparation

The name given to the colloid depends on the two phases involved:

- A **sol** is a dispersion of a solid in a liquid (such as clusters of gold atoms in water) or of a solid in a solid (such as ruby glass, which is a gold-in-glass sol, and achieves its colour by light scattering).
- An **aerosol** is a dispersion of a liquid in a gas (like fog and many sprays) or a solid in a gas (such as smoke): the particles are often large enough to be seen with a microscope.
- An **emulsion** is a dispersion of a liquid in a liquid (such as milk). A **foam** is a dispersion of a gas in a liquid.

A further classification of colloids is as **lyophilic**, or solvent attracting, and **lyophobic**, solvent repelling. If the solvent is water, the terms **hydrophilic** and **hydrophobic**, respectively, are used instead. Lyophobic colloids include the metal sols. Lyophilic colloids generally have some chemical similarity to the solvent, such as —OH groups able to form hydrogen bonds. A **gel** is a semi-rigid mass of a lyophilic sol.

The preparation of aerosols can be as simple as sneezing (which produces an imperfect aerosol). Laboratory and commercial methods make use of several techniques. Material (for example, quartz) may be ground in the presence of the dispersion medium. Passing a heavy electric current through a cell may lead to the sputtering (crumbling) of an electrode into colloidal particles. Arcing between electrodes immersed in the support medium also produces a colloid. Chemical precipitation sometimes results in a colloid. A precipitate (for example, silver iodide) already formed may be dispersed by the addition of a peptizing agent (for example, potassium iodide). Clays may be peptized by alkalis, the  $\text{OH}^-$  ion being the active agent.

Emulsions are normally prepared by shaking the two components together vigorously, although some kind of emulsifying agent usually has to be added to stabilize the product. This emulsifying agent may be a soap (the salt of a long-chain carboxylic acid) or other **surfactant** (surface active) species, or a lyophilic sol that forms a protective film around the dispersed phase. In milk, which is an emulsion of fats in water, the emulsifying agent is casein, a protein containing phosphate groups. It is clear from the formation of cream on the surface of milk that casein is not completely successful in stabilizing milk: the dispersed fats coalesce into oily droplets which float to the surface. This coagulation may be prevented by ensuring that the emulsion is dispersed very finely initially: intense agitation with ultrasonics brings this dispersion about, the product being 'homogenized' milk.

One way to form an aerosol is to tear apart a spray of liquid with a jet of gas. The dispersal is aided if a charge is applied to the liquid, for then electrostatic repulsions help to blast it apart into droplets. This procedure may also be used to produce emulsions, for the charged liquid phase may be directed into another liquid.

Colloids are often purified by **dialysis**, the process of squeezing the solution through a membrane. The aim is to remove much (but not all, for reasons explained later) of the ionic material that may have accompanied their formation. A membrane (for example, cellulose) is selected that is permeable to solvent and ions, but not to the colloid particles. Dialysis is very slow, and is normally accelerated by applying an electric field and making use of the charges carried by many colloidal particles; the technique is then called **electrodialysis**.

### (b) Structure and stability

Colloids are thermodynamically unstable with respect to the bulk. This instability can be expressed thermodynamically by noting that because the change in Helmholtz energy,  $dA$ , when the surface area of the sample changes by  $d\sigma$  at constant temperature and pressure is  $dA = \gamma d\sigma$ , where  $\gamma$  is the interfacial surface tension (Topic 16C), it follows that  $dA < 0$  if  $d\sigma < 0$ . That is, the contraction of the surface ( $d\sigma < 0$ ) is spontaneous ( $dA < 0$ ). The survival of colloids must therefore be a consequence of the

**Figure 17C.1** Although the attraction between individual molecules is proportional to  $1/R^6$ , more molecules are within range at large separations (pale region) than at small separation (dark region), so the total interaction energy declines more slowly and is proportional to a lower power of  $R$ .

kinetics of collapse: colloids are thermodynamically unstable but kinetically non-labile.

At first sight, even the kinetic argument seems to fail: colloidal particles attract each other over large distances, so there is a long-range force that tends to condense them into a single blob. The reasoning behind this remark is as follows. The energy of attraction between two individual atoms  $i$  and  $j$  separated by a distance  $R_{ij}$ , one in each colloidal particle, varies with their separation as  $1/R_{ij}^6$  (Topic 16B). The sum of all these pairwise interactions, however, decreases only as approximately  $1/R^2$  (the precise variation depending on the shape of the particles and their closeness), where  $R$  is the separation of the centres of the particles. The change in the power from 6 to 2 stems from the fact that at short distances only a few molecules interact but at large distances many individual molecules are at about the same distance from one another, and contribute equally to the sum (Fig. 17C.1), so the total interaction does not fall off as fast as the single molecule–molecule interaction.

Several factors oppose the long-range dispersion attraction. For example, there may be a protective film at the surface of the colloid particles that stabilizes the interface and cannot be penetrated when two particles touch. Thus the surface atoms of a platinum sol in water react chemically and are turned into  $-\text{Pt}(\text{OH})_3\text{H}_3$ , and this layer encases the particle like a shell. A fat can be emulsified by a soap because the long hydrocarbon tails penetrate the oil droplet but the carboxylate head groups (or other hydrophilic groups in synthetic detergents) surround the surface, form hydrogen bonds with water, and give rise to a shell of negative charge that repels a possible approach from another similarly charged particle.

### (c) The electrical double layer

A major source of kinetic non-lability of colloids is the existence of an electric charge on the surfaces of the particles. On account of this charge, ions of opposite charge tend to cluster

nearby, and an ionic atmosphere is formed, just as for ions (Topic 5F).

We need to distinguish two regions of charge. First, there is a fairly immobile layer of ions that adhere tightly to the surface of the colloidal particle, and which may include water molecules (if that is the support medium). The radius of the sphere that captures this rigid layer is called the **radius of shear** and is the major factor determining the mobility of the particles. The electric potential at the radius of shear relative to its value in the distant, bulk medium is called the **zeta potential**,  $\zeta$ , or the **electrokinetic potential**. Second, the charged unit attracts an oppositely charged atmosphere of mobile ions. The inner shell of charge and the outer ionic atmosphere is called the **electrical double layer**.

The theory of the stability of lyophobic dispersions was developed by B. Derjaguin and L. Landau and independently by E. Verwey and J.T.G. Overbeek, and is known as the **DLVO theory**.<sup>1</sup> It assumes that there is a balance between the repulsive interaction between the charges of the electric double layers on neighbouring particles and the attractive interactions arising from van der Waals interactions between the molecules in the particles. The potential energy arising from the repulsion of double layers on particles of radius  $a$  has the form

$$V_{\text{repulsion}} = + \frac{Aa^2\zeta^2}{R} e^{-s/r_D} \quad (17C.1)$$

where  $A$  is a constant,  $\zeta$  is the zeta potential,  $R$  is the separation of centres,  $s$  is the separation of the surfaces of the two particles ( $s = R - 2a$  for spherical particles of radius  $a$ ), and  $r_D$  is the thickness of the double layer. This expression is valid for small particles with a thick double layer ( $a \ll r_D$ ). When the double layer is thin ( $r_D \ll a$ ), the expression is replaced by

$$V_{\text{repulsion}} = + \frac{1}{2} Aa^2\zeta^2 \ln(1 + e^{-s/r_D}). \quad (17C.2)$$

In each case, the thickness of the double layer can be estimated from an expression like that derived for the thickness of the ionic atmosphere in the Debye–Hückel theory (Topic 5F) in which there is a competition between the assembling influences of the attraction between opposite charges and the disruptive effect of thermal motion:

$$r_D = \left( \frac{\epsilon RT}{2\rho F^2 I b^{\ominus}} \right)^{1/2} \quad \text{Thickness of the electrical double layer} \quad (17C.3)$$

where  $I$  is the ionic strength of the solution,  $\rho$  its mass density, and  $b^{\ominus} = 1 \text{ mol kg}^{-1}$  ( $F$  is Faraday's constant and  $\epsilon$  is the

<sup>1</sup> The derivation of the expressions quoted is too complicated to include here. For a full description, see Volume 1 of R. J. Hunter, *Foundations of colloid science*, Oxford University Press (1987).

**Figure 17C.2** The potential energy of interaction as a function of the separation of the centres of the two particles and its variation with the ratio of the particle size to the thickness  $a$  of the electric double layer,  $r_D$ . The regions labelled coagulation and flocculation show the dips in the potential energy curves where these processes occur.

permittivity,  $\epsilon = \epsilon_r \epsilon_0$ ). The potential energy arising from the attractive interaction has the form

$$V_{\text{attraction}} = - \frac{B}{s} \quad (17C.4)$$

where  $B$  is another constant. The variation of the total potential energy with separation is shown in Fig. 17C.2.

At high ionic strengths, the ionic atmosphere is dense and the potential shows a secondary minimum at large separations. Aggregation of the particles arising from the stabilizing effect of this secondary minimum is called **flocculation**. The flocculated material can often be redispersed by agitation because the well is so shallow. **Coagulation**, the irreversible aggregation of distinct particles into large particles, occurs when the separation of the particles is so small that they enter the primary minimum of the potential energy curve and van der Waals forces are dominant.

The ionic strength is increased by the addition of ions, particularly those of high charge type, so such ions act as flocculating agents. This increase is the basis of the empirical **Schulze–Hardy rule**, that hydrophobic colloids are flocculated most efficiently by ions of opposite charge type and high charge number. The  $\text{Al}^{3+}$  ions in alum are very effective, and are used to induce the congealing of blood. When river water containing colloidal clay flows into the sea, the salt water induces flocculation and coagulation, and is a major cause of silting in estuaries.

Metal oxide sols tend to be positively charged whereas sulfur and the noble metals tend to be negatively charged. Naturally occurring macromolecules also acquire a charge when dispersed in water, and an important feature of proteins and other natural macromolecules is that their overall charge depends on the pH of the medium. For instance, in acidic environments protons attach to basic groups, and the net charge of

the macromolecule is positive; in basic media the net charge is negative as a result of proton loss. At the **isoelectric point** the pH is such that there is no net charge on the macromolecule.

### Example 17C.1 Determining the isoelectric point of a protein

The speed with which bovine serum albumin (BSA) moves through water under the influence of an electric field was monitored at several values of pH, and the data are listed below. What is the isoelectric point of the protein?

pH	4.20	4.56	5.20	5.65	6.30	7.00
Velocity/ $(\mu\text{m s}^{-1})$	0.50	0.18	-0.25	-0.65	-0.90	-1.25

**Method** If we plot speed against pH, we can use interpolation to find the pH at which the speed is zero, which is the pH at which the molecule has zero net charge.

**Answer** The data are plotted in Fig. 17C.3. The velocity passes through zero at  $\text{pH} = 4.8$ ; hence  $\text{pH} = 4.8$  is the isoelectric point.

**Figure 17C.3** The plot of the speed of a moving macromolecule against pH allows the isoelectric point to be detected as the pH at which the speed is zero. The data are from Example 17C.1.

**Self-test 17C.1** The following data were obtained for another protein:

pH	3.5	4.5	5.0	5.5	6.0
Velocity/ $(\mu\text{m s}^{-1})$	0.10	-0.10	-0.20	-0.30	-0.40

Estimate the pH of the isoelectric point.

Answer: 4.0

The primary role of the electric double layer is to confer kinetic non-lability. Colliding colloidal particles break through the double layer and coalesce only if the collision is sufficiently energetic to disrupt the layers of ions and solvating molecules, or if thermal motion has stirred away the surface accumulation

of charge. This disruption may occur at high temperatures, which is one reason why sols precipitate when they are heated.

## 17C.2 Micelles and biological membranes

In aqueous solutions surfactant molecules or ions can cluster together as **micelles**, which are colloid-sized clusters of molecules, for their hydrophobic tails tend to congregate (through hydrophobic interactions: see Topic 16B), and their hydrophilic head groups provide protection (Fig. 17C.4).

### (a) Micelle formation

Micelles form only above the **critical micelle concentration** (CMC) and above the **Krafft temperature**. The CMC is detected by noting a pronounced change in physical properties of the solution, particularly the molar conductivity (Fig. 17C.5). There is no abrupt change in properties at the CMC; rather, there is a

**Figure 17C.4** A schematic version of a spherical micelle. The hydrophilic groups are represented by spheres and the hydrophobic hydrocarbon chains are represented by the stalks; these stalks are mobile.

**Figure 17C.5** The typical variation of some physical properties of an aqueous solution of sodium dodecylsulfate close to the critical micelle concentration (CMC).

transition region corresponding to a range of concentrations around the CMC where physical properties vary smoothly but nonlinearly with the concentration. The hydrocarbon interior of a micelle is like a droplet of oil. Nuclear magnetic resonance shows that the hydrocarbon tails are mobile, but slightly more restricted than in the bulk. Micelles are important in industry and biology on account of their solubilizing function: matter can be transported by water after it has been dissolved in their hydrocarbon interiors. For this reason, micellar systems are used as detergents, for organic synthesis, froth flotation, and petroleum recovery.

The self-assembly of a micelle has the characteristics of a cooperative process in which the addition of a surfactant molecule to a cluster that is forming becomes more probable the larger the size of the aggregate, so after a slow start there is a cascade of formation of micelles. If we suppose that the dominant micelle  $M_N$  consists of  $N$  monomers  $M$ , then the dominant equilibrium we have to consider is

We have assumed, probably dangerously on account of the large sizes of monomers, that the solution is ideal and that activities can be replaced by molar concentrations. The total concentration of surfactant is  $[M]_{\text{total}} = [M] + N[M_N]$  because each micelle consists of  $N$  monomer molecules. Therefore,

$$K = \frac{[M_N]}{([M]_{\text{total}} - N[M_N])^N} \quad (17C.5b)$$

#### Brief illustration 17C.1 The fraction of surfactant molecules in micelles

Equation 17C.5b can be solved numerically for the micelle concentration as a function of the total surfactant concentration and some results for  $K=1$  are shown in Fig. 17C.6. We see

Figure 17C.6 The micelle concentration as a function of the total surfactant concentration for  $K=1$ .

that for large  $N$ , there is a reasonably sharp transition in the relative concentrations of surfactant molecules that are present in micelles, which corresponds to the existence of a CMC.

**Self-test 17C.2** Equation 17C.5b is surprisingly tricky to solve, but it is possible to make good progress with simple cases. With  $N=2$  and  $K=1$ , find an expression for  $[M_2]$ .

$$\text{Answer: } [M_2] = [M_{\text{total}}] - \frac{1}{4} \{(1 + 8[M_{\text{total}}])^{1/2} - 1\}$$

Non-ionic surfactant molecules may cluster together in clumps of 1000 or more, but ionic species tend to be disrupted by the electrostatic repulsions between head groups and are normally limited to groups of less than about 100. However, the disruptive effect depends more on the effective size of the head group than the charge. For example, ionic surfactants such as sodium dodecyl sulfate (SDS) and cetyltrimethylammonium bromide (CTAB) form rods at moderate concentrations whereas sugar surfactants form small, approximately spherical micelles. The micelle population is often polydisperse, and the shapes of the individual micelles vary with shape of the constituent surfactant molecules, surfactant concentration, and temperature. A useful predictor of the shape of the micelle the **surfactant parameter**,  $N_s$ , defined as

$$N_s = \frac{V}{Al} \quad \text{Definition Surfactant parameter} \quad (17C.6)$$

where  $V$  is the volume of the hydrophobic surfactant tail,  $A$  is the area of the hydrophilic surfactant head group, and  $l$  is the maximum length of the surfactant tail. Table 17C.1 summarizes the dependence of aggregate structure on the surfactant parameter.

In aqueous solutions spherical micelles form, as shown in Fig. 17C.4, with the polar head groups of the surfactant molecules on the micellar surface and interacting favourably with solvent and ions in solution. Hydrophobic interactions stabilize the aggregation of the hydrophobic surfactant tails in the micellar core. Under certain experimental conditions, a **liposome** may form, with an inward pointing inner surface of molecules surrounded by an outward pointing outer layer (Fig. 17C.7). Liposomes may be used to carry nonpolar drug molecules in blood.

Table 17C.1 Variation of micelle shape with the surfactant parameter

$N_s$	Micelle shape
<0.33	Spherical
0.33 to 0.50	Cylindrical rods
0.50 to 1.00	Vesicles
1.00	Planar bilayers
>1.00	Reverse micelles and other shapes

**Figure 17C.7** The cross-sectional structure of a spherical liposome.

Increasing the ionic strength of the aqueous solution reduces repulsions between surface head groups, and cylindrical micelles can form. These cylinders may stack together in reasonably close-packed (hexagonal) arrays, forming **lyotropic mesomorphs** and, more colloquially, ‘liquid crystalline phases’.

**Reverse micelles** form in nonpolar solvents, with small polar surfactant head groups in a micellar core and more voluminous hydrophobic surfactant tails extending into the organic bulk phase. These spherical aggregates can solubilize water in organic solvents by creating a pool of trapped water molecules in the micellar core. As aggregates arrange at high surfactant concentrations to yield long-range positional order, many other types of structures are possible including cubic and hexagonal shapes.

The enthalpy of micelle formation reflects the contributions of interactions between micelle chains within the micelles and between the polar head groups and the surrounding medium. Consequently, enthalpies of micelle formation display no readily discernible pattern and may be positive (endothermic) or negative (exothermic). Many non-ionic micelles form endothermically, with  $\Delta H$  of the order of 10 kJ per mole of surfactant molecules. That such micelles do form above the CMC indicates that the entropy change accompanying their formation must then be positive, and measurements suggest a value of about  $+140 \text{ J K}^{-1} \text{ mol}^{-1}$  at room temperature. The fact that the entropy change is positive, even though the molecules are clustering together, shows that hydrophobic interactions are important in the formation of micelles (in the sense that water molecules are released to become more disordered in the process and hence make an overwhelming contribution to the entropy change).

### (b) Bilayers, vesicles, and membranes

Some micelles at concentrations well above the CMC form extended parallel sheets two molecules thick, called **planar bilayers**. The individual molecules lie perpendicular to the sheets, with hydrophilic groups on the outside in aqueous solution and on the inside in nonpolar media. When segments of planar bilayers fold back on themselves, **unilamellar vesicles** may form where the spherical hydrophobic bilayer shell separates an inner aqueous compartment from the external aqueous environment.

Bilayers show a close resemblance to biological membranes, and are often a useful model on which to base investigations of biological structures. However, actual membranes are highly sophisticated structures. The basic structural element of a membrane is a phospholipid, such as phosphatidyl choline (1), which contains long hydrocarbon chains (typically in the range  $C_{14}$ – $C_{24}$ ) and a variety of polar groups, such as  $-\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_3^+$ . The hydrophobic chains stack together to form an extensive layer about 5 nm across. The lipid molecules form layers instead of micelles because the hydrocarbon chains are too bulky to allow packing into nearly spherical clusters.

**1** Phosphatidyl choline

The bilayer is a highly mobile structure. Not only are the hydrocarbon chains ceaselessly twisting and turning in the region between the polar groups, but the phospholipid and cholesterol molecules migrate over the surface. It is better to think of the membrane as a viscous fluid rather than a permanent structure, with a viscosity about 100 times that of water. Typically, a phospholipid molecule in a membrane migrates through about  $1 \mu\text{m}$  in about 1 min.

All lipid bilayers undergo a transition from a state of high to low chain mobility at a temperature that depends on the structure of the lipid. To visualize the transition, we consider what happens to a membrane as we lower its temperature (Fig. 17C.8). There is sufficient energy available at normal temperatures for limited bond rotation to occur and the flexible chains writhe. However, the membrane is still highly organized in the sense that the bilayer structure does

**Figure 17C.8** A depiction of the variation with temperature of the flexibility of hydrocarbon chains in a lipid bilayer.

(a) At physiological temperature, the bilayer exists as a liquid crystal, in which some order exists but the chains writhe.  
(b) At a specific temperature, the chains are largely frozen and the bilayer is said to exist as a gel.

not come apart and the system is best described as a liquid crystal. At lower temperatures, the amplitudes of the writhing motion decrease until a specific temperature is reached at which motion is largely frozen. The membrane is then said to exist as a gel. Biological membranes exist as liquid crystals at physiological temperatures.

Phase transitions in membranes are often observed as ‘melting’ from gel to liquid crystal by calorimetric methods. The data show relations between the structure of the lipid and the melting temperature. Interspersed among the phospholipids of biological membranes are sterols, such as cholesterol (2), which is largely hydrophobic but does contain a hydrophilic –OH group. Sterols, which are present in different proportions in different types of cells, prevent the hydrophobic chains of lipids from ‘freezing’ into a gel and, by disrupting the packing of the chains, spread the melting point of the membrane over a range of temperatures.

2 Cholesterol

#### Brief illustration 17C.2 The melting temperatures of membranes

To predict trends in melting temperatures we need to assess the strengths of the interactions between molecules. Longer chains can be expected to be held together more strongly by hydrophobic interactions than shorter chains, so we should expect the melting temperature to increase with the length of the hydrophobic chain of the lipid. On the other hand, any structural elements that prevent alignment of the hydrophobic chains in the gel phase lead to low melting temperatures. Indeed, lipids containing unsaturated chains, those containing some C=C bonds, form membranes with lower melting temperatures than those formed from lipids with fully saturated chains, those consisting of C–C bonds only.

**Self-Test 17C.3** Why do bacterial and plant cells grown at low temperatures synthesize more phospholipids with unsaturated chains than do cells grown at higher temperatures?

Answer: Insertion of lipids with unsaturated chains lowers the plasma membrane’s melting temperature to a value that is close to the lower ambient temperature.

### (c) Self-assembled monolayers

Molecular self-assembly can be used as the basis for manipulation of surfaces on the nanometre scale. Of current interest are **self-assembled monolayers** (SAMs), ordered molecular aggregates that form a single layer of material on a surface. To understand the formation of SAMs, consider exposing molecules such as alkyl thiols, RSH, where R represents an alkyl chain, to an Au(0) surface. The thiols react with the surface, forming RS<sup>−</sup>Au(I) adducts:

If R is a sufficiently long chain, van der Waals interactions between the adsorbed RS units lead to the formation of a highly ordered monolayer on the surface (Fig. 17C.9). The Gibbs energy of formation of SAMs increases with the length of the alkyl chain, with each methylene group contributing 0.4–4 kJ mol<sup>−1</sup>.

A self-assembled monolayer alters the properties of the surface. For example, a hydrophilic surface may be rendered hydrophobic once covered with a SAM. Furthermore, attaching functional groups to the exposed ends of the alkyl groups may impart specific chemical reactivity or ligand-binding properties to the surface, leading to applications in chemical (or biochemical) sensors and reactors.

**Figure 17C.9** Self-assembled monolayers of alkylthiols formed onto a gold surface by reaction of the thiol groups with the surface and aggregation of the alkyl chains.

## Checklist of concepts

- 1. A **disperse system** is a dispersion of small particles of one material in another.
- 2. **Colloids** are classified as lyophilic and lyophobic.

- 3. A **surfactant** is a species that accumulates at the interface of two phases or substances.
- 4. Many colloid particles are thermodynamically unstable but kinetically non-labile.
- 5. The **radius of shear** is the radius of the sphere that captures the rigid layer of charge attached to a colloid particle.
- 6. The **zeta potential** is the electric potential at the radius of shear relative to its value in the distant, bulk medium.
- 7. The inner shell of charge and the outer atmosphere jointly constitute the **electric double layer**.
- 8. **Flocculation** is the reversible aggregation of colloidal particles.
- 9. **Coagulation** is the irreversible aggregation of colloidal particles.
- 10. The **Schultze–Hardy rule** states that hydrophobic colloids are flocculated most efficiently by ions of opposite charge type and high charge number.
- 11. A **micelle** is a colloid-sized cluster of molecules that forms at and above the **critical micelle concentration** and the **Krafft temperature**.
- 12. Micelles can assume a number of shapes, depending on temperature, shape and concentration of constituent molecules.
- 13. **Planar bilayers** are micelles that exist as extended parallel sheets two molecules thick that are extended.
- 14. **Unilamellar vesicles** are micelles that exist as extended parallel sheets two molecules thick that fold back on themselves.
- 15. **Self-assembled monolayers** are ordered molecular aggregates that form a single layer of material on a surface spontaneously.

### ► Why do you need to know this material?

To appreciate modern work on macromolecules in technology and biochemistry, you need to understand several experimental techniques that are used to determine the molar masses and shapes of synthetic and biological polymers.

### ► What is the key idea?

Mass spectrometry, laser light scattering, ultracentrifugation, and viscosity measurements are useful techniques for the determination of size and shape of macromolecules.

### ► What do you need to know already?

You need to be familiar with structures of macromolecules (Topic 17A) and aggregates (Topic 17C).

X-ray diffraction (Topic 18A) can reveal the position of almost every atom other than hydrogen even in very large molecules. However, there are several reasons why other techniques must also be used. In the first place, the sample might be a mixture of molecules with different chain

lengths and extents of cross-linking, in which case sharp X-ray images are not obtained. Even if all the molecules in the sample are identical, it might prove impossible to obtain a single crystal, which is essential for diffraction studies because only then does the electron density (which is responsible for the scattering) have a large-scale periodic variation. Furthermore, although work on proteins and DNA has shown how immensely interesting and motivating the data can be, the information is incomplete. For instance, what can be said about the shape of the molecule in its natural environment, a biological cell? What can be said about the response of its shape to changes in its environment?

## 17D.1 Mean molar masses

A pure protein is **monodisperse**, meaning that it has a single, definite molar mass. There may be small variations, such as one amino acid replacing another, depending on the source of the sample. A synthetic polymer, however, is **polydisperse**, in the sense that a sample is a mixture of molecules with various chain lengths and molar masses. The various techniques that are used to measure molar mass result in different types of mean values of polydisperse systems.

The mean obtained from the determination of molar mass by osmometry (Topic 5B) is the **number-average molar mass**,  $\bar{M}_n$ , which is the value obtained by weighting each molar mass by the number of molecules of that mass present in the sample:

$$\bar{M}_n = \frac{1}{N} \sum_i N_i M_i = \langle M \rangle \quad \text{Definition} \quad \text{Number-average molar mass} \quad (17D.1)$$

where  $N_i$  is the number of molecules with molar mass  $M_i$  and there are  $N$  molecules in all. The notation  $\langle X \rangle$  denotes the usual (number average) of a property  $X$ , and we shall use it again below. For reasons related to the ways in which macromolecules contribute to physical properties, viscosity measurements give the **viscosity-average molar mass**,  $\bar{M}_v$ , light-scattering experiments give the **weight-average molar mass**,  $\bar{M}_w$ , and sedimentation experiments give the **Z-average molar mass**,  $\bar{M}_z$ . (The name is derived from the  $z$ -coordinate used to depict data in a procedure for determining the average.) Although such averages are often best left as empirical quantities, some may be interpreted in terms of the composition of the sample. Thus, the weight-average molar mass is the average calculated

by weighting the molar masses of the molecules by the mass of each one present in the sample:

$$\bar{M}_w = \frac{1}{m} \sum_i m_i M_i \quad \text{Definition} \quad \text{Weight-average molar mass} \quad (17D.2a)$$

In this expression,  $m_i$  is the total mass of molecules of molar mass  $M_i$  and  $m$  is the total mass of the sample. Because  $m_i = N_i M_i / N_A$ , we can also express this average as

$$\bar{M}_w = \frac{\sum_i N_i M_i^2}{\sum_i N_i M_i} = \frac{\langle M^2 \rangle}{\langle M \rangle} \quad \text{Interpretation} \quad \text{Weight-average molar mass} \quad (17D.2b)$$

This expression shows that the weight-average molar mass is proportional to the mean square molar mass. Similarly, the Z-average molar mass turns out to be proportional to the mean cubic molar mass:

$$\bar{M}_z = \frac{\sum_i N_i M_i^3}{\sum_i N_i M_i^2} = \frac{\langle M^3 \rangle}{\langle M^2 \rangle} \quad \text{Interpretation} \quad \text{Z-average molar mass} \quad (17D.2c)$$

### Example 17D.1 Calculating number and mass averages

Determine the number-average and the weight-average molar masses of a sample of poly(vinyl chloride) from the following data:

Molar mass interval/(kg mol <sup>-1</sup> )	Average molar mass within interval/(kg mol <sup>-1</sup> )	Mass of sample within interval/g
5–9	7.5	9.6
10–14	12.5	8.7
15–19	17.5	8.9
20–24	22.5	5.6
25–29	27.5	3.1
30–35	32.5	1.7

**Method** The relevant equations are eqns 17D.2a and 17D.2b. Calculate the two averages by weighting the molar mass within each interval by the number and mass, respectively, of the molecules in each interval. Obtain the numbers in each interval by dividing the mass of the sample in each interval by the average molar mass for that interval. Because the number of molecules is proportional to the amount of substance (the number of moles), the number-weighted average can be obtained directly from the amounts in each interval. That is, on dividing the numerator and denominator by Avogadro's constant  $N_A$ , and writing  $n = N/N_A$ , eqn 17D.1 becomes

$$\bar{M}_n = \frac{1}{N/N_A} \sum_i (N_i/N_A) M_i = \frac{1}{n} \sum_i n_i M_i$$

**Answer** The amounts in each interval are as follows:

Interval	5–9	10–14	15–19	20–24	25–29	30–35
Molar mass/(kg mol <sup>-1</sup> )	7.5	12.5	17.5	22.5	27.5	32.5
Amount/mmol	1.3	0.70	0.51	0.25	0.11	0.052
Total:						2.92

The number-average molar mass is therefore

$$\bar{M}_n / (\text{kg mol}^{-1}) = \frac{1}{2.92} (1.3 \times 7.5 + 0.70 \times 12.5 + 0.51 \times 17.5 + 0.25 \times 22.5 + 0.11 \times 27.5 + 0.052 \times 32.5) = 13$$

The weight-average molar mass is calculated directly from the data after noting that the total mass of the sample is 37.6 g:

$$\bar{M}_w / (\text{kg mol}^{-1}) = \frac{1}{37.6} (9.6 \times 7.5 + 8.7 \times 12.5 + 8.9 \times 17.5 + 5.6 \times 22.5 + 3.1 \times 27.5 + 1.7 \times 32.5) = 16$$

Note the different values of the two averages. In this instance,  $\bar{M}_w / \bar{M}_n = 1.2$ .

**Self-test 17D.1** Evaluate the Z-average molar mass of the sample.

Answer: 19 kg mol<sup>-1</sup>

The ratio  $\bar{M}_w / \bar{M}_n$  is called the (molar-mass) **dispersity** (previously the 'polydispersity index', PDI) and denoted  $\mathcal{D}$  (read 'D-stroke'). It follows from eqns 17D.1 and 17D.2 that

$$\mathcal{D} = \frac{\bar{M}_w}{\bar{M}_n} \quad \text{Definition} \quad \text{Dispersity} \quad (17D.3a)$$

It then follows from the interpretation of the weight and number averages that

$$\mathcal{D} = \frac{\langle M^2 \rangle}{\langle M \rangle^2} \quad \text{Interpretation} \quad \text{Dispersity} \quad (17D.3b)$$

That is, the dispersity is proportional to the ratio of the mean square molar mass to the square of the mean molar mass. In the determination of protein molar masses we expect the various averages to be the same because the sample is monodisperse (unless there has been degradation). A synthetic polymer normally spans a range of molar masses and the different averages yield different values. Typical synthetic materials have  $\mathcal{D} \approx 4$  but much recent research has been devoted to developing methods that give much lower dispersities. The term 'monodisperse' is conventionally applied to synthetic polymers in which the dispersity is less than 1.1; commercial polyethylene samples might be much more heterogeneous, with a dispersity close to 30. One consequence of a narrow molar mass distribution for

synthetic polymers is often a higher degree of three-dimensional long-range order in the solid and therefore higher density and melting point. The spread of values is controlled by the choice of catalyst and reaction conditions. In practice, it is found that long-range order is determined more by structural factors (branching, for instance) than by molar mass.

## 17D.2 The techniques

Average molar masses may be determined by osmotic pressure of polymer solutions. The upper limit for the reliability of membrane osmometry is about  $1000 \text{ kg mol}^{-1}$ . A major problem for macromolecules of relatively low molar mass (less than about  $10 \text{ kg mol}^{-1}$ ) is their ability to percolate through the membrane. One consequence of this partial permeability is that membrane osmometry tends to overestimate the average molar mass of a polydisperse mixture. Several techniques for the determination of molar mass and dispersity that are not so limited include mass spectrometry, laser light scattering, ultracentrifugation, and viscosity measurements.

*A note on good practice* The masses of macromolecules are often reported in daltons (Da), where  $1 \text{ Da} = m_u$  (with  $m_u = 1.661 \times 10^{-27} \text{ kg}$ ). Note that 1 Da is a measure of *molecular* mass not of *molar* mass. We might say that the mass (not the molar mass) of a certain macromolecule is 100 kDa (that is, its mass is  $100 \times 10^3 \times m_u$ ); we could also say that its molar mass is  $100 \text{ kg mol}^{-1}$ ; we should not say (even though it is common practice) that its molar mass is 100 kDa.

### (a) Mass spectrometry

Mass spectrometry is among the most accurate techniques for the determination of molar masses. The procedure consists of ionizing the sample in the gas phase and then measuring the mass-to-charge number ratio ( $m/z$ ; more precisely, the dimensionless ratio  $m/zm_u$ ) of all ions. Macromolecules present a challenge because it is difficult to produce gaseous ions of large species without fragmentation. However, two techniques have emerged that circumvent this problem: **matrix-assisted laser desorption/ionization (MALDI)** and **electrospray ionization**. We shall discuss **MALDI-TOF mass spectrometry**, so called because the MALDI technique is coupled to a time-of-flight (TOF) ion detector.

Figure 17D.1 shows a schematic view of a MALDI-TOF mass spectrometer. The macromolecule is first embedded in a solid matrix which typically consists of an organic material such as *trans*-3-indoleacrylic acid and inorganic salts such as sodium chloride or silver trifluoroacetate. This sample is then irradiated with a pulsed laser. The laser energy ejects electronically excited matrix ions, cations, and neutral macromolecules, thus creating a dense gas plume above the sample surface. The

**Figure 17D.1** A matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometer. A laser beam ejects macromolecules and ions from the solid matrix. The ionized macromolecules are accelerated by an electrical potential difference over a distance  $d$  and then travel through a drift region of length  $l$ . Ions with the smallest mass to charge ratio ( $m/z$ ) reach the detector first.

macromolecule is ionized by collisions and complexation with small cations, such as  $\text{H}^+$ ,  $\text{Na}^+$ , and  $\text{Ag}^+$ .

Figure 17D.2 shows the MALDI-TOF mass spectrum of a polydisperse sample of poly(butylene adipate) (PBA, **1**). The MALDI technique produces mostly singly charged molecular ions that are not fragmented. Therefore, the multiple peaks in the spectrum arise from polymers of different lengths, with the intensity of each peak being proportional to the abundance of each polymer in the sample. Values of  $\bar{M}_n$ ,  $\bar{M}_w$  and the dispersity can be calculated from the data. It is also possible to use the mass spectrum to verify the structure of a polymer, as shown in the following example.

**Figure 17D.2** MALDI-TOF spectrum of a sample of poly(butylene adipate) (**1**) with  $\bar{M}_n = 4525 \text{ g mol}^{-1}$  (Adapted from D.C. Mudiman et al., *J. Chem. Educ.* **74**, 1288 (1997).)

### Example 17D.2 Interpreting the mass spectrum of a polymer

The mass spectrum in Fig. 17D.2 consists of peaks spaced by  $200 \text{ g mol}^{-1}$ . The peak at  $4113 \text{ g mol}^{-1}$  corresponds to the polymer for which  $n=20$ . From these data, verify that the sample consists of polymers with the general structure given by 1.

**Method** Because each peak corresponds to a different value of  $n$ , the molar mass difference,  $\Delta M$ , between peaks corresponds to the molar mass,  $M$ , of the repeating unit (the group inside the brackets in 1). Furthermore, the molar mass of the terminal groups (the groups outside the brackets in 1) may be obtained from the molar mass of any peak by using

$$M(\text{terminal groups}) = M(\text{polymer with } n \text{ repeating units}) - n\Delta M - M(\text{cation})$$

where the last term corresponds to the molar mass of the cation that attaches to the macromolecule during ionization.

**Answer** The value of  $\Delta M$  is consistent with the molar mass of the repeating unit shown in 1, which is  $200 \text{ g mol}^{-1}$ . The molar mass of the terminal group is calculated by recalling that  $\text{Na}^+$  is the cation in the matrix:

$$M(\text{terminal group}) = 4113 \text{ g mol}^{-1} - 20(200 \text{ g mol}^{-1}) - 23 \text{ g mol}^{-1} = 90 \text{ g mol}^{-1}$$

The result is consistent with the molar mass of the  $-\text{O}(\text{CH}_2)_4\text{OH}$  terminal group ( $89 \text{ g mol}^{-1}$ ) plus the molar mass of the  $-\text{H}$  terminal group ( $1 \text{ g mol}^{-1}$ ).

**Self-test 17D.2** What would be the molar mass of the  $n=20$  polymer if silver trifluoroacetate were used instead of  $\text{NaCl}$  in the preparation of the matrix?

Answer:  $4198 \text{ g mol}^{-1}$

### (b) Laser light scattering

The scattering of light by particles with diameters much smaller than the wavelength of the incident radiation is called **Rayleigh scattering**. The intensity of the scattered light is proportional to the molar mass of the particle and to  $\lambda^{-4}$ , so shorter-wavelength radiation is scattered more intensely than longer wavelengths. For example, the blue of the sky arises from the more intense scattering of the blue component of white sunlight by the molecules of the atmosphere.

Consider the experimental arrangement shown in Fig. 17D.3 for the measurement of light scattering from solutions of macromolecules. Typically, the sample is irradiated with monochromatic light from a laser. The intensity of scattered light is then measured as a function of the angle  $\theta$  that the direction of the laser beam makes with the direction of the detector from the sample at a distance  $r$ . Under these conditions, the intensity,  $I(\theta)$ , of light scattered is written as the **Rayleigh ratio**:

**Figure 17D.3** Rayleigh scattering from a sample of point-like particles. The intensity of scattered light depends on the angle  $\theta$  between the incident and scattered beams.

$$R(\theta) = \frac{I(\theta)}{I_0} \times r^2 \quad \text{Definition Rayleigh ratio} \quad (17D.4)$$

where  $I_0$  is the intensity of the incident laser radiation. The factor  $r^2$  occurs in the definition of the Rayleigh ratio because the light wave spreads out over a sphere of radius  $r$  and surface area  $4\pi r^2$ , so any sample of the radiation has its intensity  $I(\theta)$  decreased by a factor proportional to  $r^2$ .

A detailed examination of the scattering shows that the Rayleigh ratio depends on the mass concentration,  $c_p$  (units:  $\text{kg m}^{-3}$ ), of the macromolecule and its weight-average molar mass  $\bar{M}_w$  as:

$$R(\theta) = KP(\theta)c_p\bar{M}_w \quad \text{Relation of Rayleigh ratio to molar mass} \quad (17D.5)$$

where the parameter  $K$  depends on the refractive index of the solution, the incident wavelength, and the distance between the detector and the sample, which is held constant during the experiment. The parameter  $P(\theta)$  is the **structure factor**, which is related to the size of the molecule. When the radius of gyration,  $R_g$ , of the molecule (Topic 17A and Table 17D.1) is much smaller than the wavelength of the light,

$$P(\theta) \approx 1 - p(\theta) \quad \text{with } p(\theta) = \frac{16\pi^2 R_g^2 \sin^2 \frac{1}{2}\theta}{3\lambda^2} \quad \text{Small macromolecules Structure factor} \quad (17D.6)$$

Equation 17D.5 applies only to ideal solutions. In practice, even relatively dilute solutions of macromolecules can deviate considerably from ideality. Being so large, macromolecules displace a large quantity of solvent instead of replacing individual solvent molecules with negligible disturbance. To take

**Table 17D.1\*** Radius of gyration

	$M/(\text{kg mol}^{-1})$	$R_g/\text{nm}$
Serum albumin	66	2.9
Polystyrene	$3.2 \times 10^3$	50 <sup>†</sup>
DNA	$4 \times 10^3$	117

\* More values are given in the *Resource section*.

<sup>†</sup> In a poor solvent.

deviations from ideality into account, it is common to rewrite eqn 17D.5 as  $Kc_p/R(\theta)=1/P(\theta)\bar{M}_w$  and to extend it to

$$\frac{Kc_p}{R(\theta)} = \frac{1}{P(\theta)\bar{M}_w} + Bc_p \quad (17D.7)$$

where  $B$  is an empirical constant analogous to the osmotic virial coefficient (Topic 5B) and indicative of the effect of excluded volume.

The preceding discussion shows that structural properties, such as size and the molar mass of a macromolecule, can be obtained from measurements of light scattering by a sample at several angles  $\theta$  relative to the direction of propagation on an incident beam. In modern instruments, lasers are used as the radiation sources.

### Example 17D.3 Determining the size of a polymer by light scattering

The following data for a sample of polystyrene in butanone were obtained at 20 °C with plane-polarized light at  $\lambda=546$  nm.

$\theta/^\circ$	26.0	36.9	66.4	90.0	113.6
$R(\theta)/\text{m}^2$	19.7	18.8	17.1	16.0	14.4

In separate experiments, it was determined that  $K=6.42 \times 10^{-5} \text{ mol m}^3 \text{ kg}^{-2}$ . From this information, calculate  $R_g$  and  $\bar{M}_w$  for the sample. Assume that  $B$  is negligibly small, and that the polymer is small enough that eqn 17D.6 holds.

**Method** Substituting the result of eqn 17D.6 into eqn 17D.5 gives, after some rearrangement

$$\frac{1}{R(\theta)} = \frac{1}{Kc_p\bar{M}_w} + \left( \frac{16\pi^2 R_g^2}{3\lambda^2} \right) \frac{1}{R(\theta)} \sin^2 \frac{1}{2}\theta$$

Hence, a plot of  $1/R(\theta)$  against  $\{1/R(\theta)\} \sin^2 \frac{1}{2}\theta$  should be a straight line with slope  $16\pi^2 R_g^2/3\lambda^2$  and  $y$ -intercept  $1/Kc_p\bar{M}_w$ .

**Answer** We construct a table of values of  $1/R(\theta)$  and  $\{\sin^2 \frac{1}{2}\theta\}/R(\theta)$  and plot the data (Fig. 17D.4).

$\theta/^\circ$	26.0	36.9	66.4	90.0	113.6
$\{10^2/R(\theta)\}/\text{m}^{-2}$	5.06	5.32	5.83	6.25	6.96
$\{10^3 \times (\sin^2 \frac{1}{2}\theta)/R(\theta)\}/\text{m}^{-2}$	2.56	5.33	17.5	31.3	48.7

The best straight line through the data has a slope of 0.391 and a  $y$ -intercept of  $5.06 \times 10^{-2}$ . From these values and the value of  $K$ , we calculate  $R_g = 4.71 \times 10^{-8} \text{ m} = 47.1 \text{ nm}$  and  $\bar{M}_w = 987 \text{ kg mol}^{-1}$ .

**Self-test 17D.3** The following data for an aqueous solution of a protein with  $c_p=2.0 \text{ kg m}^{-3}$  were obtained at 20 °C with laser light at  $\lambda=532$  nm:

Figure 17D.4 Plot of the data for Example 17D.3.

$\theta/^\circ$	15.0	45.0	70.0	85.0	90.0
$R(\theta)/\text{m}^2$	23.8	22.9	21.6	20.7	20.4

In a separate experiment, it was determined that  $K=2.40 \times 10^2 \text{ mol m}^3 \text{ kg}^{-2}$ . From this information, calculate the radius of gyration and the molar mass of the protein. Assume the protein is small enough that eqn 17D.6 holds.

Answer:  $R_g=39.8 \text{ nm}$ ;  $\bar{M}_w=498 \text{ kg mol}^{-1}$

### (c) Sedimentation

In a gravitational field, heavy particles settle towards the foot of a column of solution by the process called **sedimentation**. The rate of sedimentation depends on the strength of the field and on the masses and shapes of the particles. Spherical molecules (and compact molecules in general) sediment faster than rod-like and extended molecules. When the sample is at equilibrium, the particles are dispersed over a range of heights in accord with the Boltzmann distribution (because the gravitational field competes with the stirring effect of thermal motion). The spread of heights depends on the masses of the molecules, so the equilibrium distribution is another way to determine molar mass.

Sedimentation is normally very slow, but it can be accelerated by **ultracentrifugation**, a technique that replaces the gravitational field with a centrifugal field. The effect can be achieved in an ultracentrifuge, which is essentially a cylinder that can be rotated at high speed about its axis with a sample in a cell near its outer edge. Modern ultracentrifuges can produce accelerations equivalent to about  $10^5$  that of gravity ( $'10^5 \text{ g}'$ ). Initially the sample is uniform, but the 'top' (innermost) boundary of the solute moves outwards as sedimentation proceeds.

A solute particle of mass  $m$  has an effective mass  $m_{\text{eff}}=bm$  on account of the buoyancy of the medium, with

$$b=1-\rho v_s \quad (17D.8)$$

where  $\rho$  is the solution density,  $v_s$  is the partial specific volume of the solute ( $v_s = (\partial V / \partial m_B)_{T, p}$  with  $m_B$  the total mass of solute), and the dimensionless quantity  $\rho v_s$  takes into account the mass of solvent displaced by the solute. The solute particles at a distance  $r$  from the axis of a rotor spinning at an angular velocity  $\omega$  experience a centrifugal force of magnitude  $m_{\text{eff}} r \omega^2$ . The acceleration outwards is countered by a frictional force proportional to the speed,  $s = dr/dt$ , of the particles through the medium. This force is written  $fs$ , where  $f$  is the **frictional coefficient**. The particles therefore adopt a **drift speed**, a constant speed through the medium, which is found by equating the two forces  $m_{\text{eff}} r \omega^2$  and  $fs$ . The forces are equal when

$$s = \frac{m_{\text{eff}} r \omega^2}{f} = \frac{b m r \omega^2}{f} \quad (17D.9)$$

The drift speed depends on the angular velocity and the radius, and it is convenient to define the **sedimentation constant**,  $S$ , as

$$S = \frac{s}{r \omega^2} \quad \text{Definition} \quad \text{Sedimentation constant} \quad (17D.10)$$

Then, because the average molecular mass is related to the average molar mass  $\bar{M}_n$  through  $m = \bar{M}_w / N_A$

$$S = \frac{b \bar{M}_n}{f N_A} \quad (17D.11)$$

For a spherical particle of radius  $a$  in a solvent of viscosity  $\eta$ , the frictional coefficient  $f$  is given by **Stokes' relation**:

$$f = 6\pi a \eta \quad \text{Stokes' relation} \quad (17D.12)$$

On substituting this expression into eqn 17D.11, we obtain

$$S = \frac{b \bar{M}_n}{6\pi a \eta N_A} \quad \text{Spherical polymer} \quad \text{Relation between } S \text{ and the molar mass} \quad (17D.13)$$

and  $S$  may be used to determine either  $\bar{M}_n$  or  $a$ . Again, if the molecules are not spherical, we use the appropriate value of  $f$  given in Table 17D.2. As always when dealing with

**Table 17D.2\*** Frictional coefficients and molecular geometry<sup>†</sup>

$a/b$	Prolate	Oblate
2	1.04	1.04
3	1.18	1.17
6	1.31	1.28
8	1.43	1.37
10	1.54	1.46

\* More values and analytical expressions are given in the *Resource section*.

<sup>†</sup> Entries are the ratio  $f/f_0$ , where  $f_0 = 6\pi\eta c$ , where  $c = (ab^2)^{1/3}$  for prolate ellipsoids and  $c = (a^2b)^{1/3}$  for oblate ellipsoids;  $2a$  is the major axis and  $2b$  is the minor axis.

macromolecules, the measurements must be carried out at a series of concentrations and then extrapolated to zero concentration to avoid the complications that arise from the interference between bulky molecules.

#### Example 17D.4 Determining a sedimentation constant

The sedimentation of the protein bovine serum albumin (BSA) was monitored at 25 °C. The initial location of the solute surface was at 5.50 cm from the axis of rotation, and during centrifugation at 56 850 r.p.m. it receded as follows:

$t/s$	0	500	1000	2000	3000	4000	5000
$r/cm$	5.50	5.55	5.60	5.70	5.80	5.91	6.01

Calculate the sedimentation coefficient.

**Method** Equation 17D.10 can be interpreted as a differential equation for  $s = dr/dt$  in terms of  $r$ ; so integrate it to obtain a formula for  $r$  in terms of  $t$ . The integrated expression, an expression for  $r$  as a function of  $t$ , will suggest how to plot the data and obtain from it the sedimentation constant.

**Answer** Equation 17D.10 may be written

$$\frac{dr}{dt} = r \omega^2 S \quad \text{and hence} \quad \frac{dr}{r} = \omega^2 S dt$$

If at  $t=0$  the surface is at  $r_0$  and at a later time  $t$  it is at  $r$ , this equation integrates to

$$\ln \frac{r}{r_0} = \omega^2 S t$$

It follows that a plot of  $\ln(r/r_0)$  against  $t$  should be a straight line of slope  $\omega^2 S$ . Use  $\omega = 2\pi\nu$ , where  $\nu$  is in cycles per second, and draw up the following table:

$t/s$	0	500	1000	2000	3000	4000	5000
$10^2 \ln(r/r_0)$	0	0.905	1.80	3.57	5.31	7.19	8.87

The straight-line graph (Fig. 17D.5) has a slope of  $1.78 \times 10^{-5}$ ; so  $\omega^2 S = 1.78 \times 10^{-5} \text{ s}^{-1}$ . Because  $\omega = 2\pi \times (56\,850/60) \text{ s}^{-1} =$

**Figure 17D.5** A plot of the data for Example 17D.4.

$5.95 \times 10^3 \text{ s}^{-1}$ , it follows that  $S = 5.02 \times 10^{-13} \text{ s}$ . The unit  $10^{-13} \text{ s}$  is sometimes called a 'svedberg' and denoted Sv; in this case  $S = 5.02 \text{ Sv}$ .

**Self-test 17D.4** Calculate the sedimentation constant given the following data (the other conditions being the same as above):

$t/\text{s}$	0	500	1000	2000	3000	4000	5000
$r/\text{cm}$	5.65	5.68	5.71	5.77	5.84	5.9	5.97

Answer: 3.11 Sv

The difficulty with using sedimentation rates to measure molar masses lies in the inaccuracies inherent in the determination of diffusion coefficients of disperse systems. This problem can be avoided by allowing the system to reach equilibrium, for the transport property  $D$  is then no longer relevant. As we show in the following *Justification*, the weight-average molar mass can be obtained from the ratio of concentrations of the macromolecules at two different radii in a centrifuge operating at angular frequency  $\omega$ :

$$\bar{M}_w = \frac{2RT}{(r_2^2 - r_1^2)b\omega^2} \ln \frac{c_2}{c_1} \quad (17D.14)$$

An alternative treatment of the data leads to the  $Z$ -average molar mass. The centrifuge is run more slowly in this technique than in the sedimentation rate method to avoid having all the solute pressed in a thin film against the bottom of the cell. At these slower speeds, several days may be needed for equilibrium to be reached.

#### Justification 17D.1 The weight-average molar mass from sedimentation experiments

The centrifugal force acting on a molecule at a radius  $r$  when it is rotating around the axis of the centrifuge at a frequency  $\omega$  is  $m\omega^2 r$ . This force corresponds to a difference in potential energy (using  $F = -dV/dr$ ) of  $-\frac{1}{2}m\omega^2 r^2$ . The difference in potential energy between  $r_1$  and  $r_2$  (with  $r_2 > r_1$ ) is therefore  $\frac{1}{2}m\omega^2(r_1^2 - r_2^2)$ . According to the Boltzmann distribution, the ratio of concentrations of molecules at these two radii should therefore be

$$\frac{c_2}{c_1} = e^{-\frac{1}{2}m_{\text{eff}}\omega^2(r_1^2 - r_2^2)/kT}$$

The effective mass, allowing for buoyancy effects, is  $m(1 - v_s\rho)$ , and  $m/k$  can be replaced by  $M/R$ , where  $R = N_A k$  is the gas constant. Then, by taking logarithms of both sides, the last equation becomes

$$\ln \frac{c_2}{c_1} = \frac{M(1 - v_s\rho)\omega^2(r_2^2 - r_1^2)}{2RT}$$

which rearranges into eqn 17D.14.

#### (d) Viscosity

The formal definition of viscosity is given in Topic 19A; for now, we need to know that highly viscous liquids flow slowly and retard the motion of objects through them. The presence of a macromolecular solute increases the viscosity of a solution. The effect is large even at low concentration, because big molecules affect the fluid flow over an extensive region surrounding them. At low concentrations the viscosity,  $\eta$ , of the solution is related to the viscosity of the pure solvent,  $\eta_0$ , by

$$\eta = \eta_0(1 + [\eta]c + [\eta]c^2 + \dots) \quad (17D.15)$$

The **intrinsic viscosity**,  $[\eta]$ , is the analogue of a virial coefficient like that encountered in the description of real gases (and has dimensions of 1/concentration). It follows from eqn 17D.15 that

$$[\eta] = \lim_{c \rightarrow 0} \left( \frac{\eta - \eta_0}{c\eta_0} \right) = \lim_{c \rightarrow 0} \left( \frac{\eta/\eta_0 - 1}{c} \right) \quad \text{Definition Intrinsic viscosity} \quad (17D.16)$$

Viscosities are measured in several ways. In the **Ostwald viscometer** shown in Fig. 17D.6, the time taken for a solution to flow through the capillary is noted, and compared with a standard sample. The method is well suited to the determination of  $[\eta]$  because the ratio of the viscosities of the solution and the pure solvent is proportional to the drainage time  $t$  and  $t_0$  after correcting for different densities  $\rho$  and  $\rho_0$ :

$$\frac{\eta}{\eta_0} = \frac{t}{t_0} \times \frac{\rho}{\rho_0} \quad (17D.17)$$

This ratio can be used directly in eqn 17D.16. Viscometers in the form of rotating concentric cylinders are also used (Fig. 17D.7), and the torque on the inner cylinder is monitored while the outer one is rotated. Such **rotating rheometers** (as in this case, some instruments for the measurement of viscosity are also called *rheometers*, from the Greek word for

**Figure 17D.6** An Ostwald viscometer. The viscosity is measured by noting the time required for the liquid to drain between the two marks.

**Figure 17D.7** A rotating rheometer. The torque on the inner drum is observed when the outer container is rotated.

‘flow’) have the advantage over the Ostwald viscometer that the shear gradient between the cylinders is simpler than in the capillary and effects of the kind discussed shortly can be studied more easily.

There are many complications in the interpretation of viscosity measurements. Much of the work is based on empirical observations, and the determination of molar mass is usually based on comparisons with standard, nearly monodisperse samples. Some regularities are observed that help in the determination. For example, it is found that solutions of macromolecules that behave nearly ideally often fit the empirical **Mark–Kuhn–Houwink–Sakurada equation**:

$$[\eta] = K\bar{M}_v^a \quad \text{Mark–Kuhn–Houwink–Sakurada equation} \quad (17D.18)$$

where  $K$  and  $a$  are constants that depend on the solvent and type of macromolecule (Table 17D.3); the viscosity-average molar mass,  $\bar{M}_v$  appears in this expression.

**Table 17D.3\*** Intrinsic viscosity

	Solvent	$\theta/^\circ\text{C}$	$K/(\text{cm}^3 \text{g}^{-1})$	$a$
Polystyrene	Benzene	25	$9.5 \times 10^{-3}$	0.74
Polyisobutylene	Benzene	23	$8.3 \times 10^{-2}$	0.50
Various proteins	Guanidine hydrochloride + HSCH <sub>2</sub> CH <sub>2</sub> OH		$7.2 \times 10^{-3}$	0.66

\* More values are given in the *Resource section*.

### Example 17D.5 Using intrinsic viscosity to measure molar mass

The viscosities of a series of solutions of polystyrene in toluene were measured at 25 °C with the following results:

$c/(\text{g dm}^{-3})$	0	2	4	6	8	10
$\eta/(10^{-4} \text{kg m}^{-1} \text{s}^{-1})$	5.58	6.15	6.74	7.35	7.98	8.64

Calculate the intrinsic viscosity and estimate the molar mass of the polymer by using eqn 17D.19 with  $K = 3.80 \times 10^5 \text{ dm}^3 \text{g}^{-1}$  and  $a = 0.63$ .

**Method** The intrinsic viscosity is defined in eqn 17D.16; therefore, form this ratio at the series of data points and extrapolate to  $c = 0$ . Interpret  $\bar{M}_v$ , as  $\bar{M}_v/(\text{g mol}^{-1})$  in eqn 17D.18.

**Answer** We draw up the following table:

$c/(\text{g dm}^{-3})$	0	2	4	6	8	10
$\eta/\eta_0$	1	1.102	1.208	1.317	1.43	1.549
$100[(\eta/\eta_0) - 1]/(c/\text{g dm}^{-3})$		5.11	5.2	5.28	5.38	5.49

The points are plotted in Fig. 17D.8. The extrapolated intercept at  $c = 0$  is 0.0504, so  $[\eta] = 0.0504 \text{ dm}^3 \text{g}^{-1}$ . Therefore,

$$\bar{M}_v = \left( \frac{[\eta]}{K} \right)^{1/a} = 9.0 \times 10^4 \text{ g mol}^{-1}$$

**Figure 17D.8** The plot used for the determination of intrinsic viscosity, which is taken from the intercept at  $c = 0$ ; see *Example 17D.5*.

**Self-test 17D.5** Show that the intrinsic viscosity may also be obtained as  $[\eta] = \lim_{c \rightarrow 0} \ln(\eta/\eta_0)$  and evaluate the viscosity-average molar mass by using this relation.

Answer:  $90 \text{ kg mol}^{-1}$

In some cases, the flow is non-Newtonian in the sense that the viscosity of the solution changes as the rate of flow increases. A decrease in viscosity with increasing rate of flow indicates the presence of long rod-like molecules that are orientated by the flow and hence slide past each other more freely. In some somewhat rare cases the stresses set up by the flow are so great that long molecules are broken up, with further consequences for the viscosity.

## Checklist of concepts

- 1. Macromolecules can be **monodisperse**, with a single molar mass, or **polydisperse**, with various molar masses.
- 2. In the **MALDI-TOF technique**, matrix-assisted laser desorption/ionization is coupled with a time-of-flight mass spectrometer to measure the molar masses of macromolecules.
- 3. The intensity of **Rayleigh light scattering** by a sample increases with decreasing wavelength of the incident radiation and increasing size of the particles in the sample.
- 4. Analysis of Rayleigh scattering leads to the determination of the molar mass of a macromolecule or aggregate.
- 5. **Dynamic light scattering** is a technique for the determination of the diffusion properties and molar masses of macromolecules and aggregates.
- 6. The rate of sedimentation in an ultracentrifuge depends on molar masses and shapes of the macromolecules in the sample.
- 7. The **weight-average** and **Z-average molar mass** of a sample of macromolecules can be determined from equilibrium measurements of sedimentation in an ultracentrifuge.
- 8. The **viscosity-average molar mass** can be determined from measurements of the viscosity of solutions of macromolecules.

## Checklist of equations

Property	Equation	Comment	Equation number
Number-average molar mass	$\bar{M}_n = (1/N) \sum_i N_i M_i$	Definition	17D.1
Weight-average molar mass	$\bar{M}_w = (1/m) \sum_i m_i M_i$	Definition	17D.2a
Z-average molar mass	$\bar{M}_Z = \langle M^3 \rangle / \langle M^2 \rangle$	Interpretation	17D.2c
Dispersity	$\mathcal{D} = \bar{M}_w / \bar{M}_n$	Definition	17D.3a
	$\mathcal{D} = \langle M^2 \rangle / \langle M \rangle^2$	Interpretation	17D.3b
Rayleigh ratio	$R(\theta) = (I(\theta)/I_0)r^2$	Definition	17D.4
	$R(\theta) = KP(\theta)c_p \bar{M}_w$	Experimental implementation; ideal solutions	17D.5
Structure factor	$P(\theta) \approx 1 - p(\theta)$	Small macromolecules	17D.6
	$p(\theta) = (16\pi^2 R_g^2 / 3\lambda^2) \sin^2 \frac{1}{2} \theta$		
Sedimentation constant	$S = s/r\omega^2$	Definition	17D.10
Stokes relation	$f = 6\pi a \eta$	$f$ is the frictional coefficient	17D.12
Relation between the sedimentation constant and the molar mass of a polymer	$S = b \bar{M}_n / 6\pi a \eta N_A$	Spherical polymer	17D.13
Intrinsic viscosity	$[\eta] = \lim_{c \rightarrow 0} \{(\eta/\eta_0 - 1)/c\}$	Definition	17D.16
Mark–Kuhn–Houwink–Sakurada equation	$[\eta] = K \bar{M}_v^a$	Nearly ideal solutions	17D.18

# CHAPTER 17 Macromolecules and self-assembly

## TOPIC 17A The structures of macromolecules

### Discussion questions

**17A.1** Distinguish between the four levels of structure of a macromolecule: primary, secondary, tertiary, and quaternary.

**17A.2** What are the consequences of there being partial rigidity in an otherwise random coil?

**17A.3** Define the terms in, and identify the limits of the generality of, the following expressions: (a)  $R_c = Nl$ , (b)  $R_{\text{rms}} = N^{1/2}l$ , (c)  $R_{\text{rms}} = (2N)^{1/2}l$ , (d)  $R_{\text{rms}} = N^{1/2}lF$ , (e)  $R_g = N^{1/2}l$ , (f)  $R_g = (N/6)^{1/2}l$ , (g)  $R_g = (N/3)^{1/2}l$ .

**17A.4** Summarize the Core–Pauling rules and explain how they explain the helical and sheet-like structures of polypeptides.

### Exercises

**17A.1(a)** A one-dimensional polymer chain consists of 700 segments, each 0.90 nm long. If the chain were ideally flexible, what would be the r.m.s. separation of the ends of the chain?

**17A.1(b)** A one-dimensional polymer chain consists of 1200 segments, each 1.125 nm long. If the chain were ideally flexible, what would be the r.m.s. separation of the ends of the chain?

**17A.2(a)** Calculate the contour length (the length of the extended chain) and the root mean square separation (the end-to-end distance) for polyethylene with a molar mass of  $280 \text{ kg mol}^{-1}$ , modelled as a one-dimensional chain.

**17A.2(b)** Calculate the contour length (the length of the extended chain) and the root mean square separation (the end-to-end distance) for polypropylene of molar mass  $174 \text{ kg mol}^{-1}$ , modelled as a one-dimensional chain.

**17A.3(a)** The radius of gyration of a long one-dimensional chain molecule is found to be 7.3 nm. The chain consists of C–C links. Assume that the chain is randomly coiled and estimate the number of links in the chain.

**17A.3(b)** The radius of gyration of a long one-dimensional chain molecule is found to be 18.9 nm. The chain consists of links of length 450 pm. Assume that the chain is randomly coiled and estimate the number of links in the chain.

**17A.4(a)** What is the probability that the ends of a polyethene chain of molar mass  $65 \text{ kg mol}^{-1}$  are 10 nm apart when the polymer is treated as a one-dimensional freely jointed chain?

**17A.4(b)** What is the probability that the ends of a polyethene chain of molar mass  $85 \text{ kg mol}^{-1}$  are 15 nm apart when the polymer is treated as a one-dimensional freely jointed chain?

**17A.5(a)** What is the probability that the ends of a polyethene chain of molar mass  $65 \text{ kg mol}^{-1}$  are between 10.0 nm and 10.1 nm apart when the polymer is treated as a three-dimensional freely jointed chain?

**17A.5(b)** What is the probability that the ends of a polyethene chain of molar mass  $75 \text{ kg mol}^{-1}$  are between 14.0 nm and 14.1 nm apart when the polymer is treated as a three-dimensional freely jointed chain?

**17A.6(a)** By what percentage does the radius of gyration of a one-dimensional polymer chain increase (+) or decrease (–) when the bond angle between units is limited to  $109^\circ$ ? What is the percentage change in volume of the coil?

**17A.6(b)** By what percentage does the root mean square separation of the ends of a one-dimensional polymer chain increase (+) or decrease (–) when the bond angle between units is limited to  $120^\circ$ ? What is the percentage change in volume of the coil?

**17A.7(a)** By what percentage does the radius of gyration of a one-dimensional polymer chain increase (+) or decrease (–) when the persistence length changes from  $l$  (the bond length) to 5.0 per cent of the contour length? What is the percentage change in volume of the coil?

**17A.7(b)** By what percentage does the root mean square separation of the ends of a one-dimensional polymer chain increase (+) or decrease (–) when the persistence length changes from  $l$  (the bond length) to 2.5 per cent of the contour length? What is the percentage change in volume of the coil?

**17A.8(a)** The radius of gyration of a three-dimensional partially rigid polymer of 1000 units each of length 150 pm was measured as 2.1 nm. What is the persistence length of the polymer?

**17A.8(b)** The radius of gyration of a three-dimensional partially rigid polymer of 1500 units each of length 164 pm was measured as 3.0 nm. What is the persistence length of the polymer?

### Problems

**17A.1** Evaluate the radius of gyration,  $R_g$ , of (a) a solid sphere of radius  $a$ , (b) a long straight rod of radius  $a$  and length  $l$ . Show that in the case of a solid sphere of specific volume  $v_s$ ,  $R_g/nm \approx 0.056902 \times \{(v_s/\text{cm}^3 \text{ g}^{-1})(M/\text{g mol}^{-1})\}^{1/3}$ . Evaluate  $R_g$  for a species with  $M = 100 \text{ kg mol}^{-1}$ ,  $v_s = 0.750 \text{ cm}^3 \text{ g}^{-1}$ , and, in the case of the rod, of radius 0.50 nm.

**17A.2** Use eqn 17A.2 to deduce expressions for (a) the root mean square separation of the ends of the chain, (b) the mean separation of the ends, and (c) their most probable separation. Evaluate these three quantities for a fully flexible chain with  $N = 4000$  and  $l = 154 \text{ pm}$ .

**17A.3** Deduce the relation  $\langle r_i^2 \rangle = Nl^2$  for the mean square distance of a monomer from the origin in a freely jointed chain of  $N$  units each of length  $l$ . *Hint:* Use the distribution in eqn 17A.2.

**17A.4** Deduce an expression for the radius of gyration of a three-dimensional freely-jointed chain (eqn 17A.6).

**17A.5** Derive expressions for the moments of inertia and hence the radii of gyration of (a) a uniform thin disk, (b) a long uniform rod, (c) a uniform sphere.

**17A.6** Construct a two-dimensional random walk by using a random number generating routine with mathematical software or electronic spreadsheet. Construct a walk of 50 and 100 steps. If there are many people working on the problem, investigate the mean and most probable separations in the plots by direct measurement. Do they vary as  $N^{1/2}$ ?

**17A.7** Confirm that for one-dimensional random coils,  $\ln P \approx \ln(2/\pi N)^{1/2} - \frac{1}{2}(N+n+1)\ln(1+\nu) - \frac{1}{2}(N-n+1)\ln(1-\nu)$ . *Hint:* See Justification 17A.1.

**17A.8** The radius of gyration is defined in *Justification* 17A.3. Show that an equivalent definition is that  $R_g$  is the average root mean square distance of the atoms or groups (all assumed to be of the same mass), that is, that  $R_g^2 = (1/N) \sum_j R_j^2$ , where  $R_j$  is the distance of atom  $j$  from the centre of mass.

**17A.9** Use the following information and the expression for  $R_g$  of a solid sphere quoted in the text (following eqn 17A.6), to classify the given species as globular or rod-like.

	$M/(\text{g mol}^{-1})$	$\nu_s/(\text{cm}^3 \text{g}^{-1})$	$R_g/\text{nm}$
Serum albumin	$66 \times 10^3$	0.752	2.98
Bushy stunt virus	$10.6 \times 10^6$	0.741	12.0
DNA	$4 \times 10^6$	0.556	117.0

## TOPIC 17B Properties of macromolecules

### Discussion questions

**17B.1** Distinguish between stress and strain.

**17B.2** Distinguish between elastic and plastic deformation.

**17B.3** Distinguish between the melting temperature and the glass transition temperature of a polymer.

**17B.4** Describe the mechanism of electrical conductivity in conducting polymers.

### Exercises

**17B.1(a)** Calculate the change in molar entropy when the ends of a one-dimensional polyethene chain of molar mass  $65 \text{ kg mol}^{-1}$  are moved apart by 1.0 nm.

**17B.1(b)** Calculate the change in molar entropy when the ends of a one-dimensional polyethene chain of molar mass  $85 \text{ kg mol}^{-1}$  are moved apart by 2.0 nm.

**17B.2(a)** Calculate the restoring force when the ends of a one-dimensional polyethene chain of molar mass  $65 \text{ kg mol}^{-1}$  are moved apart by 1.0 nm at  $20^\circ\text{C}$ .

**17B.2(b)** Calculate the restoring force when the ends of a one-dimensional polyethene chain of molar mass  $85 \text{ kg mol}^{-1}$  are moved apart by 2.0 nm at  $25^\circ\text{C}$ .

### Problems

**17B.1** Develop an expression for the fundamental vibrational frequency of a one-dimensional random coil that has been slightly stretched and then released. Evaluate this frequency for a sample of polyethene of molar mass  $65 \text{ kg mol}^{-1}$  at  $20^\circ\text{C}$ . Account physically for the dependence of frequency on temperature and molar mass.

**17B.2** On the assumption that the tension,  $t$ , required to keep a sample at a constant length is proportional to the temperature ( $t = aT$ , the analogue of  $p \propto T$ ), show that the tension can be ascribed to the dependence of the entropy on the length of the sample. Account for this result in terms of the molecular nature of the sample.

**17B.3** The following table lists the glass transition temperatures,  $T_g$ , of several polymers. Discuss the reasons why the structure of the monomer unit has an effect on the value of  $T_g$ .

Polymer	Poly (oxymethylene)	Polyethene	Poly(vinyl chloride)	Polystyrene
Structure	$-(\text{OCH}_2)_n-$	$-(\text{CH}_2\text{CH}_2)_n-$	$-(\text{CH}_2-\text{CHCl})_n-$	$-(\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5))_n-$
$T_g/\text{K}$	198	253	354	381

## TOPIC 17C Self-assembly

### Discussion questions

**17C.1** Distinguish between a sol, an emulsion, and a foam. Provide examples of each.

**17C.2** It is observed that the critical micelle concentration of sodium dodecyl sulfate in aqueous solution decreases as the concentration of added sodium chloride increases. Explain this effect.

**17C.3** What effect is the inclusion of cholesterol likely to have on the transition temperatures of a lipid bilayer?

## Exercises

**17C.1(a)** The velocity  $v$  with which a protein moves through water under the influence of an electric field varied with values of pH in the range  $3.0 < \text{pH} < 7.0$  according to the expression  $v/(\mu\text{m s}^{-1}) = a + b(\text{pH}) + c(\text{pH})^2 + d(\text{pH})^3$  with  $a = 0.50$ ,  $b = -0.10$ ,  $c = -3.0 \times 10^{-3}$ , and  $d = 5.0 \times 10^{-4}$ . Identify the isoelectric point of the protein.

**17C.1(b)** The velocity  $v$  with which a protein moves through water under the influence of an electric field varied with values of pH in the range  $3.0 < \text{pH} < 5.0$  according to the expression  $v/(\mu\text{m s}^{-1}) = a + b(\text{pH}) + c(\text{pH})^2$  with  $a = 0.80$ ,  $b = -4.0 \times 10^{-3}$ , and  $c = -5.0 \times 10^{-2}$ . Identify the isoelectric point of the protein.

## Problem

**17C.1** Use mathematical software to reproduce the features in Fig. 17C.6.

# TOPIC 17D Determination of size and shape

## Discussion questions

**17D.1** Distinguish between number-average, weight-average, and Z-average molar masses. Identify experimental techniques that can measure each of these properties.

**17D.2** Suggest reasons why different techniques produce different molar mass averages.

## Exercises

**17D.1(a)** Calculate the number-average molar mass and the weight-average molar mass of a mixture of equal amounts of two polymers, one having  $M = 62 \text{ kg mol}^{-1}$  and the other  $M = 78 \text{ kg mol}^{-1}$ .

**17D.1(b)** Calculate the number-average molar mass and the weight-average molar mass of a mixture of two polymers, one having  $M = 62 \text{ kg mol}^{-1}$  and the other  $M = 78 \text{ kg mol}^{-1}$ , with their amounts (numbers of moles) in the ratio 3:2.

**17D.2(a)** A solution consists of solvent, 30 per cent by mass, of a dimer with  $M = 30 \text{ kg mol}^{-1}$  and its monomer. What average molar mass would be obtained from measurement of (i) osmotic pressure, (ii) light scattering?

**17D.2(b)** A solution consists of 25 per cent by mass of a trimer with  $M = 22 \text{ kg mol}^{-1}$  and its monomer. What average molar mass would be obtained from measurement of: (i) osmotic pressure, (ii) light scattering?

**17D.3(a)** What is the relative rate of sedimentation for two spherical particles of the same density, but which differ in radius by a factor of 10?

**17D.3(b)** What is the relative rate of sedimentation for two spherical particles with densities  $1.10 \text{ g cm}^{-3}$  and  $1.18 \text{ g cm}^{-3}$  and which differ in radius by a factor of 8.4, the former being the larger? Use  $\rho = 0.794 \text{ g cm}^{-3}$  for the density of the solution.

**17D.4(a)** Human haemoglobin has a specific volume of  $0.749 \times 10^3 \text{ m}^3 \text{ kg}^{-1}$ , a sedimentation constant of 4.48 Sv, and a diffusion coefficient of  $6.9 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ . Determine its molar mass from this information.

**17D.4(b)** A synthetic polymer has a specific volume of  $8.01 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1}$ , a sedimentation constant of 7.46 Sv, and a diffusion coefficient of  $7.72 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ . Determine its molar mass from this information.

**17D.5(a)** Find the drift speed of a particle of radius  $20 \mu\text{m}$  and density  $1750 \text{ kg m}^{-3}$  which is settling from suspension in water (density  $1000 \text{ kg m}^{-3}$ ) under the influence of gravity alone. The viscosity of water is  $8.9 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$ .

**17D.5(b)** Find the drift speed of a particle of radius  $15.5 \mu\text{m}$  and density  $1250 \text{ kg m}^{-3}$  which is settling from suspension in water (density  $1000 \text{ kg m}^{-3}$ ) under the influence of gravity alone. The viscosity of water is  $8.9 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$ .

**17D.6(a)** At  $20^\circ\text{C}$  the diffusion coefficient of a macromolecule is found to be  $8.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ . Its sedimentation constant is 3.2 Sv in a solution of density  $1.06 \text{ g cm}^{-3}$ . The specific volume of the macromolecule is  $0.656 \text{ cm}^3 \text{ g}^{-1}$ . Determine the molar mass of the macromolecule.

**17D.6(b)** At  $20^\circ\text{C}$  the diffusion coefficient of a macromolecule is found to be  $7.9 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ . Its sedimentation constant is 5.1 Sv in a solution of density  $997 \text{ kg m}^{-3}$ . The specific volume of the macromolecule is  $0.721 \text{ cm}^3 \text{ g}^{-1}$ . Determine the molar mass of the macromolecule.

**17D.7(a)** The data from a sedimentation equilibrium experiment performed at 300 K on a macromolecular solute in aqueous solution show that a graph of  $\ln c$  against  $(r/cm)^2$  is a straight line with a slope of 729. The rotation rate of the centrifuge was 50 000 r.p.m. The specific volume of the solute is  $0.61 \text{ cm}^3 \text{ g}^{-1}$ . Calculate the molar mass of the solute.

**17D.7(b)** The data from a sedimentation equilibrium experiment performed at 293 K on a macromolecular solute in aqueous solution show that a graph of  $\ln c$  against  $(r/cm)^2$  is a straight line with a slope of 821. The rotation rate of the centrifuge was 1080 cycles per second. The specific volume of the solute is  $7.2 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1}$ . Calculate the molar mass of the solute.

## Problems

**17D.1** A polymerization process produced a Gaussian distribution of polymers in the sense that the proportion of molecules having a molar mass in the range  $M$  to  $M + dM$  was proportional to  $e^{-(M-M)^2/2\gamma}$ . What is the number average molar mass when the distribution is narrow?

**17D.2** Polystyrene is a synthetic polymer with the structure  $-(\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5))_n-$ . A batch of polydisperse polystyrene was prepared by initiating the polymerization with *t*-butyl radicals. As a result, the *t*-butyl group is expected to be covalently attached to the end of the final products.

A sample from this batch was embedded in an organic matrix containing silver trifluoroacetate and the resulting MALDI-TOF spectrum consisted of a large number of peaks separated by  $104 \text{ g mol}^{-1}$ , with the most intense peak at  $25\,578 \text{ g mol}^{-1}$ . Comment on the purity of this sample and determine the number of  $(\text{CH}_2-\text{CH}(\text{C}_6\text{H}_5))$  units in the species that gives rise to the most intense peak in the spectrum.

**17D.3** Suppose that a rod-like DNA molecule of length  $250 \text{ nm}$  undergoes a conformational change to a closed-circular (cc) form. (a) Use the information in Problem 17A.8 and an incident wavelength  $\lambda = 488 \text{ nm}$  to calculate the ratio of scattering intensities by each of these conformations,  $I_{\text{rod}}/I_{\text{cc}}$ , when  $\theta = 20^\circ$ ,  $45^\circ$ , and  $90^\circ$ . (b) Suppose that you wish to use light scattering as a technique for the study of conformational changes in DNA molecules. Based on your answer to part (a), at which angle would you conduct the experiments? Justify your choice.

**17D.4** In a sedimentation experiment the position of the boundary as a function of time was found to be as follows:

$t/\text{min}$	15.5	29.1	36.4	58.2
$r/\text{cm}$	5.05	5.09	5.12	5.19

The rotation rate of the centrifuge was  $45\,000 \text{ r.p.m.}$ . Calculate the sedimentation constant of the solute.

**17D.5** Calculate the speed of operation (in r.p.m.) of an ultracentrifuge needed to obtain a readily measurable concentration gradient in a sedimentation equilibrium experiment. Take that gradient to be a concentration at the bottom of the cell about five times greater than at the top. Use  $r_{\text{top}} = 5.0 \text{ cm}$ ,  $r_{\text{bot}} = 7.0 \text{ cm}$ ,  $M \approx 10^5 \text{ g mol}^{-1}$ ,  $\rho v_s \approx 0.75$ ,  $T = 298 \text{ K}$ .

**17D.6** In an ultracentrifugation experiment at  $20^\circ\text{C}$  on bovine serum albumin the following data were obtained:  $\rho = 1.001 \text{ g cm}^{-3}$ ,  $v_s = 1.112 \text{ cm}^3 \text{ g}^{-1}$ ,  $\omega/2\pi = 322 \text{ Hz}$ ,

$r/\text{cm}$	5.0	5.1	5.2	5.3	5.4
$c/(\text{mg cm}^{-3})$	0.536	0.284	0.148	0.077	0.039

Evaluate the molar mass of the sample.

**17D.7** Sedimentation studies on haemoglobin in water gave a sedimentation constant  $S = 4.5 \text{ Sv}$  at  $20^\circ\text{C}$ . The diffusion coefficient is  $6.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$  at the same temperature. Calculate the molar mass of haemoglobin using  $v_s = 0.75 \text{ cm}^3 \text{ g}^{-1}$  for its partial specific volume and  $\rho = 0.998 \text{ g cm}^{-3}$  for the density

of the solution. Estimate the effective radius of the haemoglobin molecule given that the viscosity of the solution is  $1.00 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-1}$ .

**17D.8** The rate of sedimentation of a recently isolated protein was monitored at  $20^\circ\text{C}$  and with a rotor speed of  $50\,000 \text{ r.p.m.}$ . The boundary receded as follows:

$t/\text{s}$	0	300	600	900	1200	1500	1800
$r/\text{cm}$	6.127	6.153	6.179	6.206	6.232	6.258	6.284

Calculate the sedimentation constant and the molar mass of the protein on the basis that its partial specific volume is  $0.728 \text{ cm}^3 \text{ g}^{-1}$  and its diffusion coefficient is  $7.62 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$  at  $20^\circ\text{C}$ , the density of the solution then being  $0.9981 \text{ g cm}^{-3}$ . Suggest a shape for the protein given that the viscosity of the solution is  $1.00 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-1}$  at  $20^\circ\text{C}$ .

**17D.9** The concentration dependence of the viscosity of a polymer solution is found to be as follows:

$c/(\text{g dm}^{-3})$	1.32	2.89	5.73	9.17
$\eta/(\text{g m}^{-1} \text{ s}^{-1})$	1.08	1.20	1.42	1.73

The viscosity of the solvent is  $0.985 \text{ g m}^{-1} \text{ s}^{-1}$ . What is the intrinsic viscosity of the polymer?

**17D.10** The times of flow of dilute solutions of polystyrene in benzene through a viscometer at  $25^\circ\text{C}$  are given in the table below. From these data, calculate the molar mass of the polystyrene samples. Because the solutions are dilute, assume that the densities of the solutions are the same as those of pure benzene.  $\eta(\text{benzene}) = 0.601 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-1}$  ( $0.601 \text{ cP}$ ) at  $25^\circ\text{C}$ .

$c/(\text{g dm}^{-3})$	0	2.22	5.00	8.00	10.00
$t/\text{s}$	208.2	248.1	303.4	371.8	421.3

**17D.11** The viscosities of solutions of polyisobutylene in benzene were measured at  $23^\circ\text{C}$  with the following results:

$c/(\text{g}/10^2 \text{ cm}^3)$	0	0.2	0.4	0.6	0.8	1.0
$\eta/(\text{kg m}^{-1} \text{ s}^{-1})$	0.647	0.690	0.733	0.777	0.821	0.865

Use the information in Table 17D.3 to deduce the molar mass of the polymer.

## Integrated activities

**17.1** In formamide as solvent, poly( $\gamma$ -benzyl-L-glutamate) is found by light scattering experiments to have a radius of gyration proportional to  $M$ ; in contrast, polystyrene in butanone has  $R_g$  proportional to  $M^{1/2}$ . Present arguments to show that the first polymer is a rigid rod whereas the second is a random coil.

**17.2** Consider the thermodynamic description of stretching rubber. The observables are the tension,  $t$ , and length,  $l$  (the analogues of  $p$  and  $V$  for gases). Because  $dw = tdl$ , the basic equation is  $dU = TdS + tdl$ . If  $G = U - TS - tl$ , find expressions for  $dG$  and  $dA$ , and deduce the Maxwell relations

$$\left(\frac{\partial S}{\partial l}\right)_T = -\left(\frac{\partial t}{\partial T}\right)_l \quad \left(\frac{\partial S}{\partial t}\right)_T = -\left(\frac{\partial l}{\partial T}\right)_t$$

Go on to deduce the equation of state for rubber,

$$\left(\frac{\partial U}{\partial l}\right)_T = t - \left(\frac{\partial t}{\partial T}\right)_l$$

**17.3** Commercial software (more specifically 'molecular mechanics' or 'conformational search' software) automate the calculations that lead to Ramachandran plots, such as those in Fig. 17A.13. In this problem our model for the protein is the dipeptide (1) in which the terminal methyl groups replace the rest of the polypeptide chain. (a) Draw three initial conformers of the dipeptide with  $\text{R}=\text{H}$ : one with  $\phi = +75^\circ$ ,  $\psi = -65^\circ$ , a second with  $\phi = \psi = +180^\circ$ , and a third with  $\phi = +65^\circ$ ,  $\psi = +35^\circ$ . Use software of your instructor's choice to optimize the geometry of each conformer and find the final  $\phi$  and  $\psi$  angles in each case. Did all the initial conformers converge to the same final conformation? If not, what do these final conformers represent? (b) Use the approach in part (a) to investigate the case  $\text{R}=\text{CH}_3$ , with the same

three initial conformers as starting points for the calculations. Rationalize any similarities and differences between the final conformers of the dipeptides with R=H and R=CH<sub>3</sub>.

**17.4** The effective radius,  $a$ , of a random coil is related to its radius of gyration,  $R_g$ , by  $a = \gamma R_g$ , with  $\gamma = 0.85$ . Deduce an expression for the osmotic virial coefficient,  $B$  (Topic 5B), in terms of the number of chain units for (a) a freely jointed chain, (b) a chain with tetrahedral bond angles. Evaluate  $B$  for  $l = 154$  pm and  $N = 4000$ . Estimate  $B$  for a randomly coiled polyethylene chain of arbitrary molar mass,  $M$ , and evaluate it for  $M = 56$  kg mol<sup>-1</sup>. Use  $B = \frac{1}{2} N_A v_p$ , where  $v_p$  is the excluded volume due to a single molecule.

**17.5** A manufacturer of polystyrene beads claims that they have an average molar mass of 250 kg mol<sup>-1</sup>. Solutions of these beads are studied by a physical chemistry student by dilute solution viscometry with an Ostwald viscometer in both toluene and cyclohexane. The drainage times,  $t_D$ , as a function of concentration for the two solvents are given in the table below. (a) Fit the data to the virial equation for viscosity,

$$\eta = \eta_0(1 + [\eta]c + k'[\eta]^2 c^2 + \dots)$$

where  $K'$  is called the *Huggins constant* and is typically in the range 0.35–0.40. From the fit, determine the intrinsic viscosity and the Huggins constant. (b) Use the empirical Mark–Kuhn–Houwink–Sakurada equation (eqn 17D.18) to determine the molar mass of polystyrene in the two solvents. For theta solvents,  $a = 0.5$  and  $K = 8.2 \times 10^{-5} \text{ dm}^{-3} \text{ g}^{-1}$  for cyclohexane; for the good solvent toluene  $a = 0.72$  and  $K = 1.15 \times 10^{-5} \text{ dm}^{-3} \text{ g}^{-1}$ . (c) According to a general theory proposed by Kirkwood and Riseman, the root mean square end-to-end distance of a polymer chain in solution is related to  $[\eta]$  by  $\Phi \langle r^2 \rangle^{3/2} / M$ , where  $\Phi$  is a universal constant with the value  $2.84 \times 10^{26}$  when  $[\eta]$  is expressed in cubic decimetres per gram and the distance is in metres. Calculate this quantity for each solvent. (d) From the molar masses calculate the average number of styrene (C<sub>6</sub>H<sub>5</sub>CH=CH<sub>2</sub>) monomer units,  $\langle N \rangle$ , (e) Calculate the length of a fully stretched, planar zigzag configuration, taking the C–C distance as 154 pm and the CCC bond angle to be 109°. (f) Use eqn 17A.6 to calculate the radius of gyration,  $R_g$ . Also calculate  $\langle r^2 \rangle^{1/2} = N^{1/2} l$ . Compare this result with that predicted by the Kirkwood–Riseman theory; which gives the better fit? (g) Compare your values for  $M$  to the results of Problem 17D.2. Is there any reason why they should or should not agree? Is the manufacturer's claim valid?

$c/(\text{g dm}^{-3} \text{ toluene})$	0	1.0	3.0	5.0
$t_D/\text{s}$	8.37	9.11	10.72	12.52
$c/(\text{g dm}^{-3} \text{ cyclohexane})$	0	1.0	1.5	2.0
$t_D/\text{s}$	8.32	8.67	8.85	9.03

# CHAPTER 18

## Solids

The solid state includes most of the materials that make modern technology possible. It includes the wide varieties of steel that are used in architecture and engineering, the semiconductors and metallic conductors that are used in information technology and power distribution, the ceramics that increasingly are replacing metals, and the synthetic and natural polymers discussed in Chapter 17 that are used in the textile industry and in the fabrication of many of the common objects of the modern world. In this chapter we explore the structures and physical properties of solids.

### 18A Crystal structure

In this Topic we see how to describe the regular arrangement of atoms in crystals and the symmetry of their arrangement. Then we consider the basic principles of 'X-ray diffraction' and see how the diffraction pattern can be interpreted in terms of the distribution of electron density in a 'unit cell'.

### 18B Bonding in solids

X-ray diffraction leads to information about the structures of metallic, ionic, and molecular solids, and in this Topic we review some typical results and their rationalization in terms of atomic and ionic radii.

### 18C Mechanical, electrical and magnetic properties of solids

In this Topic we begin to see how the bulk properties of solids stem from the arrangement and properties of the constituent

atoms. Here we focus on rigidity, electrical conductivity, and magnetic properties.

### 18D The optical properties of solids

This Topic continues the exploration of properties of solids, with a focus on optical properties that render materials as useful building blocks of devices with important technological applications.

### What is the impact of this material?

The deployment of X-ray diffraction techniques for the determination of the location of all the atoms in biological macromolecules has revolutionized the study of biochemistry. In *Impact* I18.1, the power of the techniques is demonstrated by exploring the most seminal X-ray images of all: the characteristic pattern obtained from strands of DNA and used in the construction of the double-helix model of DNA. We also turn our attention to research on nanometre-sized materials, which is motivated by the possibility that they will form the basis for cheaper and smaller electronic devices. In *Impact* I18.2 we discuss the synthesis of 'nanowires', nanometre-sized atomic assemblies that conduct electricity, which is a major step in the fabrication of nanodevices.

## ► What do you need to know already?

You need to be familiar with the wave description of electromagnetic radiation (*Foundations C*), and the significance of Fourier transforms (*Mathematical background 7*). Light use is made of the de Broglie relation (Topic 7A) and the equipartition theorem (*Foundations B*).

A crucial aspect of the link between the structure and properties of a solid is the pattern in which the atoms (and molecules) are stacked together, so here we examine how the structures of solids are described and determined. First, we see how to describe the regular arrangement of atoms in solids. Then we consider the basic principles of X-ray diffraction and see how the diffraction pattern can be interpreted in terms of the distribution of electron density in a crystal.

## 18A.1 Periodic crystal lattices

A **periodic crystal** is built up from regularly repeating 'structural motifs', which may be atoms, molecules, or groups of atoms, molecules, or ions. A **space lattice** is the pattern formed by points representing the locations of these motifs (Fig. 18A.1). A space lattice is, in effect, an abstract scaffolding for the crystal

## ► Why do you need to know this material?

You need to understand the structures of metallic, ionic, and molecular solids if you want to be able to account for the mechanical, electrical, optical, and magnetic properties that form the basis of new materials and new technologies. A central part of this understanding is knowing how the internal structures of solids are determined and described.

## ► What is the key idea?

The details of the regular arrangement of atoms in periodic crystals can be expressed in terms of unit cells and determined by diffraction techniques.

**Figure 18A.1** Each lattice point specifies the location of a structural motif (for example, a molecule or a group of molecules). The crystal lattice is the array of lattice points; the crystal structure is the collection of structural motifs arranged according to the lattice.

**Figure 18A.2** A unit cell is a parallel-sided (but not necessarily rectangular) figure from which the entire periodic crystal structure can be constructed by using only translations (not reflections, rotations, or inversions).

structure. More formally, a space lattice is a three-dimensional, infinite array of points, each of which is surrounded in an identical way by its neighbours, and which defines the basic structure of the crystal. In some cases there may be a structural motif centred on each lattice point, but that is not necessary. The crystal structure itself is obtained by associating with each lattice point an identical structural motif. The solids known as **quasicrystals** are ‘aperiodic’, in the sense that the space lattice, though still filling space, does not have translational symmetry. Our discussion will focus on periodic crystals only and, to simplify the language, we refer to these structures simply as ‘crystals’.

A **unit cell** is an imaginary parallelepiped (parallel-sided figure) that contains one unit of the translationally repeating pattern (Fig. 18A.2). It can be thought of as the fundamental region from which the entire crystal may be constructed by purely translational displacements (like bricks in a wall). A unit cell is commonly formed by joining neighbouring lattice points by straight lines (Fig. 18A.3). Such unit cells are called **primitive**. It is sometimes more convenient to draw larger **non-primitive unit cells** that also have lattice points at their centres or on pairs of opposite faces. An infinite number of different unit cells can describe the same lattice, but the one with sides that have the

**Figure 18A.3** A unit cell can be chosen in a variety of ways, as shown here. It is conventional to choose the cell that represents the full symmetry of the lattice. In this rectangular lattice, the rectangular unit cell would normally be adopted.

**Figure 18A.4** The notation for the sides and angles of a unit cell. Note that the angle  $\alpha$  lies in the plane  $(b,c)$  and perpendicular to the axis  $a$ .

shortest lengths and that are most nearly perpendicular to one another is normally chosen. The lengths of the sides of a unit cell are denoted  $a$ ,  $b$ , and  $c$ , and the angles between them are denoted  $\alpha$ ,  $\beta$ , and  $\gamma$  (Fig. 18A.4).

Unit cells are classified into seven **crystal systems** by noting the rotational symmetry elements they possess. A **symmetry operation** is an action (such as a rotation, reflection, or inversion) that leaves an object looking the same after it has been carried out. There is a corresponding **symmetry element** for each symmetry operation, which is the point, line, or plane with respect to which the symmetry operation is performed. For instance, an  **$n$ -fold rotation** (the symmetry operation) about an  **$n$ -fold axis of symmetry** (the corresponding symmetry element) is a rotation through  $360^\circ/n$ . (See Topics 11A–11C for a more detailed discussion of symmetry.)

The following are examples of unit cells:

- A **cubic unit cell** has four threefold axes in a tetrahedral array (Fig. 18A.5).
- A **monoclinic unit cell** has one twofold axis (Fig. 18A.6).
- A **triclinic unit cell** has no rotational symmetry, and typically all three sides and angles are different (Fig. 18A.7).

**Figure 18A.5** A unit cell belonging to the cubic system has four threefold axes, denoted  $C_3$ , arranged tetrahedrally. The insert shows the threefold symmetry.

**Figure 18A.6** A unit cell belonging to the monoclinic system has a twofold axis (denoted  $C_2$  and shown in more detail in the insert).

**Figure 18A.7** A triclinic unit cell has no axes of rotational symmetry.

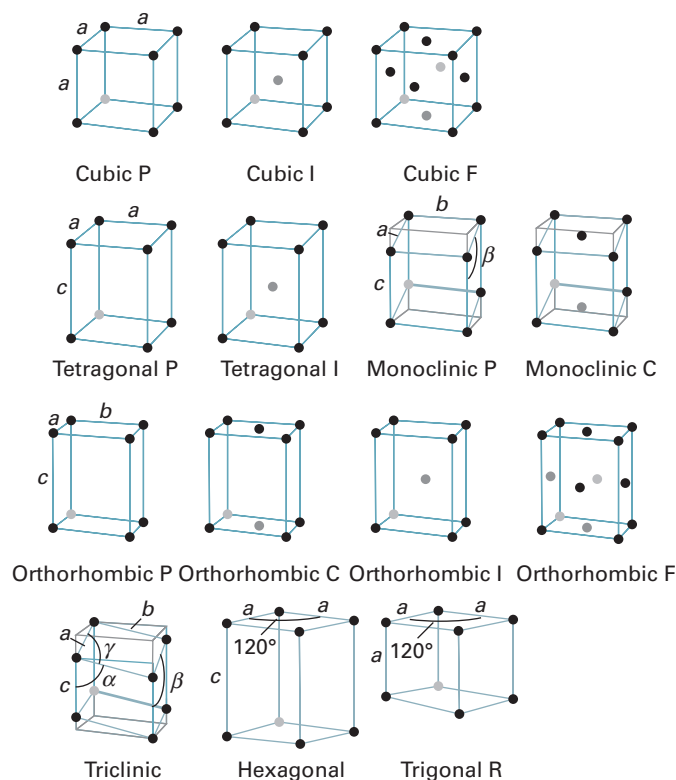

Table 18A.1 lists the **essential symmetries**, the elements that must be present for the unit cell to belong to a particular crystal system.

There are only 14 distinct space lattices in three dimensions. These **Bravais lattices** are illustrated in Fig. 18A.8. It is conventional to portray these lattices by primitive unit cells in some cases and by non-primitive unit cells in others. The following notation applies:

- A **primitive unit cell** (with lattice points only at the corners) is denoted P.

**Table 18A.1** The seven crystal systems

System	Essential symmetries
Triclinic	None
Monoclinic	One $C_2$ axis
Orthorhombic	Three perpendicular $C_2$ axes
Rhombohedral	One $C_3$ axis
Tetragonal	One $C_4$ axis
Hexagonal	One $C_6$ axis
Cubic	Four $C_3$ axes in a tetrahedral arrangement

**Figure 18A.8** The 14 Bravais lattices. The points are lattice points, and are not necessarily occupied by atoms. P denotes a primitive unit cell (R is used for a trigonal lattice), I a body-centred unit cell, F a face-centred unit cell, and C (or A or B) a cell with lattice points on two opposite faces. Trigonal lattices may belong to the rhombohedral or hexagonal systems (Table 18A.1).

- A **body-centred unit cell** (I) also has a lattice point at its centre.
- A **face-centred unit cell** (F) has lattice points at its corners and also at the centres of its six faces.
- A **side-centred unit cell** (A, B, or C) has lattice points at its corners and at the centres of two opposite faces.

For simple structures, it is often convenient to choose an atom belonging to the structural motif, or the centre of a molecule, as the location of a lattice point or the vertex of a unit cell, but that is not a necessary requirement. Equivalent lattice points within the unit cell of a Bravais lattice have identical surroundings.

#### Brief illustration 18A.1 Bravais lattices

Consider a body-centred cubic unit cell of sides  $a$  and one of its corners with coordinates  $x=0, y=0, z=0$  (Fig. 18A.9).

**Figure 18A.9** The body-centred cubic unit cell used in *Brief illustration 18A.1*. The arrows show some of the ways in which the initial (black) point is related by symmetry operations to the remaining points half-way along each edge.

Starting from this corner, the centre of the edge that runs along the  $y$ -axis has coordinates  $x=0, y=\frac{1}{2}a, z=0$ . It follows that the centres of each edge are equivalent to this point with coordinates  $x=0, y=\frac{1}{2}a, z=0$ .

**Self-test 18A.1** What points within a face-centred cubic unit cell are equivalent to the point  $x=\frac{1}{2}a, y=0, z=\frac{1}{2}a$ ?

Answer: The centres of each face

## 18A.2 The identification of lattice planes

There are many different sets of lattice planes in a crystal (Fig. 18A.10), and we need to be able to identify them. Two-dimensional lattices are easier to visualize than three-dimensional lattices, so we shall introduce the concepts involved by

**Figure 18A.10** Some of the planes that can be drawn through the points of a rectangular space lattice and their corresponding Miller indices  $(hkl)$ : (a)  $(110)$ , (b)  $(230)$ , (c)  $(\bar{1}10)$ , and (d)  $(010)$ .

referring to two dimensions initially, and then extend the conclusions by analogy to three dimensions.

### (a) The Miller indices

Consider a two-dimensional rectangular lattice formed from a unit cell of sides  $a, b$  (as in Fig. 18A.10). Each plane in the illustration (except the plane passing through the origin) can be distinguished by the distances at which it intersects the  $a$  and  $b$  axes. One way to label a plane would therefore be to quote the smallest intersection distances. For example, we could denote a representative plane of each type in Fig. 18A.10 as (a)  $(1a, 1b)$ , (b)  $(\frac{1}{2}a, \frac{1}{3}b)$ , (c)  $(-1a, 1b)$ , and (d)  $(\infty a, 1b)$ , where  $\infty$  is used to show that the planes intersect an axis at infinity. However, if we agree to quote distances along the axes as multiples of the corresponding lengths of the unit cell, then we can label the planes more simply as  $(1, 1)$ ,  $(\frac{1}{2}, \frac{1}{3})$ ,  $(-1, 1)$ , and  $(\infty, 1)$ , respectively. If the lattice in Fig. 18A.10 is the top view of a three-dimensional orthorhombic lattice in which the unit cell has a length  $c$  in the  $z$ -direction, all four sets of planes intersect the  $z$ -axis at infinity. Therefore, the full labels are  $(1, 1, \infty)$ ,  $(\frac{1}{2}, \frac{1}{3}, \infty)$ ,  $(-1, 1, \infty)$ , and  $(\infty, 1, \infty)$ .

The presence of fractions and infinity in the labels is inconvenient. They can be eliminated by taking the reciprocals of the labels. As we shall see, taking reciprocals turns out to have further advantages. The **Miller indices**,  $(hkl)$ , are the reciprocals of intersection distances. To simplify the notation while providing a great deal of information, the following rules apply:

- Negative indices are written with a bar over the number, as in  $(\bar{1}10)$ .
- If taking the reciprocal results in a fraction, then the fraction can be cleared by multiplying through by an appropriate factor.

For example, a  $(\frac{1}{3}, \frac{1}{2}, \infty)$  plane is denoted  $(230)$  after multiplication of all three indices by 6.

- The notation  $(hkl)$  denotes an *individual* plane. To specify a *set* of parallel planes we use the notation  $\{hkl\}$ .

Thus, we speak of the  $(110)$  plane in a lattice, and the set of all  $\{110\}$  planes that lie parallel to the  $(110)$  plane.

A helpful feature to remember is that the smaller the absolute value of  $h$  in  $\{hkl\}$ , the more nearly parallel the set of planes is to the  $a$  axis (the  $\{h00\}$  planes are an exception). The same is true of  $k$  and the  $b$  axis and  $l$  and the  $c$  axis. When  $h=0$ , the planes intersect the  $a$  axis at infinity, so the  $\{0kl\}$  planes are parallel to the  $a$  axis. Similarly, the  $\{h0l\}$  planes are parallel to the  $b$  axis and the  $\{hk0\}$  planes are parallel to the  $c$  axis.

**Brief illustration 18A.2** Miller indices

The  $\{1,1,\infty\}$  planes in Fig. 18A.10a are the  $\{110\}$  planes in the Miller notation. Similarly, the  $\{\frac{1}{3},\frac{1}{2},\infty\}$  planes are denoted  $\{230\}$ . Fig. 18A.10c shows the  $\{\bar{1}10\}$  planes. The Miller indices for the four types of plane in Fig. 18A.10 are therefore  $\{110\}$ ,  $\{230\}$ ,  $\{\bar{1}10\}$ , and  $\{010\}$ . Figure 18A.11 shows a three-dimensional representation of a selection of planes, including one in a lattice with non-orthogonal axes.

**Figure 18A.11** Some representative planes in three dimensions and their Miller indices. Note that a 0 indicates that a plane is parallel to the corresponding axis, and that the indexing may also be used for unit cells with non-orthogonal axes.

**Self-test 18A.2** Find the Miller indices of the planes that intersect the crystallographic axes at the distances  $(3a, 2b, c)$  and  $(2a, \infty b, \infty c)$

Answer:  $\{236\}$  and  $\{100\}$

**(b) The separation of planes**

The Miller indices are very useful for expressing the separation of planes. It is shown in the following *Justification* that the separation of the  $\{hk0\}$  planes in the square lattice in Fig. 18A.12 is given by

**Figure 18A.12** The dimensions of a unit cell and their relation to the plane passing through the lattice points.

$$\frac{1}{d_{hk0}^2} = \frac{h^2 + k^2}{a^2} \quad \text{or} \quad d_{hk0} = \frac{a}{(h^2 + k^2)^{1/2}} \quad \begin{array}{l} \text{Square} \\ \text{lattice} \end{array} \quad \begin{array}{l} \text{Separation} \\ \text{of planes} \end{array} \quad (18A.1a)$$

**Justification 18A.1** The separation of lattice planes

Consider the  $\{hk0\}$  planes of a square lattice built from a unit cell with sides of length  $a$  (Fig. 18A.12). We can write the following trigonometric expressions for the angle  $\phi$  shown in the illustration:

$$\sin \phi = \frac{d}{(a/h)} = \frac{hd_{hk0}}{a} \quad \cos \phi = \frac{d}{(a/k)} = \frac{kd_{hk0}}{a}$$

Because the lattice planes intersect the horizontal axis  $h$  times and the vertical axis  $k$  times, the length of each hypotenuse is calculated by dividing  $a$  by  $h$  and  $a$  by  $k$ . Then, because  $\sin^2 \phi + \cos^2 \phi = 1$ , it follows that

$$\left(\frac{hd_{hk0}}{a}\right)^2 + \left(\frac{kd_{hk0}}{a}\right)^2 = 1$$

which we can rearrange by dividing both sides by  $d_{hk0}^2$  into

$$\frac{1}{d_{hk0}^2} = \frac{h^2}{a^2} + \frac{k^2}{a^2} = \frac{h^2 + k^2}{a^2}$$

This expression is eqn 18A.1a.

By extension to three dimensions, the separation of the  $\{hkl\}$  planes of a cubic lattice is given by

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2 + l^2}{a^2} \quad \text{or} \quad d_{hkl} = \frac{a}{(h^2 + k^2 + l^2)^{1/2}} \quad \begin{array}{l} \text{Cubic lattice} \\ \text{Separation} \\ \text{of planes} \end{array} \quad (18A.1b)$$

The corresponding expression for a general orthorhombic lattice (one in which the axes are mutually perpendicular) is the generalization of this expression:

$$\frac{1}{d_{hkl}^2} = \frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2} \quad \begin{array}{l} \text{Orthorhombic} \\ \text{lattice} \end{array} \quad \begin{array}{l} \text{Separation} \\ \text{of planes} \end{array} \quad (18A.1c)$$

**Example 18A.1** Using the Miller indices

Calculate the separation of (a) the  $\{123\}$  planes and (b) the  $\{246\}$  planes of an orthorhombic unit cell with  $a=0.82$  nm,  $b=0.94$  nm, and  $c=0.75$  nm.

**Method** For the first part, simply substitute the information into eqn 18A.1c. For the second part, instead of repeating the calculation, note that if all three Miller indices are multiplied by  $n$ , then their separation is reduced by that factor (Fig. 18A.13):

$$\frac{1}{d_{nh,nk,nl}^2} = \frac{(nh)^2}{a^2} + \frac{(nk)^2}{b^2} + \frac{(nl)^2}{c^2} = n^2 \left( \frac{h^2}{a^2} + \frac{k^2}{b^2} + \frac{l^2}{c^2} \right) = \frac{n^2}{d_{hkl}^2}$$

which implies that

$$d_{nh,nk,nl} = \frac{d_{hkl}}{n}$$

**Figure 18A.13** The separation of the {220} planes is half that of the {110} planes. In general, the separation of the planes { $nh,nk,nl$ } is  $n$  times smaller than the separation of the { $hkl$ } planes.

**Answer** Substituting the indices into eqn 18A.1c gives

$$\frac{1}{d_{123}^2} = \frac{1^2}{(0.82 \text{ nm})^2} + \frac{2^2}{(0.94 \text{ nm})^2} + \frac{3^2}{(0.75 \text{ nm})^2} = 22 \text{ nm}^{-2}$$

Hence,  $d_{123} = 0.21 \text{ nm}$ . It then follows immediately that  $d_{246}$  is one-half this value, or  $0.11 \text{ nm}$ .

*A note on good practice* It is always sensible to look for analytical relations between quantities rather than to evaluate expressions numerically each time, for that emphasizes the relations between quantities (and avoids unnecessary work).

**Self-test 18A.3** Calculate the separation of (a) the {133} planes and (b) the {399} planes in the same lattice.

Answer:  $0.19 \text{ nm}$ ,  $0.063 \text{ nm}$

### 18A.3 X-ray crystallography

A characteristic property of waves is that when they are present in the same region of space they interfere with one another, giving a greater displacement where peaks or troughs coincide and a smaller displacement where peaks coincide with troughs (Fig. 18A.14 and *Foundations C*). According to classical electromagnetic theory, the intensity of electromagnetic radiation is proportional to the square of the amplitude of the waves. Therefore, the regions of constructive or destructive interference show up as regions of enhanced or diminished intensities. The phenomenon of **diffraction** is the interference caused by an object in the path of waves, and the pattern of varying intensity that results is called the **diffraction pattern**. Diffraction occurs when the dimensions of the

**Figure 18A.14** When two waves are in the same region of space they interfere. Depending on their relative phase, they may interfere (a) constructively, to give an enhanced amplitude, or (b) destructively, to give a smaller amplitude. The component waves are shown in green and purple and the resultant in black.

diffracting object are comparable to the wavelength of the radiation.

#### (a) X-ray diffraction

Wilhelm Röntgen discovered X-rays in 1895. Seventeen years later, Max von Laue suggested that they might be diffracted when passed through a crystal, for by then he had realized that their wavelengths are comparable to the separation of lattice planes. This suggestion was confirmed almost immediately by Walter Friedrich and Paul Knipping and has grown since then into a technique of extraordinary power. The bulk of this section will deal with the determination of structures using X-ray diffraction. The mathematical procedures necessary for the determination of structure from X-ray diffraction data are enormously complex, but such is the degree of integration of computers into the experimental apparatus that the technique is almost fully automated, even for large molecules and complex solids. The analysis is aided by molecular modelling techniques, which can guide the investigation towards a plausible structure.

X-rays are electromagnetic radiation with wavelengths of the order of  $10^{-10} \text{ m}$ . They are typically generated by bombarding a metal with high-energy electrons (Fig. 18A.15). The electrons decelerate as they plunge into the metal and generate radiation with a continuous range of wavelengths called **Bremsstrahlung** (*Bremse* is German for deceleration, *Strahlung* for ray). Superimposed on the continuum are a few high-intensity, sharp peaks (Fig. 18A.16). These peaks arise from collisions of the incoming electrons with the electrons in the inner shells of the atoms. A collision expels an electron from an inner shell, and an electron of higher energy drops into the vacancy, emitting the excess energy as an X-ray photon (Fig. 18A.17). If the electron falls into a K shell (a shell with  $n=1$ ), the X-rays are classified as **K-radiation**, and similarly for transitions into the L ( $n=2$ ) and M ( $n=3$ ) shells. Strong, distinct lines are labelled  $K_{\alpha}$ ,  $K_{\beta}$ , and so on. Increasingly, X-ray diffraction makes use of

**Figure 18A.15** X-rays are generated by directing an electron beam on to a cooled metal target. Beryllium is transparent to X-rays (on account of the small number of electrons in each atom) and is used for the windows.

**Figure 18A.16** The X-ray emission from a metal consists of a broad, featureless Bremsstrahlung background, with sharp transitions superimposed on it. The label K indicates that the radiation comes from a transition in which an electron falls into a vacancy in the K shell of the atom.

**Figure 18A.17** The processes that contribute to the generation of X-rays. An incoming electron collides with an electron (in the K shell), and ejects it. Another electron (from the L shell in this illustration) falls into the vacancy and emits its excess energy as an X-ray photon.

the radiation available from synchrotron sources (Topic 12A), for its high intensity greatly enhances the sensitivity of the technique.

Von Laue's original method consisted of passing a broadband beam of X-rays into a single crystal, and recording the diffraction pattern photographically. The idea behind the approach was that a crystal might not be suitably orientated to act as a diffraction grating for a single wavelength but, whatever its orientation, diffraction would be achieved for at least one of the wavelengths if a range of wavelengths were used. There is currently a resurgence of interest in this approach because synchrotron radiation spans a range of X-ray wavelengths.

An alternative technique was developed by Peter Debye and Paul Scherrer and independently by Albert Hull. They used monochromatic radiation and a powdered sample. When the sample is a powder, at least some of the crystallites will be orientated so as to give rise to diffraction. In modern powder diffractometers the intensities of the reflections are monitored electronically as the detector is rotated around the sample in a plane containing the incident ray (Fig. 18A.18). Powder diffraction techniques are used to identify the composition of a sample of a solid substance by comparison of the positions of the diffraction lines and their intensities with diffraction patterns stored in a large data bank. Powder diffraction data are also used to help determine phase diagrams, for different crystalline phases result in different diffraction patterns, and to determine the relative amounts of each phase present in a mixture. The technique is also used for the initial determination of the dimensions and symmetries of unit cells.

The method developed by the Braggs (William and his son Lawrence, who later jointly won the Nobel Prize) is the foundation of almost all modern work in X-ray crystallography. They used a single crystal and a monochromatic beam of X-rays, and rotated the crystal until a reflection was detected. There are many different sets of planes in a crystal, so there are many angles at which a reflection occurs. The complete set of data consists of the list of angles at which reflections are observed and their intensities.

**Figure 18A.18** X-ray powder diffraction patterns of (a) NaCl, (b) KCl. The smaller number of lines in (b) is a consequence of the similarity of the  $K^+$  and  $Cl^-$  scattering factors, as discussed later in the Topic.

**Figure 18A.19** A four-circle diffractometer. The settings of the orientations ( $\phi$ ,  $\chi$ ,  $\theta$ , and  $\Omega$ ) of the components are controlled by computer; each  $(hkl)$  reflection is monitored in turn, and their intensities are recorded.

Single-crystal diffraction patterns are measured by using a **four-circle diffractometer** (Fig. 18A.19). An integrated computer identifies the angular settings of the diffractometer's four circles that are needed to observe any particular intensity peak in the diffraction pattern. The diffraction intensity is measured at each setting and background intensities are assessed by making measurements at slightly different settings. Computing techniques are now available that lead not only to automatic indexing but also to the automated determination of the shape, symmetry, and size of the unit cell. Moreover, several techniques are now available for sampling large amounts of data, including area detectors and image plates, which sample whole regions of diffraction patterns simultaneously.

### (b) Bragg's law

An early approach to the analysis of diffraction patterns produced by crystals was to regard a lattice plane as a semi-transparent mirror and to model a crystal as a stack of reflecting lattice planes of separation  $d$  (Fig. 18A.20). The model makes it easy to calculate the angle the crystal must make to the

**Figure 18A.20** The conventional derivation of Bragg's law treats each lattice plane as a plane reflecting the incident radiation. The path lengths differ by  $AB + BC$ , which depends on the angle  $\theta$ . Constructive interference (a 'reflection') occurs when  $AB + BC$  is equal to an integer number of wavelengths.

incoming beam of X-rays for constructive interference to occur. It has also given rise to the name **reflection** to denote an intense beam arising from constructive interference.

Consider the reflection of two parallel rays of the same wavelength by two adjacent planes of a lattice, as shown in Fig. 18A.20. One ray strikes point D on the upper plane but the other ray must travel an additional distance  $AB$  before striking the plane immediately below. The reflected rays also differ in path length by an additional distance  $BC$ . The total path length difference of the two rays is then

$$AB + BC = 2d \sin \theta$$

where  $2\theta$  is the **glancing angle** ( $2\theta$  rather than  $\theta$ , because the beam is deflected through  $2\theta$  from its initial direction). For many glancing angles the path-length difference is not an integer number of wavelengths, and the waves interfere largely destructively. However, when the path-length difference is an integer number of wavelengths ( $AB + BC = n\lambda$ ), the reflected waves are in phase and interfere constructively. It follows that a reflection should be observed when the glancing angle satisfies **Bragg's law**:

$$n\lambda = 2d \sin \theta \quad \text{Bragg's law} \quad (18A.2a)$$

Reflections with  $n=2, 3, \dots$  are called *second order*, *third order*, and so on; they correspond to path-length differences of 2, 3, ... wavelengths. In modern work it is normal to absorb the  $n$  into  $d$ , to write Bragg's law as

$$\lambda = 2d \sin \theta \quad \text{Alternative form Bragg's law} \quad (18A.2b)$$

and to regard the  $n$ th-order reflection as arising from the  $\{nh, nk, nl\}$  planes (see *Example 18A.1*).

The primary use of Bragg's law is in the determination of the spacing between the layers in the lattice, for once the angle  $\theta$  corresponding to a reflection has been determined,  $d$  may readily be calculated.

#### Brief illustration 18A.3 Bragg's law 1

A first-order reflection from the  $\{111\}$  planes of a cubic crystal was observed at a glancing angle of  $11.2^\circ$  when X-rays of wavelength 154 pm were used. According to eqn 18A.2b, the  $\{111\}$  planes responsible for the diffraction have separation  $d_{111} = \lambda / (2 \sin \theta)$ . The separation of the  $\{111\}$  planes of a cubic lattice of side  $a$  is given by eqn 18A.1 as  $d_{111} = a/3^{1/2}$ . Therefore,

$$a = \frac{3^{1/2} \lambda}{2 \sin \theta} = \frac{3^{1/2} \times (154 \text{ pm})}{2 \sin 11.2^\circ} = 687 \text{ pm}$$

**Self-test 18A.4** Calculate the angle  $\theta$  at which the same crystal will give a reflection from the  $\{123\}$  planes.

Answer:  $24.8^\circ$

**Brief illustration 18A.4** Bragg's law 2

Some types of unit cell give characteristic and easily recognizable patterns of lines. In a cubic lattice of unit cell dimension  $a$  the spacing is given by eqn 18A.2, so the angles at which the  $\{hkl\}$  planes give first-order reflections are given by

$$\sin \theta = (h^2 + k^2 + l^2)^{1/2} \frac{\lambda}{2a}$$

The reflections are then predicted by substituting the values of  $h, k,$  and  $l$ :

$\{hkl\}$	$\{100\}$	$\{110\}$	$\{111\}$	$\{200\}$	$\{210\}$	$\{211\}$	$\{220\}$	$\{300\}$	$\{221\}$	$\{310\}$	...
$h^2+k^2+l^2$	1	2	3	4	5	6	8	9	9	10	...
$p$											

Notice that 7 (and 15, ...) is missing because the sum of the squares of three integers cannot equal 7 (or 15, ...). Such absences from the pattern are characteristic of the cubic P lattice.

**Self-test 18A.5** Normally, experimental procedures measure the glancing angle  $2\theta$  rather than  $\theta$  itself. A diffraction examination of the element polonium gave lines at the following values of  $2\theta$  (in degrees) when 71.0 pm X-rays were used: 12.1, 17.1, 21.0, 24.3, 27.2, 29.9, 34.7, 36.9, 38.9, 40.9, 42.8. Identify the unit cell and determine its dimensions.

Answer: cubic P;  $a = 337$  pm

**(c) Scattering factors**

To prepare the way to discussing methods of structural analysis we need to note that the scattering of X-rays is caused by the oscillations an incoming electromagnetic wave generates in the electrons of atoms. Heavy, electron-rich atoms give rise to stronger scattering than light atoms. This dependence on the number of electrons is expressed in terms of the **scattering factor**,  $f$ , of the element. If the scattering factor is large, then the atoms scatter X-rays strongly. An analysis that we do not repeat here concludes that the scattering factor of an atom is related to the electron density distribution in a spherically symmetrical atom,  $\rho(r)$ , and the angle through which the beam is scattered,  $2\theta$ , by

$$f = 4\pi \int_0^\infty \rho(r) \frac{\sin kr}{kr} r^2 dr \quad k = \frac{4\pi}{\lambda} \sin \theta \quad \text{Scattering factor} \quad (18A.3)$$

The value of  $f$  is greatest in the forward direction ( $\theta=0$ , Fig. 18A.21). The detailed analysis of the intensities of reflections must take this dependence on direction into account. We show in the following *Justification* that, in the forward direction  $f$  is equal to the total number of electrons in the atom. For example, the scattering factors of  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$  are 8, 18, and 18, respectively.

**Figure 18A.21** The variation of the scattering factor of atoms and ions with atomic number and angle. The scattering factor in the forward direction (at  $\theta=0$ , and hence at  $(\sin \theta)/\lambda=0$ ) is equal to the number of electrons present in the species.

**Justification 18A.2** The forward scattering factor

As  $\theta \rightarrow 0$ , so  $k \propto \sin \theta \rightarrow 0$ . Because  $\sin x = x - \frac{1}{6}x^3 + \dots$ ,

$$\lim_{k \rightarrow 0} \frac{\sin kr}{kr} = \lim_{k \rightarrow 0} \frac{kr - \frac{1}{6}(kr)^3 + \dots}{kr} = \lim_{k \rightarrow 0} (1 - \frac{1}{6}(kr)^2 + \dots) = 1$$

The factor  $(\sin kr)/kr$  is therefore equal to 1 for forward scattering. It follows that in the forward direction

$$f = 4\pi \int_0^\infty \rho(r) r^2 dr$$

The integral over the electron density  $\rho$  (the number of electrons in an infinitesimal region divided by the volume of the region) multiplied by the volume element  $4\pi r^2 dr$ , the volume of a spherical shell of radius  $r$  and thickness  $dr$ , is the total number of electrons,  $N_e$ , in the atom. Hence, in the forward direction,  $f = N_e$ .

**(d) The electron density**

If a unit cell contains several atoms with scattering factors  $f_j$  and coordinates  $(x_j a, y_j b, z_j c)$ , then we show in the following *Justification* that the overall amplitude of a wave diffracted by the  $\{hkl\}$  planes is given by

$$F_{hkl} = \sum_j f_j e^{i\phi_{hkl}(j)} \quad \text{Structure factor} \quad (18A.4)$$

where  $\phi_{hkl}(j) = 2\pi(hx_j + ky_j + lz_j)$

The sum is over all the atoms in the unit cell. The quantity  $F_{hkl}$  is called the **structure factor**.

### Justification 18A.3 The structure factor

We begin by showing that, if in the unit cell there is an A atom at the origin and a B atom at the coordinates  $(xa, yb, zc)$ , where  $x$ ,  $y$ , and  $z$  lie in the range 0 to 1, then the phase difference between the  $hkl$  reflections of the A and B atoms is  $\phi_{hkl} = 2\pi(hx + ky + lz)$ .

Consider the crystal shown schematically in Fig. 18A.22. The reflection corresponds to two waves from adjacent A planes, the phase difference of the waves being  $2\pi$ . If there is a B atom at a fraction  $x$  of the distance between the two A planes, then it gives rise to a wave with a phase difference  $2\pi x$  relative to an A reflection. To see this conclusion, note that, if  $x=0$ , there is no phase difference; if  $x=\frac{1}{2}$  the phase difference is  $\pi$ ; if  $x=1$ , the B atom lies where the upper A atom is and the phase difference is  $2\pi$ . Now consider a (200) reflection. There is now a  $2 \times 2\pi$  difference between the waves from the two A layers, and if B were to lie at  $x=0.5$  it would give rise to a wave that differed in phase by  $2\pi$  from the wave from the lower A layer. Thus, for a general fractional position  $x$ , the phase difference for a (200) reflection is  $2 \times 2\pi x$ . For a general  $(h00)$  reflection, the phase difference is therefore  $h \times 2\pi x$ . For three dimensions, this result generalizes to  $\phi_{hkl} = 2\pi(hx + ky + lz)$ .

**Figure 18A.22** Diffraction from a crystal containing two kinds of atoms. (a) For a (100) reflection from the A planes, there is a phase difference of  $2\pi$  between waves reflected by neighbouring planes. (b) For a (200) reflection, the phase difference is  $4\pi$ . The reflection from a B plane at a fractional distance  $xa$  from an A plane has a phase that is  $x$  times these phase differences.

If the amplitude of the waves scattered from A is  $f_A$  at the detector, that of the waves scattered from B is  $f_B e^{i\phi_{hkl}}$ . The total amplitude at the detector is therefore

$$F_{hkl} = f_A + f_B e^{i\phi_{hkl}}$$

This expression generalizes to eqn 18A.4 when there are several atoms present each with scattering factor  $f_i$ .

### Example 18A.2 Calculating a structure factor

Calculate the structure factors for the unit cell in Fig. 18A.23.

**Figure 18A.23** The location of the atoms for the structure factor calculation in Example 18A.2. The red spheres are  $\text{Na}^+$ , the green spheres are  $\text{Cl}^-$ .

**Method** The structure factor is defined by eqn 18A.4. To use this equation, consider the ions at the locations specified in Fig. 18A.23. Write  $f^+$  for the  $\text{Na}^+$  scattering factor and  $f^-$  for the  $\text{Cl}^-$  scattering factor. Note that ions in the body of the cell contribute to the scattering with a strength  $f$ . However, ions on faces are shared between two cells (use  $\frac{1}{2}f$ ), those on edges by four cells (use  $\frac{1}{4}f$ ), and those at corners by eight cells (use  $\frac{1}{8}f$ ). Two useful relations are (Mathematical background 3)

$$e^{i\pi} = -1 \quad \cos \phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi})$$

**Answer** From eqn 18A.4, and summing over the coordinates of all 27 atoms in the illustration:

$$F_{hkl} = f^+ \left( \frac{1}{8} + \frac{1}{8} e^{2\pi i l} + \dots + \frac{1}{2} e^{2\pi i (\frac{1}{2}h + \frac{1}{2}k + l)} \right) + f^- \left( e^{2\pi i (\frac{1}{2}h + \frac{1}{2}k + \frac{1}{2}l)} + \frac{1}{4} e^{2\pi i (\frac{1}{2}h)} + \dots + \frac{1}{4} e^{2\pi i (\frac{1}{2}h + l)} \right)$$

To simplify this 27-term expression, we use  $e^{2\pi i h} = e^{2\pi i k} = e^{2\pi i l} = 1$  because  $h$ ,  $k$ , and  $l$  are all integers:

$$F_{hkl} = f^+ \{1 + \cos(h+k)\pi + \cos(h+l)\pi + \cos(k+l)\pi\} + f^- \{(-1)^{h+k+l} + \cos k\pi + \cos l\pi + \cos h\pi\}$$

Then, because  $\cos h\pi = (-1)^h$ ,

$$F_{hkl} = f^+ \{1 + (-1)^{h+k} + (-1)^{h+l} + (-1)^{k+l}\} + f^- \{(-1)^{h+k+l} + (-1)^h + (-1)^k + (-1)^l\}$$

Now note that:

- if  $h$ ,  $k$ , and  $l$  are all even,  $F_{hkl} = f^+ \{1 + 1 + 1 + 1\} + f^- \{1 + 1 + 1 + 1\} = 4(f^+ + f^-)$
- if  $h$ ,  $k$ , and  $l$  are all odd,  $F_{hkl} = 4(f^+ - f^-)$
- if one index is odd and two are even, or vice versa,  $F_{hkl} = 0$

The  $hkl$  all-odd reflections are less intense than the  $hkl$  all-even. For  $f^+ = f^-$ , which is the case for identical atoms in a cubic P arrangement, the  $hkl$  all-odd have zero intensity, corresponding to the absences that are characteristic of cubic P unit cells (see *Brief illustration 18A.4*).

**Self-test 18A.6** Which reflections cannot be observed for a cubic I lattice?

Answer: for  $h+k+l$  odd,  $F_{hkl}=0$

Because the intensity is proportional to the square modulus of the amplitude of the wave, the intensity,  $I_{hkl}$  at the detector is

$$I_{hkl} \propto F_{hkl}^* F_{hkl} = (f_A + f_B e^{-i\phi_{hkl}})(f_A + f_B e^{i\phi_{hkl}})$$

This expression expands to

$$I_{hkl} \propto f_A^2 + f_B^2 + f_A f_B (e^{i\phi_{hkl}} + e^{-i\phi_{hkl}}) = f_A^2 + f_B^2 + 2f_A f_B \cos \phi_{hkl}$$

The cosine term either adds to or subtracts from  $f_A^2 + f_B^2$  depending on the value of  $\phi_{hkl}$ , which in turn depends on  $h$ ,  $k$ , and  $l$  and  $x$ ,  $y$ , and  $z$ . Hence, there is a variation in the intensities of the lines with different  $hkl$ . The A and B reflections interfere destructively when the phase difference is  $\pi$ , and the total intensity is zero if the atoms have the same scattering power. For example, if the unit cells are cubic I with a B atom at  $x=y=z=\frac{1}{2}$ , then the A,B phase difference is  $(h+k+l)\pi$ . Therefore, all reflections for odd values of  $h+k+l$  vanish (as we saw in *Example 18A.2*) because the waves are displaced in phase by  $\pi$ . Hence the diffraction pattern for a cubic I lattice can be constructed from that for the cubic P lattice (a cubic lattice without points at the centre of its unit cells) by striking out all reflections with odd values of  $h+k+l$ . Recognition of these **systematic absences** in a powder spectrum immediately indicates a cubic I lattice (Fig. 18A.24).

The intensity of the  $(hkl)$  reflection is proportional to  $|F_{hkl}|^2$ , so in principle we can determine the structure factors experimentally by taking the square root of the corresponding intensities (but see next section). Then, once we know all the structure factors  $F_{hkl}$  we can calculate the electron density distribution,  $\rho(r)$ , in the unit cell by using the expression

$$\rho(r) = \frac{1}{V} \sum_{hkl} F_{hkl} e^{-2\pi i(hx+ky+lz)} \quad \text{Fourier synthesis} \quad (18A.5)$$

where  $V$  is the volume of the unit cell. Equation 18A.5 is called a **Fourier synthesis** of the electron density. Fourier transforms occur throughout chemistry in a variety of guises, and are described in more detail in *Mathematical background 7* following this chapter.

plot. Terms corresponding to high values of  $h$  (short wavelength cosine terms in the sum) account for the finer details of the electron density; low values of  $h$  account for the broad features.

**Figure 18A.25** The plot of the electron density calculated in Example 18A.3 (green) and Self-test 18A.7 (purple).

**Self-test 18A.7** Use mathematical software to experiment with different structure factors (including changing signs as well as amplitudes). For example, use the same values of  $F_h$  as above, but with positive signs for  $h \geq 6$ .

Answer: See Fig. 18A.25 (purple line).

### (e) Determination of the structure

A problem with the procedure outlined above is that the observed intensity  $I_{hkl}$  is proportional to the square modulus  $|F_{hkl}|^2$ , so we do not know whether to use  $+|F_{hkl}|$  or  $-|F_{hkl}|$  in the sum in eqn 18A.5. In fact, the difficulty is more severe for non-centrosymmetric unit cells, because if we write  $F_{hkl}$  as the complex number  $|F_{hkl}|e^{i\alpha}$ , where  $\alpha$  is the phase of  $F_{hkl}$  and  $|F_{hkl}|$  is its magnitude, then the intensity lets us determine  $|F_{hkl}|$  but tells us nothing of its phase, which may lie anywhere from 0 to  $2\pi$ . This ambiguity is called the **phase problem**; its consequences are illustrated by comparing the two plots in Fig. 18A.25. Some way must be found to assign phases to the structure factors, for otherwise the sum for  $\rho$  cannot be evaluated and the method would be useless.

The phase problem can be overcome to some extent by a variety of methods. One procedure that is widely used for inorganic materials with a reasonably small number of atoms in a unit cell, and for organic molecules with a small number of heavy atoms, is the **Patterson synthesis**. Instead of the structure factors  $F_{hkl}$ , the values of  $|F_{hkl}|^2$ , which can be obtained without ambiguity from the intensities, are used in an expression that resembles eqn 18A.5:

$$P(\mathbf{r}) = \frac{1}{V} \sum_{hkl} |F_{hkl}|^2 e^{-2\pi i(hx+ky+lz)} \quad \text{Patterson synthesis} \quad (18A.6)$$

where the  $\mathbf{r}$  values correspond to the vector separations between the atoms in the unit cell; that is, the distances and directions between atoms. Whereas the electron density function  $\rho(\mathbf{r})$  is the probability density of the positions of atoms, the function  $P(\mathbf{r})$  is a map of the probability density of the separations between atoms: a peak in  $P$  at a vector separation  $\mathbf{r}$  arises from pairs of atoms that are separated by the same separation  $\mathbf{r}$ . Thus, if atom A is at the coordinates  $(x_A, y_A, z_A)$  and atom B is at  $(x_B, y_B, z_B)$ , then there will be a peak at  $(x_A - x_B, y_A - y_B, z_A - z_B)$  in the Patterson map. There will also be a peak at the negative of these coordinates, because there is a separation vector from B to A as well as a separation vector from A to B. The height of the peak in the map is proportional to the product of the atomic numbers of the two atoms,  $Z_A Z_B$ .

#### Brief illustration 18A.5 The Patterson synthesis

If the unit cell has the structure shown in Fig. 18A.26a, the Patterson synthesis would be the map shown in Fig. 18A.26b, where the location of each spot relative to the origin gives the separation and relative orientation of each pair of atoms in the original structure.

**Figure 18A.26** The Patterson synthesis corresponding to the pattern in (a) is the pattern in (b). The distance and orientation of each spot from the origin gives the orientation and separation of one atom–atom separation in (a). Some of the typical distances and their contribution to (b) are shown as  $R_1$ , etc.

**Self-test 18A.8** Consider the data in Example 18A.3. Show that  $VP(x) = |F_0|^2 + 2 \sum_{h=1}^{\infty} |F_h|^2 \cos 2\pi hx$  and plot the Patterson synthesis.

Figure 18A.27 Patterson synthesis of the data from Example 18A.3.

Heavy atoms dominate the scattering because their scattering factors are large, of the order of their atomic numbers, and their locations may be deduced quite readily. The sign of  $F_{hkl}$  can now be calculated from the locations of the heavy atoms in the unit cell, and to a high probability the phase calculated for them will be the same as the phase for the entire unit cell. To see why this is so, we have to note that a structure factor of a centrosymmetric cell has the form

$$F = (\pm)f_{\text{heavy}} + (\pm)f_{\text{light}} + (\pm)f_{\text{light}} + \dots \quad (18A.7)$$

where  $f_{\text{heavy}}$  is the scattering factor of the heavy atom and  $f_{\text{light}}$  the scattering factors of the light atoms. The  $f_{\text{light}}$  are all much smaller than  $f_{\text{heavy}}$ , and their phases are more or less random if the atoms are distributed throughout the unit cell. Therefore, the net effect of the  $f_{\text{light}}$  is to change  $F$  only slightly from  $f_{\text{heavy}}$ , and we can be reasonably confident that  $F$  will have the same sign as that calculated from the location of the heavy atom. This phase can then be combined with the observed  $|F|$  (from the reflection intensity) to perform a Fourier synthesis of the full electron density in the unit cell, and hence to locate the light atoms as well as the heavy atoms.

Modern structural analyses make extensive use of **direct methods**. Direct methods are based on the possibility of treating the atoms in a unit cell as being virtually randomly distributed (from the radiation's point of view), and then to use statistical techniques to compute the probabilities that the phases have a particular value. It is possible to deduce relations between some structure factors and sums (and sums of squares) of others, which have the effect of constraining the phases to particular values (with high probability, so long as the structure factors are large). For example, the **Sayre probability relation** has the form

$$\begin{aligned} \text{sign of } F_{h+h',k+k',l+l'} &\text{ is probably equal to } (\text{sign of } F_{hkl}) \\ &\times (\text{sign of } F_{h'k'l'}) \end{aligned} \quad \text{Sayre probability relation} \quad (18A.8)$$

For example, if  $F_{122}$  and  $F_{232}$  are both large and negative, then it is highly likely that  $F_{354}$ , provided it is large, will be positive.

In the final stages of the determination of a crystal structure, the parameters describing the structure (atom positions, for instance) are adjusted systematically to give the best fit between the observed intensities and those calculated from the model of the structure deduced from the diffraction pattern. This process is called **structure refinement**. Not only does the procedure give accurate positions for all the atoms in the unit cell, but it also gives an estimate of the errors in those positions and in the bond lengths and angles derived from them. The procedure also provides information on the vibrational amplitudes of the atoms.

## 18A.4 Neutron and electron diffraction

According to the de Broglie relation (Topic 7A,  $\lambda = h/p$ ), particles have wavelengths and may therefore undergo diffraction. Neutrons generated in a nuclear reactor and then slowed to thermal velocities have wavelengths similar to those of X-rays and may also be used for diffraction studies. For instance, a neutron generated in a reactor and slowed to thermal velocities by repeated collisions with a moderator (such as graphite) until it is travelling at about  $4 \text{ km s}^{-1}$  has a wavelength of about 100 pm. In practice, a range of wavelengths occurs in a neutron beam, but a monochromatic beam can be selected by diffraction from a crystal, such as a single crystal of germanium.

### Example 18A.4 Calculating the typical wavelength of thermal neutrons

Calculate the typical wavelength of neutrons after reaching thermal equilibrium with their surroundings at 373 K. For simplicity, assume that the particles are travelling in one dimension.

**Method** We need to relate the wavelength to the temperature. There are two linking steps. First, the de Broglie relation expresses the wavelength in terms of the linear momentum. Then the linear momentum can be expressed in terms of the kinetic energy, the mean value of which is given in terms of the temperature by the equipartition theorem (*Foundations* B).

**Answer** From the equipartition principle, we know that the mean translational kinetic energy of a neutron at a temperature  $T$  travelling in the  $x$ -direction is  $E_k = \frac{1}{2}kT$ . The kinetic energy is also equal to  $p^2/2m$ , where  $p$  is the momentum of the neutron and  $m$  is its mass. Hence,  $p = (mkT)^{1/2}$ . It follows from the de Broglie relation  $\lambda = h/p$  that the neutron's wavelength is

$$\lambda = \frac{h}{(mkT)^{1/2}}$$

Therefore, at 373 K,

$$\lambda = \frac{6.626 \times 10^{-34} \text{ J s}}{\{(1.675 \times 10^{-27} \text{ kg}) \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (373 \text{ K})\}^{1/2}}$$

$$\stackrel{1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}}{=} \frac{6.626 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-1}}{(1.675 \times 10^{-27} \times 1.381 \times 10^{-23} \times 373)^{1/2} (\text{kg}^2 \text{ m}^2 \text{ s}^{-2})^{1/2}}$$

$$= 2.26 \times 10^{-10} \text{ m} = 226 \text{ pm}$$

**Self-test 18A.9** Calculate the temperature needed for the average wavelength of the neutrons to be 100 pm.

Answer: 1.90 kK

Neutron diffraction differs from X-ray diffraction in two main respects. First, the scattering of neutrons is a nuclear phenomenon. Neutrons pass through the extranuclear electrons of atoms and interact with the nuclei through the 'strong force' that is responsible for binding nucleons together. As a result, the intensity with which neutrons are scattered is independent of the number of electrons and neighbouring elements in the periodic table might scatter neutrons with markedly different intensities. Neutron diffraction can be used to distinguish atoms of elements such as Ni and Co that are present in the same compound and to study order–disorder phase transitions in FeCo. A second difference is that neutrons possess a magnetic moment due to their spin. This magnetic moment can couple to the magnetic fields of atoms or ions in a crystal (if the ions have unpaired electrons) and modify the diffraction pattern. One consequence is that neutron diffraction is well suited to the investigation of magnetically ordered lattices in which neighbouring atoms may be of the same element but have different orientations of their electronic spin (Fig. 18A.28).

**Figure 18A.28** If the spins of atoms at lattice points are orderly, as in this material, where the spins of one set of atoms are aligned antiparallel to those of the other set, neutron diffraction detects two interpenetrating simple cubic lattices on account of the magnetic interaction of the neutron with the atoms, but X-ray diffraction would see only a single bcc lattice.

Electrons accelerated through a potential difference of 40 kV have wavelengths of about 6 pm, and so are also suitable for diffraction studies of molecules. Consider the scattering of electrons (or neutrons) from a pair of nuclei separated by a distance  $R_{ij}$  and orientated at a definite angle  $\theta$  to an incident beam of electrons (or neutrons). When the molecule consists of a number of atoms, the scattering intensity can be calculated by summing over the contribution from all pairs. The total intensity  $I(\theta)$  is given by the **Wierl equation**:

$$I(\theta) = \sum_{i,j} f_i f_j \frac{\sin s R_{ij}}{s R_{ij}} \quad s = \frac{4\pi}{\lambda} \sin \frac{1}{2} \theta \quad \text{Wierl equation} \quad (18A.9)$$

where  $\lambda$  is the wavelength of the electrons in the beam, and  $f$  is the **electron scattering factor**, a measure of the electron scattering power of the atom. The main application of electron diffraction techniques is to the study of surfaces (Topic 22A), and you are invited to explore the Wierl equation in Problem 18A.17.

## Checklist of concepts

- 1. A **space lattice** is the pattern formed by points representing the locations of structural motifs (atoms, molecules, or groups of atoms, molecules, or ions).
- 2. The **Bravais lattices** are the 14 distinct space lattices in three dimensions (Fig. 18A.8).
- 3. A **unit cell** is an imaginary parallelepiped that contains one unit of a translationally repeating pattern.
- 4. Unit cells are classified into seven **crystal systems** according to their rotational symmetries.
- 5. A crystal plane is specified by a set of **Miller indices** ( $hkl$ ); sets of planes are denoted  $\{hkl\}$ .
- 6. The **scattering factor** is a measure of the ability of an atom to diffract radiation.
- 7. The **structure factor** is the overall amplitude of a wave diffracted by the  $\{hkl\}$  planes.
- 8. **Fourier synthesis** is the construction of the electron density distribution from structure factors.
- 9. A **Patterson synthesis** is a map of interatomic vectors obtained by Fourier analysis of diffraction intensities.
- 10. **Structure refinement** is the adjustment of structural parameters to give the best fit between the observed intensities and those calculated from the model of the structure deduced from the diffraction pattern.

## Checklist of equations

Property	Equation	Comment	Equation number
Separation of planes in a rectangular lattice	$1/d_{hkl}^2 = h^2/a^2 + k^2/b^2 + l^2/c^2$	$h, k,$ and $l$ are Miller indices	18A.1c
Bragg's law	$\lambda = 2d \sin \theta$	$d$ is the lattice spacing, $2\theta$ the glancing angle	18A.2b
Scattering factor	$f = 4\pi \int_0^\infty [\rho(r) \sin kr] / kr r^2 dr, k = (4\pi/\lambda) \sin \theta$	Spherically symmetrical atom	18A.3
Structure factor	$F_{hkl} = \sum_j f_j e^{i\phi_{hkl}(j)}, \phi_{hkl}(j) = 2\pi(hx_j + ky_j + lz_j)$	Definition	18A.4
Fourier synthesis	$\rho(r) = (1/V) \sum_{hkl} F_{hkl} e^{-2\pi i(hx + ky + lz)}$	$V$ is the volume of the unit cell	18A.5
Patterson synthesis	$P(r) = (1/V) \sum_{hkl}  F_{hkl} ^2 e^{-2\pi i(hx + ky + lz)}$		18A.6
Wierl equation	$I(\theta) = \sum_{i,j} f_i f_j (\sin sR_{ij} / sR_{ij}), s = (4\pi/\lambda) \sin \frac{1}{2} \theta$		18A.9

### ► Why do you need to know this material?

To prepare for the study of the properties of materials and the structures they adopt, you need to know how atoms and molecules interact to form metallic, covalent, ionic, and molecular solids.

### ► What is the key idea?

Four characteristic types of bonding result in metals, ionic solids, covalent solids, and molecular solids.

### ► What do you need to know already?

You need to be familiar with molecular interactions (Topic 16B) and the general features of crystal structure (Topic 18A). For the discussion of metallic bonding you should be aware of the principles of Hückel molecular orbital theory (Topic 10E). The discussion of ionic bonding makes use of the concept of enthalpy and the fact that it is a state function (Topic 2C).

The bonding within a solid may be of various kinds. Simplest of all (in concept, at least) are **metals**, where electrons are delocalized over arrays of identical cations and bind the whole together into a rigid but ductile and malleable structure. **Ionic solids** consist of cations and anions packed together by electrostatic

interactions in a crystal (Topic 18A). In **covalent solids**, covalent bonds in a definite spatial orientation link the atoms in a network extending through a crystal. **Molecular solids** are bonded together by van der Waals interactions (Topic 16B).

## 18B.1 Metallic solids

The crystalline forms of metallic elements can be discussed in terms of a model in which their atoms are represented as identical hard spheres. Most metallic elements crystallize in one of three simple forms, two of which can be explained in terms of the hard spheres packing together in the closest possible arrangement. In this section we consider not only the geometrical arrangement of the atoms in the crystal, but also the distribution of electrons over the atoms.

### (a) Close packing

Figure 18B.1 shows a **close-packed** layer of identical spheres, one with maximum utilization of space. A close-packed three-dimensional structure is obtained by stacking such close-packed layers on top of one another. However, this stacking can be done in different ways, which result in close-packed **polytypes**, or structures that are identical in two dimensions (the close-packed layers) but differ in the third dimension.

In all polytypes, the spheres of second close-packed layer lie in the depressions of the first layer (Fig. 18B.2). The third layer may be added in either of two ways. In one, the spheres are placed directly above the first layer to give an ABA pattern of layers (Fig. 18B.3a). Alternatively, the spheres may be placed over the gaps in the first layer, so giving an ABC pattern (Fig.

**Figure 18B.1** The first layer of close-packed spheres used to build a three-dimensional close-packed structure.

**Figure 18B.2** The second layer of close-packed spheres occupies the dips of the first layer. The two layers are the AB component of the close-packed structure.

18B.3b). Two polytypes are formed if the two stacking patterns are repeated in the vertical direction:

- **Hexagonally close-packed (hcp):** the ABA pattern is repeated, to give the sequence of layers ABABAB....
- **Cubic close-packed (ccp):** the ABC pattern is repeated, to give the sequence ABCABC....

The origins of these names can be seen by referring to Fig. 18B.4. The ccp structure gives rise to a face-centred unit cell, so may also be denoted cubic F (or fcc, for face-centred cubic). It is also possible to have random sequences of layers; however, the hcp and ccp polytypes are the most important. Table 18B.1 lists some elements possessing these structures.

The compactness of close-packed structures is indicated by their **coordination number**, the number of spheres immediately surrounding any selected sphere, which is 12 in all cases. Another measure of their compactness is the **packing fraction**, the fraction of space occupied by the spheres, which is 0.740 (see *Example 18B.1*). That is, in a close-packed solid of identical hard spheres, only 26.0 per cent of the volume is empty space. The fact that many metals are close-packed accounts for their high mass densities.

**Figure 18B.3** (a) The third layer of close-packed spheres might occupy the dips lying directly above the spheres in the first layer, resulting in an ABA structure, which corresponds to hexagonal close-packing. (b) Alternatively, the third layer might lie in the dips that are not above the spheres in the first layer, resulting in an ABC structure, which corresponds to cubic close-packing.

**Figure 18B.4** A fragment of the structure shown in Fig. 18B.3 revealing the (a) hexagonal, (b) cubic symmetry. The colours of the spheres are the same as for the layers in Fig. 18B.3.

**Table 18B.1** The crystal structures of some elements\*

Structure	Element
hcp <sup>‡</sup>	Be, Cd, Co, He, Mg, Sc, Ti, Zn
fcc <sup>‡</sup> (ccp, cubic F)	Ag, Al, Ar, Au, Ca, Cu, Kr, Ne, Ni, Pd, Pb, Pt, Rh, Rn, Sr, Xe
bcc (cubic I)	Ba, Cs, Cr, Fe, K, Li, Mn, Mo, Rb, Na, Ta, W, V
cubic P	Po

\* The notation used to describe primitive unit cells is introduced in Topic 18A.

<sup>‡</sup> Close-packed structures.

### Example 18B.1 Calculating a packing fraction

Calculate the packing fraction of a ccp structure with spheres of radius  $R$ .

**Method** Refer to Fig. 18B.5. First calculate the volume of a unit cell, and then calculate the total volume of the spheres that occupy it fully or partially. The first part of the calculation is an exercise in geometry and the use of the Pythagorean theorem ( $a^2 + b^2 = c^2$  in a right-angled triangle). The second part involves counting the fraction of spheres that occupy the cell.

**Answer** We see in Fig. 18B.5 that a diagonal of any face passes completely through one sphere and halfway through two other spheres. Therefore, the length of a diagonal is  $4R$ . The length of

**Figure 18B.5** The calculation of the packing fraction of a ccp unit cell.

a side  $l$  is such that  $l^2 + l^2 = (4R)^2$  and is therefore  $l = 8^{1/2}R$ . The volume of the unit cell is  $l^3 = 8^{3/2}R^3$ . As Fig 18B.5 shows, each of the eight vertices of the cube contains the equivalent of  $\frac{1}{8}$  of a sphere. Also, each of the six remaining spheres contributes  $\frac{1}{2}$  of its volume to the cell. Therefore, each cell contains the equivalent of  $6 \times \frac{1}{2} + 8 \times \frac{1}{8} = 4$  spheres. Because the volume of each sphere is  $\frac{4}{3}\pi R^3$ , the total occupied volume is  $\frac{16}{3}\pi R^3$ . The fraction of space occupied is therefore

$$\frac{\frac{16}{3}\pi R^3}{8^{3/2}R^3} = \frac{16\pi}{3 \times 8^{3/2}} = 0.740$$

Because an hcp structure has the same coordination number, its packing fraction is the same.

**Self-test 18B.1** The packing fractions of structures that are not close-packed are calculated similarly. Calculate the packing fraction of a structure with one sphere at the centre of a cube formed by eight others: this is a cubic I (bcc) structure.

Answer: 0.68

As shown in Table 18B.1, a number of common metals adopt structures that are less than close-packed. The departure from close packing suggests that factors such as specific covalent bonding between neighbouring atoms are beginning to influence the structure and impose a specific geometrical arrangement. One such arrangement results in a cubic I (bcc, for body-centred cubic) structure, with one sphere at the centre of a cube formed by eight others. The coordination number of a bcc structure is only 8, but there are six more atoms not much further away than the eight nearest neighbours. The packing fraction of 0.68 (*Self-test 18B.1*) is not much smaller than the value for a close-packed structure (0.74), and shows that about two-thirds of the available space is actually occupied.

## (b) Electronic structure of metals

The central aspect of solids that determines their electrical properties (Topic 18C) is the distribution of their electrons. There are two models of this distribution. In one, the **nearly-free electron approximation**, the valence electrons are assumed to be trapped in a box with a periodic potential, with low energy corresponding to the locations of cations. In the **tight-binding approximation**, the valence electrons are assumed to occupy molecular orbitals delocalized throughout the solid. The latter model is more in accord with our discussion of electrical properties of solids (Topic 18C), so we confine our attention to it.

Consider a one-dimensional solid, which consists of a single, infinitely long line of atoms. At first sight, this model may seem too restrictive and unrealistic. However, not only does it give us the concepts we need to understand the structure and

electrical properties of three-dimensional, macroscopic samples of metals and semiconductors, it is also the starting point for the description of long and thin structures, such as carbon nanotubes.

Suppose that each atom has one s orbital available for forming molecular orbitals. We can construct the LCAO-MOs of the solid by adding  $N$  atoms in succession to a line, and then infer the electronic structure by using the building-up principle. One atom contributes one s orbital at a certain energy (Fig. 18B.6). When a second atom is brought up it overlaps the first and forms bonding and antibonding orbitals. The third atom overlaps its nearest neighbour (and only slightly the next-nearest), and from these three atomic orbitals, three molecular orbitals are formed: one is fully bonding, one fully antibonding, and the intermediate orbital is nonbonding between neighbours. The fourth atom leads to the formation of a fourth molecular orbital. At this stage, we can begin to see that the general effect of bringing up successive atoms is to spread the range of energies covered by the molecular orbitals, and also to fill in the range of energies with more and more orbitals (one more for each atom). When  $N$  atoms have been added to the line, there are  $N$  molecular orbitals covering a band of energies of finite width, and the Hückel secular determinant (Topic 10E) is

$$\begin{vmatrix} \alpha - E & \beta & 0 & 0 & 0 & \dots & 0 \\ \beta & \alpha - E & \beta & 0 & 0 & \dots & 0 \\ 0 & \beta & \alpha - E & \beta & 0 & \dots & 0 \\ 0 & 0 & \beta & \alpha - E & \beta & \dots & 0 \\ 0 & 0 & 0 & \beta & \alpha - E & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \dots & \vdots \\ 0 & 0 & 0 & 0 & 0 & \dots & \alpha - E \end{vmatrix} = 0$$

where  $\alpha$  is the Coulomb integral and  $\beta$  is the (s,s) resonance integral. The theory of determinants applied to such a

**Figure 18B.6** The formation of a band of  $N$  molecular orbitals by successive addition of  $N$  atoms to a line. Note that the band remains of finite width as  $N$  becomes infinite and, although it then looks continuous, it consists of  $N$  different orbitals.

symmetrical example as this (technically a ‘tridiagonal determinant’) leads to the following expression for the roots:

$$E_k = \alpha + 2\beta \cos \frac{k\pi}{N+1} \quad k=1,2,\dots,N \quad \text{Linear array of } s \text{ orbitals} \quad \text{Energy levels} \quad (18B.1)$$

We show in the following *Justification* that when  $N$  is infinitely large, the separation between neighbouring levels,  $E_{k+1} - E_k$ , is infinitely small, but the band still has finite width overall (Fig. 18B.6):

$$E_N - E_1 \rightarrow -4\beta \quad \text{as } N \rightarrow \infty \quad \text{Linear array of } s \text{ orbitals} \quad \text{Band width} \quad (18B.2)$$

(Note that because  $\beta < 0$ ,  $-4\beta > 0$ .) We can think of this band as consisting of  $N$  different molecular orbitals, the lowest-energy orbital ( $k=1$ ) being fully bonding, and the highest-energy orbital ( $k=N$ ) being fully antibonding between adjacent atoms (Fig. 18B.7). The molecular orbitals of intermediate energy have  $k-1$  nodes distributed along the chain of atoms. Similar bands form in three-dimensional solids.

### Justification 18B.1 The properties of a band

From eqn 18B.1 we see that the energy separation between neighbouring energy levels  $k$  and  $k+1$  is

$$\begin{aligned} E_{k+1} - E_k &= \left( \alpha + 2\beta \cos \frac{(k+1)\pi}{N+1} \right) - \left( \alpha + 2\beta \cos \frac{k\pi}{N+1} \right) \\ &= 2\beta \left( \cos \frac{(k+1)\pi}{N+1} - \cos \frac{k\pi}{N+1} \right) \end{aligned}$$

By using the trigonometric identity  $\cos(A+B) = \cos A \cos B - \sin A \sin B$  followed by  $\cos 0 = 1$  and  $\sin 0 = 0$  the first (blue) term in parentheses is

$$\cos \frac{(k+1)\pi}{N+1} = \cos \frac{k\pi}{N+1} \overset{\rightarrow 1 \text{ as } N \rightarrow \infty}{\cos \frac{\pi}{N+1}} - \sin \frac{k\pi}{N+1} \overset{\rightarrow 0 \text{ as } N \rightarrow \infty}{\sin \frac{\pi}{N+1}}$$

Therefore, as  $N \rightarrow \infty$ ,

$$E_{k+1} - E_k \rightarrow 2\beta \left( \cos \frac{k\pi}{N+1} - \cos \frac{k\pi}{N+1} \right) = 0$$

It follows that when  $N$  is infinitely large, the difference between neighbouring energy levels is infinitely small.

To assess the effect of  $N$  on the width  $E_N - E_1$  of a band, we proceed as follows. The energy of the level with  $k=1$  is

$$E_1 = \alpha + 2\beta \cos \frac{\pi}{N+1}$$

As  $N \rightarrow \infty$ , the cosine approaches  $\cos 0 = 1$ . Therefore, in this limit

$$E_1 = \alpha + 2\beta$$

When  $k$  has its maximum value of  $N$ ,

$$E_N = \alpha + 2\beta \cos \frac{N\pi}{N+1}$$

As  $N \rightarrow \infty$ , we can ignore the 1 in the denominator, and the cosine term becomes  $\cos \pi = -1$ . Therefore, in this limit  $E_N = \alpha - 2\beta$ , and  $E_N - E_1 \rightarrow -4\beta$ , as in eqn 18B.2.

### Brief illustration 18B.1 Energy levels in a band

To illustrate the dependence of  $E_{k+1} - E_k$  on  $N$ , we use the first equation in the *Justification* to calculate

$$N=3: \quad E_2 - E_1 = 2\beta \left( \cos \frac{2\pi}{4} - \cos \frac{\pi}{4} \right) \approx -1.414\beta$$

$$N=30: \quad E_2 - E_1 = 2\beta \left( \cos \frac{2\pi}{31} - \cos \frac{\pi}{31} \right) \approx -0.0307\beta$$

$$N=300: \quad E_2 - E_1 = 2\beta \left( \cos \frac{2\pi}{301} - \cos \frac{\pi}{301} \right) \approx -0.00036\beta$$

We see that the energy difference decreases with increasing  $N$ .

**Self-test 18B.2** For  $N=300$ , at which value of  $k$  would  $E_{k+1} - E_k$  have its maximum value? *Hint:* Use mathematical software.

Answer:  $k=150$

The band formed from overlap of  $s$  orbitals is called the **s band**. If the atoms have  $p$  orbitals available, the same procedure leads to a **p band** (as shown in the upper half of Fig. 18B.7). If the atomic  $p$  orbitals lie higher in energy than the  $s$  orbitals, then the  $p$  band lies higher than the  $s$  band, and there may be a **band gap**, a range of energies to which no orbital corresponds.

**Figure 18B.7** The overlap of  $s$  orbitals gives rise to an  $s$  band and the overlap of  $p$  orbitals gives rise to a  $p$  band. In this case, the  $s$  and  $p$  orbitals of the atoms are so widely spaced in energy that there is a band gap. In many cases the separation is less and the bands overlap.

**Figure 18B.8** When  $N$  electrons occupy a band of  $N$  orbitals, it is only half full and the electrons near the Fermi level (the top of the filled levels) are mobile.

However, the  $s$  and  $p$  bands may also be contiguous with the highest orbital of the  $s$  band coincident with the lowest level of the  $p$  band or even overlap (as is the case for the  $3s$  and  $3p$  bands in magnesium).

Now consider the electronic structure of a solid formed from atoms each able to contribute one electron (for example, the alkali metals). There are  $N$  atomic orbitals and therefore  $N$  molecular orbitals packed into an apparently continuous band. There are  $N$  electrons to accommodate. At  $T=0$ , only the lowest  $\frac{1}{2}N$  molecular orbitals are occupied (Fig. 18B.8), and the HOMO is called the **Fermi level**. However, unlike in molecules, there are empty orbitals very close in energy to the Fermi level, so it requires hardly any energy to excite the uppermost electrons. Some of the electrons are therefore very mobile and give rise to electrical conductivity (Topic 18C). Only the small number of electrons close to the Fermi level can undergo thermal excitation, so only these electrons contribute to the heat capacity of the metal. It is for this reason that Dulong and Petit's law for heat capacities (Topic 7A) gives reasonable agreement with experiment at normal temperatures by counting only the atoms in a sample, not the atoms plus the 'free' electrons.

## 18B.2 Ionic solids

Two questions arise when we consider ionic solids: the relative locations adopted by the ions and the energetics of the resulting structure.

### (a) Structure

When crystals of compounds of monatomic ions (such as NaCl and MgO) are modelled by stacks of hard spheres it is necessary to allow for the different ionic radii (typically with the cations smaller than the anions) and different electrical charges. The coordination number of an ion is the number of nearest neighbours of opposite charge; the structure itself is characterized as having  $(N_+, N_-)$  **coordination**, where  $N_+$  is the coordination number of the cation and  $N_-$  that of the anion.

**Figure 18B.9** The caesium chloride structure consists of two interpenetrating simple cubic arrays of ions, one of cations and the other of anions, so that each cube of ions of one kind has a counter-ion at its centre.

Even if, by chance, the ions have the same size, the problems of ensuring that the unit cells are electrically neutral make it impossible to achieve 12-coordinate close-packed ionic structures. As a result, ionic solids are generally less dense than metals. The best packing that can be achieved is the (8,8)-coordinate **caesium chloride structure** in which each cation is surrounded by eight anions and each anion is surrounded by eight cations (Fig. 18B.9). In this structure, an ion of one charge occupies the centre of a cubic unit cell with eight counter ions at its corners. The structure is adopted by CsCl itself and also by CaS.

When the radii of the ions differ more than in CsCl, even eight-coordinate packing cannot be achieved. One common structure adopted is the (6,6)-coordinate **rock salt structure** typified by rock salt itself, NaCl (Fig. 18B.10). In this structure, each cation is surrounded by six anions and each anion is surrounded by six cations. The rock salt structure can be pictured as consisting of two interpenetrating slightly expanded cubic F (fcc) arrays, one composed of cations and the other of anions. This structure is adopted by NaCl itself and also by several other MX compounds, including KBr, AgCl, MgO, and ScN.

The switch from the caesium chloride structure to the rock salt structure is related to the value of the **radius ratio**,  $\gamma$ :

$$\gamma = \frac{r_{\text{smaller}}}{r_{\text{larger}}} \quad \text{Definition} \quad \text{Radius ratio} \quad (18B.3)$$

**Figure 18B.10** The rock salt (NaCl) structure consists of two mutually interpenetrating slightly expanded face-centred cubic arrays of ions. The entire assembly shown here is the unit cell.

**Figure 18B.11** The structure of the sphalerite form of ZnS showing the location of the Zn atoms in the tetrahedral holes formed by the array of S atoms. (There is an S atom at the centre of the cube inside the tetrahedron of Zn atoms.)

The two radii are those of the larger and smaller ions in the crystal. The **radius-ratio rule**, which is derived by considering the geometrical problem of packing the maximum number of hard spheres of one radius around a hard sphere of a different radius, can be summarized as follows:

Radius ratio	Structural type
$\gamma < 2^{1/2} - 1 = 0.414$	sphalerite (or zinc blende, Fig. 18B.11)
$0.414 < \gamma < 3^{1/2} - 1 = 0.732$	rock salt (Fig. 18B.10)
$\gamma > 0.732$	caesium chloride (Fig. 18B.9)

The deviation of a structure from that expected on the basis of this rule is often taken to be an indication of a shift from ionic towards covalent bonding. A major source of unreliability, though, is the arbitrariness of ionic radii (as we explain in a moment) and their variation with coordination number.

Ionic radii are derived from the distance between centres of adjacent ions in a crystal. However, we need to apportion the total distance between the two ions by defining the radius of one ion and then inferring the radius of the other ion. One scale that is widely used is based on the value 140 pm for the radius of the  $O^{2-}$  ion (Table 18B.2). Other scales are also available (such as one based on  $F^-$  for discussing halides), and it is essential not to mix values from different scales. Because ionic radii are so arbitrary, predictions based on them must be viewed cautiously.

**Table 18B.2\*** Ionic radii,  $r/\text{pm}$

$Na^+$	102 (6 <sup>‡</sup> ), 116 (8)
$K^+$	138 (6), 151 (8)
$F^-$	128 (2), 131 (4)
$Cl^-$	181 (close packing)

\* This scale is based on a value 140 pm for the radius of the  $O^{2-}$  ion. More values are given in the *Resource section*.

‡ Coordination number.

### Brief illustration 18B.2 The radius ratio

Using values of ionic radii from the *Resource section*, the radius ratio for MgO is

$$\gamma = \frac{\overbrace{72 \text{ pm}}^{\text{radius of } Mg^{2+}}}{\underbrace{140 \text{ pm}}_{\text{radius of } O^{2-}}} = 0.51$$

which is consistent with the observed rock salt structure of MgO crystals.

**Self-test 18B.3** Predict the crystal structure of TlCl.

Answer:  $\gamma = 0.88$ ; caesium chloride structure

## (b) Energetics

The **lattice energy** of a solid is the difference in Coulombic potential energy of the ions packed together in a solid and widely separated as a gas. The lattice energy is always positive; a high lattice energy indicates that the ions interact strongly with one another to give a tightly bonded solid. The **lattice enthalpy**,  $\Delta H_L$ , is the change in standard molar enthalpy for the process

and its equivalent for other charge types and stoichiometries. At  $T=0$  the lattice enthalpy is equal to the lattice energy; at normal temperatures they differ by only a few kilojoules per mole, and the difference is normally neglected.

Each ion in a solid experiences electrostatic attractions from all the other oppositely charged ions and repulsions from all the other like-charged ions. The total Coulomb potential energy is the sum of all the electrostatic contributions. Each cation is surrounded by anions, and there is a large negative contribution from the attraction of the opposite charges. Beyond those nearest neighbours, there are cations that contribute a positive term to the total potential energy of the central cation. There is also a negative contribution from the anions beyond those cations, a positive contribution from the cations beyond them, and so on to the edge of the solid. These repulsions and attractions become progressively weaker as the distance from the central ion increases, but the net outcome of all these contributions is dominated by the interaction between nearest neighbours and is a lowering of energy.

First, consider a simple one-dimensional model of a solid consisting of a long line of uniformly spaced alternating cations and anions, with  $d$  the distance between their centres, the sum of the ionic radii (Fig. 18B.12). If the charge numbers of the ions have the same absolute value (+1 and -1, or +2 and -2, for instance), then  $z_1 = +z$ ,  $z_2 = -z$ , and  $z_1 z_2 = -z^2$ . The potential

**Figure 18B.12** A line of alternating cations and anions used in the calculation of the Madelung constant in one dimension.

energy of the central ion is calculated by summing all the terms, with negative terms representing attractions to oppositely charged ions and positive terms representing repulsions from like-charged ions. For the interaction with ions extending in a line to the right of the central ion, the lattice energy is

$$\begin{aligned} E_p &= \frac{1}{4\pi\epsilon_0} \times \left( -\frac{z^2 e^2}{d} + \frac{z^2 e^2}{2d} - \frac{z^2 e^2}{3d} + \frac{z^2 e^2}{4d} - \dots \right) \\ &= \frac{z^2 e^2}{4\pi\epsilon_0 d} \times \left( -1 + \frac{1}{2} - \frac{1}{3} + \frac{1}{4} - \dots \right) \\ &= -\frac{z^2 e^2}{4\pi\epsilon_0 d} \times \ln 2 \end{aligned}$$

We have used the relation  $1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \dots = \ln 2$ . Finally, we multiply  $E_p$  by 2 to obtain the total energy arising from interactions on each side of the ion and then multiply by Avogadro's constant,  $N_A$ , to obtain an expression for the (molar) lattice energy. The outcome is

$$E_p = -2 \ln 2 \times \frac{z^2 N_A e^2}{4\pi\epsilon_0 d}$$

with  $d = r_{\text{cation}} + r_{\text{anion}}$ . This energy is negative, corresponding to a net attraction. This calculation can be extended to three-dimensional arrays of ions with different charges:

$$E_p = -A \times \frac{|z_A z_B| N_A e^2}{4\pi\epsilon_0 d} \quad (18B.4)$$

The factor  $A$  is a positive numerical constant called the **Madelung constant**; its value depends on how the ions are arranged about one another. For a rock salt structure,  $A = 1.748$ . Table 18B.3 lists Madelung constants for other common structures.

There are also repulsions arising from the overlap of the filled atomic orbitals of the ions and, consequently, the role of the Pauli principle. These repulsions are taken into account by supposing that, because wavefunctions decay exponentially with distance at large distances from the nucleus, and repulsive interactions depend on the overlap of orbitals, the repulsive contribution to the potential energy has the form

$$E_p^* = N_A C' e^{-d/d^*} \quad (18B.5)$$

**Table 18B.3** Madelung constants

Structural type	$A$
Caesium chloride	1.763
Fluorite	2.519
Rock salt	1.748
Rutile	2.408
Sphalerite (zinc blende)	1.638
Wurtzite	1.641

with  $C'$  and  $d^*$  constants; the value of  $C'$  is not needed (it cancels in expressions that make use of this formula; see below) and that of  $d^*$  is commonly taken to be 34.5 pm. The total potential energy is the sum of  $E_p$  and  $E_p^*$ , and passes through a minimum when  $d(E_p + E_p^*)/dd = 0$  (Fig. 18B.13). A short calculation leads to the following expression for the minimum total potential energy (see Problem 18B.9):

$$E_{p,\text{min}} = -\frac{N_A |z_A z_B| e^2}{4\pi\epsilon_0 d} \left( 1 - \frac{d^*}{d} \right) A \quad \text{Born-Mayer equation} \quad (18B.6)$$

This expression is called the **Born-Mayer equation**. Provided we ignore zero-point contributions to the energy, the negative of this potential energy can be identified with the lattice energy. The important features of this equation are:

- Because  $E_{p,\text{min}} \propto |z_A z_B|$ , the potential energy decreases (becomes more negative) with increasing charge number of the ions.
- Because  $E_{p,\text{min}} \propto 1/d$ , the potential energy decreases (becomes more negative) with decreasing ionic radius.

Physical interpretation

The second conclusion follows from the fact that the smaller the ionic radii, the smaller the value of  $d$ . We see that large lattice energies are expected when the ions are highly charged (so  $|z_A z_B|$  is large) and small (so  $d$  is small).

**Figure 18B.13** The contributions to the total potential energy of an ionic crystal.

**Brief illustration 18B.3** The Born–Mayer equation

To estimate  $E_{p,\min}$  for MgO, which has a rock salt structure ( $A = 1.748$ ), we use  $d = r(\text{Mg}^{2+}) + r(\text{O}^{2-}) = 72 + 140 \text{ pm} = 212 \text{ pm}$ . We also use

$$\frac{N_A e^2}{4\pi\epsilon_0} = \frac{(6.02214 \times 10^{23} \text{ mol}^{-1}) \times (1.601176 \times 10^{-19} \text{ C})^2}{4\pi \times (8.85419 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1})} = 1.38762 \times 10^{-4} \text{ J m mol}^{-1}$$

and obtain

$$E_{p,\min} = - \frac{4}{2.12 \times 10^{-10} \text{ m}} \times (1.38762 \times 10^{-4} \text{ J m mol}^{-1}) \times \left(1 - \frac{34.5 \text{ pm}}{212 \text{ pm}}\right) \times 1.748 = -3.83 \times 10^3 \text{ kJ mol}^{-1}$$

**Self-test 18B.4** Which can be expected to have the greater lattice energy, magnesium oxide or strontium oxide?

Answer: MgO

Experimental values of the lattice enthalpy (the enthalpy, rather than the energy) are obtained by using a **Born–Haber cycle**, a closed path of transformations starting and ending at the same point, one step of which is the formation of the solid compound from a gas of widely separated ions.

**Example 18B.2** Using the Born–Haber cycle

Use the Born–Haber cycle to calculate the lattice enthalpy of KCl.

**Method** The Born–Haber cycle for KCl is shown in Fig 18B.14. It consists of the following steps (for convenience, starting at the elements):

	$\Delta H / (\text{kJ mol}^{-1})$	
1. Sublimation of K(s)	+89	[dissociation enthalpy of K(s)]
2. Dissociation of $\frac{1}{2} \text{Cl}_2(\text{g})$	+122	$[\frac{1}{2} \times \text{dissociation enthalpy of } \text{Cl}_2(\text{g})]$
3. Ionization of K(g)	+418	[ionization enthalpy of K(g)]
4. Electron attachment to Cl(g)	−349	[electron gain enthalpy of Cl(g)]
5. Formation of solid from gaseous ions	$-\Delta H_L / (\text{kJ mol}^{-1})$	
6. Decomposition of compound	+437	[negative of enthalpy of formation of KCl(s)]

Because this is a closed cycle, the sum of these enthalpy changes is equal to zero, and the lattice enthalpy can be inferred from the resulting equation.

**Figure 18B.14** The Born–Haber cycle for KCl at 298 K. Enthalpy changes are in kilojoules per mole.

**Answer** The equation associated with the cycle is

$$89 + 122 + 418 - 349 - \Delta H_L / (\text{kJ mol}^{-1}) + 437 = 0$$

It follows that  $\Delta H_L = +717 \text{ kJ mol}^{-1}$ .

**Self-test 18B.5** Calculate the lattice enthalpy of CaO from the following data:

	$\Delta H / (\text{kJ mol}^{-1})$
Sublimation of Ca(s)	+178
Ionization of Ca(g) to $\text{Ca}^{2+}(\text{g})$	+1735
Dissociation of $\text{O}_2(\text{g})$	+249
Electron attachment to O(g)	−141
Electron attachment to $\text{O}^-(\text{g})$	+844
Formation of CaO(s) from Ca(s) and $\text{O}_2(\text{g})$	−635

Answer: +3500 kJ mol<sup>−1</sup>

Some lattice enthalpies obtained by the Born–Haber cycle are listed in Table 18B.4. As can be seen from the data, the trends in values are in general accord with the predictions of the Born–Mayer equation. Agreement is typically taken to imply that the ionic model of bonding is valid for the substance; disagreement

**Table 18B.4\*** Lattice enthalpies at 298 K,  $\Delta H_L / (\text{kJ mol}^{-1})$

NaF	787
NaBr	751
MgO	3850
MgS	3406

\* More values are given in the Resource section.

implies that there is a covalent contribution to the bonding. It is important, though, to be cautious, because numerical agreement might be coincidental.

### 18B.3 Covalent and molecular solids

X-ray diffraction studies of solids reveal a huge amount of information, including interatomic distances, bond angles, stereochemistry, and vibrational parameters. In this section we can do no more than hint at the diversity of types of solids found when molecules pack together or atoms link together in extended networks.

In **covalent solids**, (or *covalent network solids*) covalent bonds in a definite spatial orientation link the atoms in a network extending through the crystal. The demands of directional bonding, which have only a small effect on the structures of many metals, now override the geometrical problem of packing spheres together, and elaborate and extensive structures may be formed.

#### Brief illustration 18B.4 Diamond and graphite

Diamond and graphite are two allotropes of carbon. In diamond each  $sp^3$ -hybridized carbon is bonded tetrahedrally to its four neighbours (Fig. 18B.15). The network of strong C—C bonds is repeated throughout the crystal and, as a result, diamond is very hard (in fact, the hardest known substance). In graphite,  $\sigma$  bonds between  $sp^2$ -hybridized carbon atoms form hexagonal rings which, when repeated throughout a plane, give rise to 'graphene' sheets (Fig. 18B.16). Because the sheets can slide against each other when impurities are present, impure graphite is used widely as a lubricant.

**Self-test 18B.6** Identify the solids that form covalent networks: silicon, boron nitride, red phosphorus, and calcium carbonate.

Answer: Silicon, boron nitride, and red phosphorus are covalent networks; calcium carbonate is an ionic solid

**Figure 18B.15** A fragment of the structure of diamond. Each C atom is tetrahedrally bonded to four neighbours. This framework-like structure results in a rigid crystal.

**Figure 18B.16** Graphite consists of flat planes of hexagons of carbon atoms lying above one another. (a) The arrangement of carbon atoms in a 'graphene' sheet; (b) the relative arrangement of neighbouring sheets. The planes can slide over one another easily when impurities are present.

**Molecular solids**, which are the subject of the overwhelming majority of modern structural determinations, are held together by van der Waals interactions between the individual molecular components (Topic 16B). The observed crystal structure is nature's solution to the problem of condensing objects of various shapes into an aggregate of minimum energy (actually, for  $T > 0$ , of minimum Gibbs energy). The prediction of the structure is difficult, but software specifically designed to

**Figure 18B.17** A fragment of the crystal structure of ice (ice-I). Each O atom is at the centre of a tetrahedron of four O atoms at a distance of 276 pm. The central O atom is attached by two short O—H bonds to two H atoms and by two long hydrogen bonds to the H atoms of two of the neighbouring molecules. Both alternative H atoms locations are shown for each O—O separation. Overall, the structure consists of planes of hexagonal puckered rings of  $H_2O$  molecules (like the chair form of cyclohexane).

explore interaction energies can now make reasonably reliable predictions. The problem is made more complicated by the role of hydrogen bonds, which in some cases dominate the crystal

structure, as in ice (Fig. 18B.17), but in others (for example, in phenol) distort a structure that is determined largely by the van der Waals interactions.

## Checklist of concepts

- 1. The **coordination number** of an atom in a metal is the number of its nearest neighbours.
- 2. Many elemental metals have **close-packed structures** with coordination number 12.
- 3. Close-packed structures may be either cubic (ccp) or hexagonal (hcp).
- 4. The **packing fraction** is the fraction of space occupied by spheres in a crystal.
- 5. Electrons in metals occupy molecular orbitals formed from the overlap of atomic orbitals.
- 6. The **Fermi level** is the highest occupied molecular orbital at  $T=0$ .
- 7. Representative ionic structures include the caesium chloride, rock salt, and zinc blende structures.
- 8. The **coordination number of an ionic lattice** is denoted  $(N_+, N_-)$ , with  $N_+$  the number of nearest neighbour anions around a cation and  $N_-$  the number of nearest neighbour cations around an anion.
- 9. The **radius ratio** (see below) is a guide to the likely lattice type.
- 10. The **lattice enthalpy** is the change in enthalpy (per mole of formula units) accompanying the complete separation of the components of the solid.
- 11. A **Born–Haber cycle** is a closed path of transformations starting and ending at the same point, one step of which is the formation of the solid compound from a gas of widely separated ions.
- 12. A covalent network solid is a solid in which covalent bonds in a definite spatial orientation link the atoms in a network extending through the crystal.
- 13. A molecular solid is a solid consisting of discrete molecules held together by van der Waals interactions.

## Checklist of equations

Property	Equation	Comment	Equation number
Energy levels of a linear array of orbitals	$E_k = \alpha + 2\beta \cos(k\pi/(N+1)), k=1,2,\dots,N$	Hückel approximation	18B.1
Band width	$E_N - E_1 \rightarrow -4\beta$ as $N \rightarrow \infty$	Hückel approximation	18B.2
Radius ratio	$\gamma = r_{\text{smaller}}/r_{\text{larger}}$	For criteria, see Section 18B.2.	18B.3
Born–Mayer equation	$E_{\text{p,min}} = -\{N_A  z_A z_B  e^2 / 4\pi\epsilon_0 d\} (1 - d^*/d) A$	$A$ is the Madelung constant	18B.6

### ► Why do you need to know this material?

Careful consideration and manipulation of the physical properties of solids are needed for the development of modern materials and an understanding of their properties.

### ► What is the key idea?

The mechanical, electrical, and magnetic properties of solids stem from the properties of their constituent atoms and how they stack together.

### ► What do you need to know already?

You need to be familiar with electromagnetic fields (*Foundations C*), atomic structure (Topics 9A and 9B), and

bonding arrangements in solids (Topic 18B), especially the formation of bands of orbitals. This Topic draws a little on the properties of the Boltzmann distribution (*Foundations B* and Topic 15A).

This Topic addresses the mechanical, electrical, and magnetic properties of solids. Optical properties are covered in Topic 18D.

## 18C.1 Mechanical properties

The fundamental concepts for the discussion of the mechanical properties of solids are stress and strain. The **stress** on an object is the applied force divided by the area to which it is applied. The **strain** is the resulting fractional distortion of the sample. The general field of the relations between stress and strain is called **rheology** from the Greek word for 'flow'.

Stress may be applied in a number of different ways (Fig. 18C.1):

- **Uniaxial stress** is a simple compression or extension in one direction.
- **Hydrostatic stress** is a stress applied simultaneously in all directions, as in a body immersed in a fluid.
- **Pure shear** is a stress that tends to push opposite faces of the sample in opposite directions.

Figure 18C.1 Types of stress applied to a body. (a) Uniaxial stress, (b) shear stress, (c) hydrostatic pressure.

A sample subjected to a small stress typically undergoes **elastic deformation** in the sense that it recovers its original shape when the stress is removed. For low stresses, the strain is linearly proportional to the stress, and the stress–strain relation is a Hooke’s law of force (as depicted in Fig. 17B.2 and reproduced here as Fig. 18C.2). The response becomes nonlinear at high stresses but may remain elastic. Above a certain threshold, the strain becomes **plastic** in the sense that recovery does not occur when the stress is removed. Plastic deformation occurs when bond breaking takes place and, in pure metals, typically takes place through the agency of dislocations. Brittle solids, such as ionic solids, exhibit sudden fracture as the stress focused by cracks causes them to spread catastrophically.

The response of a solid to an applied stress is commonly summarized by a number of coefficients of proportionality known as **moduli**:

$$E = \frac{\text{normal stress}}{\text{normal strain}} \quad \text{Definition} \quad \text{Young's modulus} \quad (18C.1a)$$

$$K = \frac{\text{pressure}}{\text{fractional change in volume}} \quad \text{Definition} \quad \text{Bulk modulus} \quad (18C.1b)$$

$$G = \frac{\text{shear stress}}{\text{shear strain}} \quad \text{Definition} \quad \text{Shear modulus} \quad (18C.1c)$$

‘Normal stress’ refers to stretching and compression of the material, as shown in Fig. 18C.3a, and ‘shear stress’ refers to the stress depicted in Fig. 18C.3b. The fractional change in volume is  $\delta V/V$ , where  $\delta V$  is the change in volume of a sample of volume  $V$ ; similarly, the strains are (dimensionless) fractional changes in dimensions. The bulk modulus is the inverse of the isothermal compressibility,  $\kappa$ , first encountered in Topic

**Figure 18C.2** At small strains, a body obeys Hooke’s law (stress proportional to strain) and is elastic (recovers its shape when the stress is removed). At high strains, the body is no longer elastic, may yield and become plastic. At even higher strains, the solid fails (at its limiting tensile strength) and finally fractures.

**Figure 18C.3** (a) Normal stress and the resulting strain. (b) Shear stress. Poisson’s ratio indicates the extent to which a body changes shape when subjected to a uniaxial stress.

2D (eqn 2D.7,  $\kappa = -(\partial V/\partial p)_T/V$ ). A third ratio, called **Poisson’s ratio**, indicates how the sample changes its shape:

$$\nu_p = \frac{\text{transverse strain}}{\text{normal strain}} \quad \text{Definition} \quad \text{Poisson's ratio} \quad (18C.2)$$

The moduli are interrelated (see Problem 18C.1):

$$G = \frac{E}{2(1+\nu_p)} \quad K = \frac{E}{3(1-2\nu_p)} \quad \text{Relations between moduli} \quad (18C.3)$$

#### Brief illustration 18C.1 Young’s modulus

Young’s modulus for iron at room temperature is 215 GPa. The normal strain produced when a mass of  $m = 10.0$  kg is suspended from an iron wire of diameter  $d = 0.10$  mm is

$$\text{normal strain} = \frac{\text{normal stress}}{E}$$

where the normal stress is the force  $F$  on the wire divided by the area on which the force acts. This area is  $\pi(d/2)^2$ , the area at the base of the cylindrical wire. The force is  $mg$ , where  $g$  is the acceleration of free fall. It follows that

$$\begin{aligned} \text{normal strain} &= \frac{\overbrace{mg}^F / \overbrace{\pi(d/2)^2}^A}{E} \\ &= \frac{(10.0 \text{ kg}) \times \frac{9.81 \text{ m s}^{-2}}{\underbrace{\pi(5.0 \times 10^{-5} \text{ m})^2}_{\text{Pa}}}}{2.15 \times 10^{11} \text{ kg m}^{-1} \text{ s}^{-2}} \\ &= 0.058 \end{aligned}$$

which corresponds to elongation of the wire by 5.8 per cent.

**Self-test 18C.1** Young’s modulus for polyethene at room temperature is 1.2 GPa. What strain will be produced when a mass of 1.0 kg is suspended from a polyethene thread of diameter 1.0 mm?

Answer: 0.010

We can use thermodynamic arguments to discover the relation of the moduli to the molecular properties of the solid. Thus, in the following *Justification*, we show that, if neighbouring molecules interact by a Lennard-Jones potential energy (Topic 16B), then the bulk modulus and the compressibility of the solid are related to the Lennard-Jones parameter  $\varepsilon$  (the depth of the potential well) by

$$K = \frac{8N_A \varepsilon}{V_m} \quad \kappa = \frac{V_m}{8N_A \varepsilon} \quad (18C.4)$$

We see that the bulk modulus is large (the solid stiff) if the potential well represented by the Lennard-Jones potential energy is deep and the solid is dense (its molar volume small).

### Justification 18C.1 The relation between compressibility and molecular interactions

First, we combine the relations  $K = 1/\kappa$  and  $\kappa = -(\partial V/\partial p)_T/V$  with the thermodynamic relation  $p = -(\partial U/\partial V)_T$  (this is eqn 3D.3 of Topic 3D), to obtain

$$K = -V \left( \frac{\partial p}{\partial V} \right)_T = V \left( \frac{\partial^2 U}{\partial V^2} \right)_T$$

This expression shows that the bulk modulus (and through eqn 18C.3, the other two moduli) depends on the curvature of a plot of the internal energy against volume. To develop this conclusion, we note that the variation of internal energy with volume can be expressed in terms of its variation with a lattice parameter,  $R$ , such as the length of the side of a unit cell:

$$\frac{\partial U}{\partial V} = \frac{\partial U}{\partial R} \frac{\partial R}{\partial V}$$

and so

$$\begin{aligned} \frac{\partial^2 U}{\partial V^2} &= \frac{\partial U}{\partial R} \left( \frac{\partial^2 R}{\partial V^2} \right) + \left( \frac{\partial^2 U}{\partial V \partial R} \right) \frac{\partial R}{\partial V} \\ &\stackrel{\text{red}}{=} \left( \frac{\partial^2 U}{\partial R^2} \right) \left( \frac{\partial R}{\partial V} \right)^2 \\ &\stackrel{\text{blue}}{=} \frac{\partial U}{\partial R} \left( \frac{\partial^2 R}{\partial V^2} \right) + \frac{\partial^2 U}{\partial R^2} \left( \frac{\partial R}{\partial V} \right)^2 \end{aligned}$$

To calculate  $K$  at the equilibrium volume of the sample, we set  $R = R_0$  and recognize that  $\partial U/\partial R = 0$  at equilibrium, so the first (blue) term on the right disappears and we are left with

$$K = V \left( \frac{\partial^2 U}{\partial R^2} \right)_{T,0} \left( \frac{\partial R}{\partial V} \right)_{T,0}^2$$

where the 0 denotes that the derivatives are evaluated at the equilibrium dimensions of the unit cell by setting  $R = R_0$  after the derivative has been calculated. At this point we can write  $V = aR^3$ , where  $a$  is a constant that depends on the crystal structure, which implies that  $\partial R/\partial V = 1/3aR^2$ . Then, if the internal

energy is given by a pairwise Lennard-Jones (12,6)-potential energy, eqn 16B.14 of Topic 16B in the form  $U = nN_A E_p$ , with  $E_p = 4\varepsilon\{(R_0/R)^{12} - (R_0/R)^6\}$ , we can write

$$\left( \frac{\partial^2 U}{\partial R^2} \right)_{T,0} = \frac{72nN_A \varepsilon}{R_0^2}$$

where  $n$  is the amount of substance in the sample of volume  $V_0$ . It then follows that

$$K = \frac{72nN_A \varepsilon}{9aR^3} = \frac{8nN_A \varepsilon}{V_0} = \frac{8N_A \varepsilon}{V_m}$$

where we have used  $V_m = V_0/n$ , which is the first of eqn 18C.4. The reciprocal of  $K$  is  $\kappa$ . To obtain the expression for  $(\partial^2 U/\partial R^2)_{T,0}$ , we have used the fact that, at equilibrium,  $R = R_0$  and  $\sigma^6/R_0^6 = \frac{1}{2}$  where  $\sigma$  is the scale parameter for the intermolecular potential energy ( $R_0$  in the expression for  $E_p$ ).

The differing rheological characteristics of metals can be traced to the presence of **slip planes**, which are planes of atoms that under stress may slip or slide relative to one another. The slip planes of a ccp structure are the close-packed planes, and careful inspection of a unit cell shows that there are eight sets of slip planes in different directions. As a result, metals with cubic close-packed structures, like copper, are malleable: they can easily be bent, flattened, or pounded into shape. In contrast, a hexagonal close-packed structure has only one set of slip planes; and metals with hexagonal close packing, like zinc or cadmium, tend to be brittle.

## 18C.2 Electrical properties

We confine attention to electronic conductivity, but note that some ionic solids display ionic conductivity in which complete ions migrate through the lattice. Two types of solid are distinguished by the temperature dependence of their electrical conductivity (Fig. 18C.4):

- A **metallic conductor** is a substance with a conductivity that decreases as the temperature is raised.
- A **semiconductor** is a substance with a conductivity that increases as the temperature is raised.

A semiconductor generally has a lower conductivity than that typical of metals, but the magnitude of the conductivity is not the criterion of the distinction. It is conventional to classify semiconductors with very low electrical conductivities, such as most synthetic polymers, as **insulators**. We shall use this term, but it should be appreciated that it is one of convenience rather than one of fundamental significance. A **superconductor** is a solid that conducts electricity without resistance.

**Figure 18C.4** The variation of the electrical conductivity of a substance with temperature is the basis of its classification as a metallic conductor, a semiconductor, or a superconductor. Conductivity is expressed in siemens per metre ( $\text{S m}^{-1}$  or, as here,  $\text{S cm}^{-1}$ ), where  $1 \text{ S} = 1 \Omega^{-1}$  (the resistance is expressed in ohms,  $\Omega$ ).

### (a) Conductors

To understand the origins of electronic conductivity in conductors and semiconductors, we need to explore the consequences of the formation of bands in different materials (Topic 18B). Our starting point is Fig 18B.8, which is repeated here for convenience (Fig. 18C.5). It shows the electronic structure of a solid formed from atoms each able to contribute one electron (such as the alkali metals). At  $T=0$ , only the lowest  $\frac{1}{2}N$  molecular orbitals are occupied, up to the Fermi level.

At temperatures above absolute zero, electrons are excited by the thermal motion of the atoms. The electrical conductivity of a metallic conductor decreases with increasing temperature even though more electrons are excited into empty orbitals. This apparent paradox is resolved by noting that the increase in temperature causes more vigorous thermal motion of the atoms, so collisions between the moving electrons and an atom are more likely. That is, the electrons are scattered out of their paths through the solid, and are less efficient at transporting charge.

**Figure 18C.5** When  $N$  electrons occupy a band of  $N$  orbitals, it is only half full and the electrons near the Fermi level (the top of the filled levels) are mobile.

A more quantitative treatment of conductivity in metals requires an expression for the variation with temperature of the distribution of electrons over the available states. We begin by considering the density of states,  $\rho(E)$ , at the energy  $E$ : the number of states between  $E$  and  $E + dE$  divided by  $dE$ . Note that the 'state' of an electron includes its spin, so each spatial orbital counts as two states. Then it follows that  $\rho(E)dE$  is the number of states between  $E$  and  $E + dE$ . To obtain the number of electrons  $dN(E)$  that occupy states between  $E$  and  $E + dE$ , we multiply  $\rho(E)dE$  by the probability  $f(E)$  of occupation of the state with energy  $E$ . That is,

$$dN(E) = \overbrace{\rho(E)dE}^{\text{Number of states between } E \text{ and } E+dE} \times \overbrace{f(E)}^{\text{Probability of occupation of a state with energy } E} \quad (18C.5)$$

The function  $f(E)$  is the **Fermi–Dirac distribution**, a version of the Boltzmann distribution that takes into account the Pauli exclusion principle that each orbital can be occupied by no more than two electrons (Fig. 18C.6):

$$f(E) = \frac{1}{e^{(E-\mu)/kT} + 1} \quad \text{Fermi–Dirac distribution} \quad (18C.6a)$$

where  $\mu$  is a temperature-dependent parameter known as the 'chemical potential' (it has a subtle relation to the familiar chemical potential of thermodynamics), and provided  $T > 0$  is the energy of the state for which  $f = \frac{1}{2}$ . At  $T=0$ , only states up to a certain energy known as the **Fermi energy**,  $E_F$ , are occupied (Fig. 18C.5). Provided the temperature is not so high that many electrons are excited to states above the Fermi energy, the chemical potential can be identified with  $E_F$ , in which case the Fermi–Dirac distribution becomes

**Figure 18C.6** The Fermi–Dirac distribution, which gives the probability of occupation of the state at a temperature  $T$ . The high-energy tail decays exponentially towards zero. The curves are labelled with the value of  $\mu/kT$ . The tinted region shows the occupation of levels at  $T=0$ .

$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1} \quad \text{Fermi-Dirac distribution} \quad (18C.6b)$$

Moreover, for energies well above  $E_F$ , the exponential term in the denominator is so large that the 1 in the denominator can be neglected, and then

$$f(E) \approx e^{-(E-E_F)/kT} \quad \text{Approximate form for } E > E_F \quad \text{Fermi-Dirac distribution} \quad (18C.6c)$$

The function now resembles a Boltzmann distribution, decaying exponentially with increasing energy; the higher the temperature, the longer the exponential tail.

There is a distinction between the Fermi energy and the Fermi level. First, note that if  $E = E_F$ , then from eqn 18C.6b,  $f(E_F) = \frac{1}{2}$ . That is:

- The Fermi level is the uppermost occupied level at  $T = 0$ .
- The Fermi energy is the energy level at which  $f(E) = \frac{1}{2}$  at any temperature.

The Fermi energy coincides with the Fermi level as  $T \rightarrow 0$ .

#### Brief illustration 18C.2 The Fermi-Dirac distribution at $T = 0$

Consider cases in which  $E < E_F$ . Then, as  $T \rightarrow 0$  we write

$$\lim_{T \rightarrow 0} \{E - E_F\} / kT = -\infty$$

because  $E_F > 0$  and  $E - E_F < 0$ . It follows that

$$\lim_{T \rightarrow 0} f(E) = \lim_{T \rightarrow 0} \frac{1}{\underbrace{e^{(E-E_F)/kT}}_{\rightarrow 0} + 1} = 1$$

We conclude that as  $T \rightarrow 0$ ,  $f(E) \rightarrow 1$ , and all the energy levels below  $E = E_F$  are populated. A similar calculation for  $E > E_F$  (Self-test 18C.2) shows that  $f(E) \rightarrow 0$  as  $T \rightarrow 0$ . The Fermi-Dirac distribution function confirms that only the levels below  $E_F$  are populated as  $T \rightarrow 0$ .

**Self-test 18C.2** Repeat the calculation for  $E > E_F$ .

Answer:  $f(E) \rightarrow 0$  as  $T \rightarrow 0$

### (b) Insulators and semiconductors

Now consider a one-dimensional solid in which each atom provides two electrons: the  $2N$  electrons fill the  $N$  orbitals of the band. The Fermi level now lies at the top of the band (at  $T = 0$ ), and there is a gap before the next band begins (Fig. 18C.7). As the temperature is increased, the tail of the Fermi-Dirac distribution extends across the gap, and electrons leave the lower band, which is called the **valence band** and populate the empty orbitals of the upper band, which is called the **conduction**

**Figure 18C.7** (a) When  $2N$  electrons are present, the band is full and the material is an insulator at  $T = 0$ . (b) At temperatures above  $T = 0$ , electrons populate the levels of the upper conduction band and the solid is a semiconductor.

**band.** As a consequence of electron promotion, positively charged ‘holes’ are left in the valence band. The holes and promoted electrons are now mobile, and the material is now a conductor. In fact, we call it a semiconductor, because the electrical conductivity depends on the number of electrons that are promoted across the gap, and that number increases as the temperature is raised. If the gap is large, though, very few electrons are promoted at ordinary temperatures and the conductivity remains close to zero, resulting in an insulator. Thus, the conventional distinction between an insulator and a semiconductor is related to the size of the band gap and is not an absolute distinction like that between a metal (incomplete bands at  $T = 0$ ) and a semiconductor (full bands at  $T = 0$ ).

Figure 18C.7 depicts conduction in an **intrinsic semiconductor**, in which semiconduction is a property of the band structure of the pure material. Examples of intrinsic semiconductors include silicon and germanium. A **compound semiconductor** is an intrinsic semiconductor that is a combination of different elements, such as GaN, CdS, and many d-metal oxides. An **extrinsic semiconductor** is one in which charge carriers are present as a result of the replacement of some atoms (to the extent of about 1 in  $10^9$ ) by **dopant** atoms, the atoms of another element. If the dopants can trap electrons, they withdraw electrons from the filled band, leaving holes which allow the remaining electrons to move (Fig. 18C.8a). This procedure gives rise to **p-type semiconductivity**, the p indicating that the holes are positive relative to the electrons in the band. An example is silicon doped with indium. We can picture the semiconduction as arising from the transfer of an electron from a Si atom to a neighbouring In atom. The electrons at the top of the silicon valence band are now mobile, and carry current through the solid. Alternatively, a dopant might carry excess electrons (for example, phosphorus atoms introduced into germanium), and these additional electrons occupy otherwise empty bands, giving **n-type semiconductivity**, where n denotes the negative charge of the carriers (Fig. 18C.8b).

**Figure 18C.8** (a) A dopant with fewer electrons than its host can form a narrow band that accepts electrons from the valence band. The holes in the band are mobile and the substance is a p-type semiconductor. (b) A dopant with more electrons than its host forms a narrow band that can supply electrons to the conduction band. The electrons it supplies are mobile and the substance is an n-type semiconductor.

### Brief illustration 18C.3 The effect of doping on semiconductivity

Consider the doping of pure silicon (a Group 14 element) by arsenic (a Group 15 element). Because each Si atom has four valence electrons and each As atom has five valence electrons, the addition of arsenic increases the number of electrons in the solid. These electrons populate the empty conduction band of silicon, and the doped material is an n-type semiconductor.

**Self-test 18C.3** Is gallium-doped germanium a p-type or an n-type semiconductor?

Answer: p-type semiconductor

Now consider the properties of a **p–n junction**, the interface of a p-type and an n-type semiconductor. When a ‘reverse bias’ is applied to the junction, in the sense that a negative electrode is attached to the p-type semiconductor and a positive electrode is attached to the n-type semiconductor, the positively charged holes in the p-type semiconductor are attracted to the negative electrode and the negatively charged electrons in the n-type semiconductor are attracted to the positive electrode (Fig. 18C.9a). As a consequence, charge does not flow across the junction. Now consider the application of a ‘forward bias’ to the junction, in the sense that the positive electrode is attached to the p-type semiconductor and the negative electrode is attached to the n-type semiconductor (Fig. 18C.9b). Now charge flows across the junction, with electrons in the n-type semiconductor moving towards the positive electrode and holes moving in the opposite direction. It follows that a p–n junction affords a great deal of control over the magnitude and direction of current through a material. This control is essential for the operation

**Figure 18C.9** A p–n junction under (a) reverse bias, (b) forward bias.

of transistors and diodes, which are key components of modern electronic devices.

As electrons and holes move across a p–n junction under forward bias, they recombine and release energy. However, as long as the forward bias continues to be applied, the flow of charge from the electrodes to the semiconductors replenishes them with electrons and holes, so the junction sustains a current. In some solids, the energy of electron–hole recombination is released as heat and the device becomes warm. The reason lies in the fact that the return of the electron to a hole involves a change in the electron’s linear momentum. The atoms of the lattice must absorb the difference, and therefore electron–hole recombination stimulates lattice vibrations. This is the case for silicon semiconductors, and is one reason why computers need efficient cooling systems.

### (c) Superconductivity

The resistance to flow of electrical current of a normal metallic conductor decreases smoothly with decreasing temperature but never vanishes. However, certain solids known as **superconductors** conduct electricity without resistance below a critical temperature,  $T_c$ . Following the discovery in 1911 that mercury is a superconductor below 4.2 K, the normal boiling point of liquid helium, physicists and chemists made slow but steady progress in the discovery of superconductors with higher values of  $T_c$ . Metals, such as tungsten, mercury, and lead, tend to have  $T_c$  values below about 10 K. Intermetallic compounds, such as  $Nb_3X$  ( $X = Sn, Al, \text{ or } Ge$ ), and alloys, such as Nb/Ti and Nb/Zr, have intermediate  $T_c$  values ranging between 10 K and 23 K. In 1986, **high-temperature superconductors** (HTSC) were discovered. Several *ceramics*, inorganic powders that have been fused and hardened by heating to a high temperature, containing oxocuprate motifs,  $Cu_mO_n$ , are now known with  $T_c$  values well above 77 K, the boiling point of the inexpensive refrigerant liquid nitrogen. For example,  $HgBa_2Ca_2Cu_2O_8$  has  $T_c = 153$  K.

There is a degree of periodicity in the elements that exhibit superconductivity. The metals iron, cobalt, nickel, copper, silver, and gold do not display superconductivity; nor do the alkali metals. One of the most widely studied oxocuprate superconductors  $YBa_2Cu_3O_7$  (informally known as ‘123’ on account of

**Figure 18C.10** Structure of the  $\text{YBa}_2\text{Cu}_3\text{O}_7$  superconductor. (a) Metal atom positions. (b) The polyhedra show the positions of oxygen atoms and indicate that the metal ions are in square-planar and square-pyramidal coordination environments.

the proportions of the metal atoms in the compound) has the structure shown in Fig. 18C.10. The square-pyramidal  $\text{CuO}_5$  units arranged as two-dimensional layers and the square planar  $\text{CuO}_4$  units arranged in sheets are common structural features of oxocuprate HTSCs.

The mechanism of superconduction is well-understood for low-temperature materials, and is based on the properties of a **Cooper pair**, a pair of electrons that exists on account of the indirect electron–electron interactions mediated by the nuclei of the atoms in the lattice. Thus, if one electron is in a particular region of a solid, the nuclei there move toward it to give a distorted local structure (Fig. 18C.11). Because that local distortion is rich in positive charge, it is favourable for a second electron to join the first. Hence, there is a virtual attraction between the two electrons and they move together as a pair. The local distortion is disrupted by thermal motion of the ions in the solid, so the virtual attraction occurs only at very low temperatures. A Cooper pair undergoes less scattering than an individual electron as it travels through the solid

**Figure 18C.11** The formation of a Cooper pair. One electron distorts the crystal lattice and the second electron has a lower energy if it goes to that region. These electron–lattice interactions effectively bind the two electrons into a pair.

because the distortion caused by one electron can attract back the other electron should it be scattered out of its path in a collision. Because the Cooper pair is stable against scattering, it can carry charge freely through the solid, and hence give rise to superconduction.

The Cooper pairs responsible for low-temperature superconductivity are likely to be important in HTSCs, but the mechanism for pairing is hotly debated. There is evidence implicating the arrangement of  $\text{CuO}_5$  layers and  $\text{CuO}_4$  sheets in the mechanism of high-temperature superconduction. It is believed that movement of electrons along the linked  $\text{CuO}_4$  units accounts for superconductivity, whereas the linked  $\text{CuO}_5$  units act as ‘charge reservoirs’ that maintain an appropriate number of electrons in the superconducting layers.

### 18C.3 Magnetic properties

The magnetic properties of metallic solids and semiconductors depend strongly on the band structures of the material. Here we confine our attention largely to magnetic properties that stem from collections of individual molecules or ions such as d-metal complexes. Much of the discussion applies to liquid and gas phase samples as well as to solids.

#### (a) Magnetic susceptibility

The magnetic and electric properties of molecules and solids are analogous. For instance, some molecules possess permanent magnetic dipole moments, and an applied magnetic field can induce a magnetic moment, with the result that the entire solid sample becomes magnetized. The **magnetization**,  $\mathcal{M}$ , is the average molecular magnetic dipole moment multiplied by the number density of molecules in the sample. The magnetization induced by a field of strength  $\mathcal{H}$  is proportional to  $\mathcal{H}$ , and we write

$$\mathcal{M} = \chi \mathcal{H} \quad \text{Magnetization} \quad (18C.7)$$

where  $\chi$  is the dimensionless **volume magnetic susceptibility**. A closely related quantity is the **molar magnetic susceptibility**,  $\chi_m$ :

$$\chi_m = \chi V_m \quad \text{Molar magnetic susceptibility} \quad (18C.8)$$

where  $V_m$  is the molar volume of the substance.

We can think of the magnetization as contributing to the density of lines of force in the material (Fig. 18C.12). Materials for which  $\chi > 0$  are called **paramagnetic**; they tend to move into a magnetic field and the density of lines of force within them is greater than in a vacuum. Those for which  $\chi < 0$  are called **diamagnetic** and tend to move out of a magnetic field; the density

**Figure 18C.12** (a) In a vacuum, the strength of a magnetic field can be represented by the density of lines of force; (b) in a diamagnetic material, the lines of force are reduced; (c) in a paramagnetic material, the lines of force are increased.

of lines of force within them is lower than in a vacuum. A paramagnetic material consists of ions or molecules with unpaired electrons, such as radicals and many d-metal complexes; a diamagnetic substance (a far more common property) is one with no unpaired electrons.

#### Brief illustration 18C.4 The magnetic character of metallic solids and molecules

Solid magnesium is a metal in which the two valence electrons of each Mg atom are donated to a band of orbitals constructed from 3s orbitals. From  $N$  atomic orbitals we can construct  $N$  molecular orbitals spreading through the metal. Each atom supplies two electrons, so there are  $2N$  electrons to accommodate. These occupy and fill the  $N$  molecular orbitals. There are no unpaired electrons, so the metal is diamagnetic. An  $O_2$  molecule has the electronic structure described in Topic 10C, where we see that two electrons occupy separate antibonding  $\pi$  orbitals with parallel spins. We conclude that  $O_2$  is a paramagnetic gas.

**Self-test 18C.4** Repeat the analysis for Zn(s) and NO(g).

Answer: Zn diamagnetic, NO paramagnetic

The magnetic susceptibility is traditionally measured with a **Gouy balance**. This instrument consists of a sensitive balance from which the sample hangs in the form of a narrow cylinder and lies between the poles of a magnet. If the sample is paramagnetic, it is drawn into the field, and its apparent weight is greater than when the field is off. A diamagnetic sample tends to be expelled from the field and appears to weigh less when the field is turned on. The balance is normally calibrated against a sample of known susceptibility. The modern version of the determination makes use of a **superconducting quantum interference device** (SQUID, Fig. 18C.13). A SQUID takes advantage of the quantization of magnetic flux and the property of current loops in superconductors that, as part of the circuit, include a weakly conducting link through which electrons must tunnel. The current that flows in the loop in a magnetic field depends on the value of the magnetic flux, and a SQUID can be exploited as a very sensitive magnetometer. Table 18C.1 lists some experimental values.

**Figure 18C.13** The arrangement used to measure magnetic susceptibility with a SQUID. The sample is moved upwards in small increments and the potential difference across the SQUID is measured.

### (b) Permanent and induced magnetic moments

The permanent magnetic moment of a molecule arises from any unpaired electron spins in the molecule. The magnitude of the magnetic moment of an electron is proportional to the magnitude of the spin angular momentum,  $\{s(s+1)\}^{1/2}\hbar$ :

$$m = g_e \{s(s+1)\}^{1/2} \mu_B \quad \mu_B = \frac{e\hbar}{2m_e} \quad \text{Magnitude of Magnetic moment} \quad (18C.9)$$

where  $g_e = 2.0023$  and  $\mu_B$ , the Bohr magneton, has the value  $9.274 \times 10^{-24} \text{ J T}^{-1}$ . If there are several electron spins in each molecule, they combine to give a total spin  $S$ , and then  $s(s+1)$  should be replaced by  $S(S+1)$ .

The magnetization and consequently the magnetic susceptibility depend on the temperature because the orientations of the electron spins fluctuate, whether the molecules are in fluid phases or trapped in solids: some orientations have lower energy than others, and the magnetization depends on the randomizing influence of thermal motion. Thermal averaging of the permanent magnetic moments in the presence of an applied magnetic field contributes to the magnetic susceptibility an amount proportional to  $m^2/3kT$ .<sup>1</sup> It follows that the spin contribution to the molar magnetic susceptibility is

**Table 18C.1\*** Magnetic susceptibilities at 298 K

	$\chi/10^{-6}$	$\chi_m/(10^{-10} \text{ m}^3 \text{ mol}^{-1})$
$H_2O(l)$	-9.02	-1.63
$NaCl(s)$	-16	-3.8
$Cu(s)$	-9.7	-0.69
$CuSO_4 \cdot 5H_2O(s)$	+167	+183

\* More values are given in the *Resource section*.

<sup>1</sup> See our *Physical chemistry: Quanta, matter, and change* (2014) for the derivation of this contribution.

$$\chi_m = \frac{N_A g_e^2 \mu_0 \mu_B^2 S(S+1)}{3kT} \quad \begin{array}{l} \text{Spin} \\ \text{contribution} \end{array} \quad \begin{array}{l} \text{Molar magnetic} \\ \text{susceptibility} \end{array} \quad (18C.10a)$$

The susceptibility is positive, so the spin magnetic moments contribute to the paramagnetic susceptibilities of materials. This expression may also be written as the **Curie law**:

$$\chi_m = \frac{C}{T} \quad C = \frac{N_A g_e^2 \mu_0 \mu_B^2 S(S+1)}{3k} \quad \text{Curie law} \quad (18C.10b)$$

The spin contribution to the susceptibility decreases with increasing temperature because the thermal motion randomizes the spin orientations. In practice, a contribution to the paramagnetism also arises from the orbital angular momenta of electrons: we have discussed the spin-only contribution.

### Example 18C.1 Calculating a molar magnetic susceptibility

Consider a complex salt with three unpaired electrons per complex cation at 298 K and molar volume  $61.7 \text{ cm}^3 \text{ mol}^{-1}$ . Calculate the molar magnetic susceptibility and the volume magnetic susceptibility of the complex.

**Method** Use the data and eqn 18C.10 to calculate the molar magnetic susceptibility. Then use the values of  $\chi_m$  and  $V_m$ , and eqn 18C.8 to calculate the volume magnetic susceptibility.

**Answer** First note that the constants can be collected into the term:

$$\frac{N_A g_e^2 \mu_0 \mu_B^2}{3k} = 6.3001 \times 10^{-6} \text{ m}^3 \text{ K}^{-1} \text{ mol}^{-1}$$

Consequently eqn 18C.10 becomes

$$\chi_m = 6.3001 \times 10^{-6} \times \frac{S(S+1)}{T/\text{K}} \text{ m}^3 \text{ mol}^{-1}$$

Substitution of the data with  $S = \frac{3}{2}$  gives

$$\chi_m = 6.3001 \times 10^{-6} \times \frac{\frac{3}{2}(\frac{3}{2}+1)}{298} \text{ m}^3 \text{ mol}^{-1} = 7.93 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}$$

It follows from eqn 18C.8 that, to obtain the volume magnetic susceptibility, the molar susceptibility is divided by the molar volume  $V_m = 61.7 \text{ cm}^3 \text{ mol}^{-1} = 6.17 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}$  and

$$\chi = \frac{\chi_m}{V_m} = \frac{7.93 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}}{6.17 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}} = 1.29 \times 10^{-3}$$

**Self-test 18C.5** Repeat the calculation for a complex with five unpaired electrons, molar mass  $322.4 \text{ g mol}^{-1}$ , and a mass density of  $2.87 \text{ g cm}^{-3}$  at 273 K.

Answer:  $\chi_m = 2.02 \times 10^{-7} \text{ m}^3 \text{ mol}^{-1}$ ;  $\chi = 1.79 \times 10^{-3}$

At low temperatures, some paramagnetic solids make a phase transition to a state in which large domains of spins align with parallel orientations. This cooperative alignment gives rise to a very strong magnetization and is called **ferromagnetism** (Fig. 18C.14). In other cases, exchange interactions lead to alternating spin orientations: the spins are locked into a low-magnetization arrangement to give an **antiferromagnetic phase**. The ferromagnetic phase has a nonzero magnetization in the absence of an applied field, but the antiferromagnetic phase has a zero magnetization because the spin magnetic moments cancel. The ferromagnetic transition occurs at the **Curie temperature**, and the antiferromagnetic transition occurs at the **Néel temperature**. Which type of cooperative behaviour occurs depends on the details of the band structure of the solid.

Magnetic moments can also be induced in molecules. To see how this effect arises, we need to note that the circulation of electronic currents induced by an applied field gives rise to a magnetic field which usually opposes the applied field, so the substance is diamagnetic. In these cases, the induced electron currents occur within the orbitals of the molecule that are occupied in its ground state. In the few cases in which molecules are paramagnetic despite having no unpaired electrons, the induced electron currents flow in the opposite direction because they can make use of unoccupied orbitals that lie close to the HOMO in energy. This orbital paramagnetism can be distinguished from spin paramagnetism by the fact that it is temperature independent: this is why it is called **temperature-independent paramagnetism (TIP)**.

We can summarize these remarks as follows. All molecules have a diamagnetic component to their susceptibility, but it is dominated by spin paramagnetism if the molecules have unpaired electrons. In a few cases (where there are low-lying excited states) TIP is strong enough to make the molecules paramagnetic even though their electrons are paired.

**Figure 18C.14** (a) In a paramagnetic material, the electron spins are aligned at random in the absence of an applied magnetic field. (b) In a ferromagnetic material, the electron spins are locked into a parallel alignment over large domains. (c) In an antiferromagnetic material, the electron spins are locked into an antiparallel arrangement. The latter two arrangements survive even in the absence of an applied field.

### (c) Magnetic properties of superconductors

Superconductors have unique magnetic properties. Some superconductors, classed as *Type I*, show abrupt loss of superconductivity when an applied magnetic field exceeds a critical value  $\mathcal{H}_c$  characteristic of the material. It is observed that the value of  $\mathcal{H}_c$  depends on temperature and  $T_c$  as

$$\mathcal{H}_c(T) = \mathcal{H}_c(0) \left( 1 - \frac{T^2}{T_c^2} \right) \quad \text{Dependence of } \mathcal{H}_c \text{ on } T_c \quad (18C.11)$$

where  $\mathcal{H}_c(0)$  is the value of  $\mathcal{H}_c$  as  $T \rightarrow 0$ .

#### Example 18C.2 Calculating the temperature at which a material becomes superconducting

Lead has  $T_c = 7.19 \text{ K}$  and  $\mathcal{H}_c(0) = 63.9 \text{ kA m}^{-1}$ . At what temperature does lead become superconducting in a magnetic field of strength  $20 \text{ kA m}^{-1}$ ?

**Method** Rearrange eqn 18C.11 and use the data to calculate the temperature at which the substance becomes superconducting.

**Answer** Rearrangement of eqn 18C.11 gives

$$T = T_c \left( 1 - \frac{\mathcal{H}_c(T)}{\mathcal{H}_c(0)} \right)^{1/2}$$

and substitution of the data gives

$$T = 7.19 \text{ K} \times \left( 1 - \frac{20 \text{ kA m}^{-1}}{63.9 \text{ kA m}^{-1}} \right)^{1/2} = 6.0 \text{ K}$$

We conclude that lead becomes superconducting at temperatures below  $6.0 \text{ K}$ .

**Self-test 18C.6** Tin has  $T_c = 3.72 \text{ K}$  and  $\mathcal{H}_c(0) = 25 \text{ kA m}^{-1}$ . At what temperature does tin become superconducting in a magnetic field of strength  $15 \text{ kA m}^{-1}$ ?

Answer:  $2.4 \text{ K}$

Type I superconductors are also completely diamagnetic below  $\mathcal{H}_c$ , meaning that the magnetic field does not penetrate into the material. This complete exclusion of a magnetic field from a material is known as the **Meissner effect**, which can be demonstrated by the levitation of a superconductor above a magnet. *Type II* superconductors, which include the HTSCs, show a gradual loss of superconductivity and diamagnetism with increasing magnetic field.

## Checklist of concepts

- 1. **Uniaxial stress** is a simple compression or extension in one direction.
- 2. **Hydrostatic stress** is a stress applied simultaneously in all directions, as in a body immersed in a fluid.
- 3. A **pure shear** is a stress that tends to push opposite faces of the sample in opposite directions.
- 4. A sample subjected to a small stress typically undergoes **elastic deformation**.
- 5. The response of a solid to an applied stress is summarized by the **Young's modulus**, the **bulk modulus**, the **shear modulus**, and **Poisson's ratio**.
- 6. The differing rheological characteristics of metals can be traced to the presence of **slip planes**.
- 7. Electronic conductors are classified as **metallic conductors** or **semiconductors** according to the temperature dependence of their conductivities.
- 8. Semiconductors are classified as **p-type** or **n-type** according to whether conduction is due to holes in the valence band or electrons in the conduction band.
- 9. An **insulator** is a semiconductor with a very low electrical conductivity.
- 10. A **superconductor** conducts electricity without resistance below a critical temperature  $T_c$ .
- 11. A **Cooper pair** is a pair of electrons that exists on account of the indirect electron–electron interactions mediated by the nuclei of the atoms in the lattice.
- 12. A **diamagnetic material** moves out of a magnetic field; it has a negative magnetic susceptibility.
- 13. A **paramagnetic material** moves into a magnetic field; it has a positive magnetic susceptibility.
- 14. The **Curie law** describes the temperature dependence of the magnetic susceptibility.
- 15. **Ferromagnetism** is the cooperative alignment of electron spins in a material and gives rise to strong permanent magnetization.
- 16. **Antiferromagnetism** results from alternating spin orientations in a material and leads to weak magnetization.
- 17. **Temperature-independent paramagnetism** arises from induced electron currents that make use of excited states of molecules.

### ► Why do you need to know this material?

The optical properties of solids are of ever increasing importance in modern technology, not only for the generation of light but for the propagation and manipulation of information. You need to be aware of these properties to understand and contribute to the development of new optical technologies.

### ► What is the key idea?

The optical properties of solids stem from electronic transitions between the available orbitals in the material and the interaction between the transition dipoles.

### ► What do you need to know already?

You need to be familiar with basic properties of electromagnetic fields (*Foundations C*) and bonding arrangements in solids (Topic 18B), especially the band structure of solids. The Topic draws on the factors that determine the absorption of light by atoms and molecules (especially Topic 12A) and the operation of lasers (Topic 13C).

In this Topic we explore the consequences of interactions between electromagnetic radiation and solids. Our focus is on the origins of phenomena that are the basis of the design of a variety of useful devices, such as lasers and light-emitting diodes.

## 18D.1 Light absorption by excitons in molecular solids

Topic 12A explains the factors that determine the energy and intensity of light absorbed by isolated atoms and molecules in the gas phase and in solution. Here we consider the effects on their electronic absorption spectra that result from bringing the atoms or molecules together to form a solid.

Consider an electronic excitation of a molecule (or an ion) in a crystal. If the excitation corresponds to the removal of an electron from one orbital of a molecule and its elevation to an orbital of higher energy, then the excited state of the molecule can be envisaged as the coexistence of an electron and a hole. This electron–hole pair, which behaves as a particle-like **exciton**, migrates from molecule to molecule in the crystal (Fig. 18D.1). A migrating excitation of this kind is called a **Frenkel exciton**. Frenkel excitons are more common in molecular solids. The electron and hole can also be on different molecules, but in each other's vicinity. A migrating excitation of this kind, which is now spread over several molecules (more usually ions), is called a **Wannier exciton**. Exciton formation causes spectral lines to shift, split, and change intensity.

The migration of a Frenkel exciton (the only type we consider) implies that there is an interaction between the species that constitute the crystal, for otherwise the excitation on one unit could not move to another. This interaction affects the energy levels of the system. The strength of the interaction also governs the rate at which an exciton moves through the crystal: a strong interaction results in fast migration and a vanishingly

**Figure 18D.1** The electron–hole pair shown on the left can migrate through a solid lattice as the excitation hops from molecule to molecule. The mobile excitation is called an exciton.

small interaction leaves the exciton localized on its original molecule. The specific mechanism of interaction that leads to exciton migration is the interaction between the transition dipole moments of the excitation (Topic 12A). Thus, an electric dipole transition in a molecule is accompanied by a shift of charge, and the transient dipole exerts a force on an adjacent molecule. The latter responds by shifting its charge. This process continues and the excitation migrates through the crystal.

The energy shift arising from the interaction between transition dipoles can be understood in terms of their electrostatic interaction. As we see in the following *Justification*, an all-parallel arrangement of the transition dipoles (Fig. 18D.2a) is energetically unfavourable, so the absorption occurs at a higher frequency than in the isolated molecule. Conversely, a head-to-tail alignment of transition dipoles (Fig. 18D.2b) is energetically favourable, and the transition occurs at a lower frequency than in the isolated molecules.

#### Justification 18D.1 The energy of interaction of transition dipoles

The potential energy of interaction between two parallel electric dipole moments  $\mu_1$  and  $\mu_2$  separated by a distance  $r$  is  $V = \mu_1 \mu_2 (1 - 3 \cos^2 \theta) / 4\pi \epsilon_0 r^3$ , where the angle  $\theta$  is defined in 1 (Topic 16B). We see that  $\theta = 0^\circ$  for a head-to-tail alignment and  $\theta = 90^\circ$  for a parallel alignment. It follows that  $V < 0$  (an attractive interaction) for  $0^\circ \leq \theta < 54.7^\circ$ ,  $V = 0$  when  $\theta = 54.7^\circ$  (for then  $1 - 3 \cos^2 \theta = 0$ ), and  $V > 0$  (a repulsive interaction) for  $54.7^\circ < \theta \leq 90^\circ$ . This result is expected on the basis of qualitative arguments. In a head-to-tail arrangement, the interaction between the region of partial positive charge in one molecule and the region of partial negative charge in the other molecule is attractive. By contrast, in a parallel arrangement, the molecular interaction is repulsive because of the close approach of regions of partial charge with the same sign.

It follows from this discussion that, when  $0^\circ \leq \theta < 54.7^\circ$ , the frequency of exciton absorption is lower than the corresponding absorption frequency for the isolated molecule (a *red shift* in the spectrum of the solid with respect to that of the isolated molecule). Conversely, when  $54.7^\circ < \theta \leq 90^\circ$ , the frequency of exciton absorption is higher than the corresponding absorption frequency for the isolated molecule (a *blue shift* in the spectrum of the solid with respect to that of the isolated molecule). In the special case  $\theta = 54.7^\circ$  the solid and the isolated molecule have absorption lines at the same frequency.

**Figure 18D.2** (a) The alignment of transition dipoles (the yellow arrows) is energetically unfavourable, and the exciton absorption is shifted to higher energy (higher frequency). (b) The alignment is energetically favourable for a transition in this orientation, and the exciton band occurs at lower frequency than in the isolated molecules.

If there are  $N$  molecules per unit cell, there are  $N$  **exciton bands** in the spectrum (if all of them are allowed). The splitting between the bands is the **Davydov splitting**. To understand the origin of the splitting, consider the case  $N=2$  with the molecules arranged as in Fig. 18D.3 and suppose that the transition dipoles are along the length of the molecules. The radiation stimulates the collective excitation of the transition dipoles that are in-phase between neighbouring unit cells. Within each unit cell the transition dipoles may be arrayed in the two different ways shown in the illustration. The two orientations correspond to different interaction energies, with interaction being repulsive in one and attractive in the other, so the two transitions appear in the spectrum at two bands of different frequencies. The magnitude of the Davydov splitting is determined by the energy of interaction between the transition dipoles within the unit cell.

**Figure 18D.3** When the transition moments within a unit cell lie in different relative directions, as depicted in (a) and (b), the energies of the transitions are shifted and give rise to the two bands labelled (a) and (b) in the spectrum. The separation of the bands is the Davydov splitting.

## 18D.2 Light absorption by metals and semiconductors

Now we turn our attention to metallic conductors and semiconductors. Again we need to consider the consequences of interactions between particles, in this case atoms, which are now so strong that we need to abandon arguments based primarily on van der Waals interactions in favour of a full molecular orbital treatment, the band model of Topic 18B.

Consider again Fig. 18C.5, reproduced here as Fig. 18D.4, which shows bands in an idealized metallic conductor. The absorption of a photon can excite electrons from the occupied levels to the unoccupied levels. There is a near continuum of unoccupied energy levels above the Fermi level, so we expect to observe absorption over a wide range of frequencies. In metals, the bands are sufficiently wide that radiation from the radio-frequency to the middle of the ultraviolet region of the electromagnetic spectrum is absorbed. Metals are transparent to very high-frequency electromagnetic radiation, such as X-rays and  $\gamma$ -rays. Because this range of absorbed frequencies includes the entire visible spectrum, we might therefore expect all metals to appear black. However, we know that metals are lustrous (that is, they reflect light) and some are coloured (that is, they absorb light of only certain wavelengths), so we need to extend our model.

To explain the lustrous appearance of a smooth metal surface, we need to realize that the absorbed energy can be re-emitted very efficiently as light, with only a small fraction of

**Figure 18D.4** When  $N$  electrons occupy a band of  $N$  orbitals, it is only half full and the electrons near the Fermi level (the top of the filled levels) are mobile.

**Figure 18D.5** In some materials, the band gap  $E_g$  is very large and electron promotion can occur only by excitation with electromagnetic radiation.

the energy being released to the surroundings as heat. Because the atoms near the surface of the material absorb most of the radiation, emission also occurs primarily from the surface. In essence, if the sample is excited with visible light, then electrons near the surface are driven into oscillation at the same frequency, and visible light will be emitted from the surface, so accounting for the lustre of the material.

The perceived colour of a metal depends on the frequency range of reflected light which, in turn, depends on the frequency range of light that can be absorbed and, by extension, on the band structure. Silver reflects light with nearly equal efficiency across the visible spectrum because its band structure has many unoccupied energy levels that can be populated by absorption of, and depopulated by emission of, visible light. On the other hand, copper has its characteristic colour because it has relatively fewer unoccupied energy levels that can be excited with violet, blue, and green light. The material reflects at all wavelengths, but more light is emitted at lower frequencies (corresponding to yellow, orange, and red). Similar arguments account for the colours of other metals, such as the yellow of gold. The colour of gold, incidentally, can be accounted for only by including relativistic effects in the calculation of its band structure.

Now consider semiconductors. We have already seen that promotion of electrons from the conduction to the valence band of a semiconductor can be the result of thermal excitation, if the band gap  $E_g$  is comparable to the energy that can be supplied by heating. In some materials, the band gap is very large and electron promotion can occur only by excitation with electromagnetic radiation. However, we see from Fig. 18D.5 that there is a frequency  $\nu_{\min} = E_g/h$  below which light absorption cannot occur. Above this frequency threshold, a wide range of frequencies can be absorbed by the material, as in a metal.

### Brief illustration 18D.1 The optical properties of a semiconductor

The energy of the band gap in semiconductor cadmium sulfide (CdS) is 2.4 eV (equivalent to  $3.8 \times 10^{-19}$  J). It follows that the minimum electronic absorption frequency is

$$\nu_{\min} = \frac{3.8 \times 10^{-19} \text{ J}}{6.626 \times 10^{-34} \text{ J}} = 5.8 \times 10^{14} \text{ s}^{-1}$$

This frequency, of 580 THz, corresponds to a wavelength of 520 nm (green light). Lower frequencies, corresponding to yellow, orange, and red, are not absorbed and consequently CdS appears yellow-orange.

**Self-test 18D.1** Predict the colours of the following materials, given their band-gap energies (in parentheses): GaAs (1.43 eV), HgS (2.1 eV), and ZnS (3.6 eV).

Answer: Black, red, and colourless

### 18D.3 Light-emitting diodes and diode lasers

The unique electrical properties of p–n junctions between semiconductors can be put to good use in optical devices. In some materials, most notably gallium arsenide, GaAs, energy from electron–hole recombination is released not as heat but is carried away by photons as electrons move across the junction under forward bias. Practical **light-emitting diodes** of this kind are widely used in electronic displays. The wavelength of emitted light depends on the band gap of the semiconductor. Gallium arsenide itself emits infrared light, but its band gap is widened by incorporating phosphorus, and a material of composition approximately  $\text{GaAs}_{0.6}\text{P}_{0.4}$  emits light in the red region of the spectrum.

A light-emitting diode is not a laser, because neither a resonance cavity nor stimulated emission is involved. In **diode lasers**, light emission due to electron–hole recombination is employed as the basis of laser action. The population inversion can be sustained by sweeping away the electrons that fall into the holes of the p-type semiconductor, and a resonant cavity can be formed by using the high refractive index of the semiconducting material and cleaving single crystals so that the light is trapped by the abrupt variation of refractive index. One widely used material is  $\text{Ga}_{1-x}\text{Al}_x\text{As}$ , which produces infrared laser radiation and is widely used in compact-disc (CD) players.

High-power diode lasers are also used to pump other lasers. One example is the pumping of Nd:YAG lasers (Topic 13C) by  $\text{Ga}_{0.91}\text{Al}_{0.09}\text{As}/\text{Ga}_{0.7}\text{Al}_{0.3}\text{As}$  diode lasers. The Nd:YAG laser is often used to pump yet another laser, such as a Ti:sapphire laser (Topic 13C). As a result, it is now possible to construct a laser system for steady-state or time-resolved spectroscopy entirely out of solid-state components.

### 18D.4 Nonlinear optical phenomena

Nonlinear optical phenomena arise from changes in the optical properties of a material in the presence of an intense electric

field from electromagnetic radiation. In **frequency doubling**, or **second harmonic generation**, an intense laser beam is converted to radiation with twice (and in general a multiple) of its initial frequency as it passes through a suitable material. It follows that frequency doubling and tripling of a Nd:YAG laser, which emits radiation at 1064 nm (Topic 13C), produce green light at 532 nm and ultraviolet radiation at 355 nm, respectively.

We can account for frequency doubling by examining how a substance responds nonlinearly to incident radiation of frequency  $\omega = 2\pi\nu$ . Radiation of a particular frequency arises from oscillations of an electric dipole at that frequency and the incident electric field  $\mathcal{E}$  induces an electric dipole of magnitude  $\mu$ , in the substance. At low light intensity, most materials respond linearly, in the sense that  $\mu = \alpha\mathcal{E}$ , where  $\alpha$  is the polarizability (Topic 16A). At high light intensity, the hyperpolarizability  $\beta$  of the material becomes important (Topic 16B) and we write.

$$\mu = \alpha\mathcal{E} + \frac{1}{2}\beta\mathcal{E}^2 + \dots$$

Induced dipole moment in terms of the hyperpolarizability

(18D.1)

The nonlinear term  $\beta\mathcal{E}^2$  can be expanded as follows if we suppose that the incident electric field is  $\mathcal{E}_0 \cos \omega t$ :

$$\beta\mathcal{E}^2 = \beta\mathcal{E}_0^2 \cos^2 \omega t = \frac{1}{2}\beta\mathcal{E}_0^2 (1 + \cos 2\omega t)$$
(18D.2)

Hence, the nonlinear term contributes an induced electric dipole that oscillates at the frequency  $2\omega$  and that can act as a source of radiation of that frequency. Common materials that can be used for frequency doubling in laser systems include crystals of potassium dihydrogenphosphate ( $\text{KH}_2\text{PO}_4$ ), lithium niobate ( $\text{LiNbO}_3$ ), and  $\beta$ -barium borate ( $\beta\text{-BaB}_2\text{O}_4$ ). Another important nonlinear optical phenomenon is the optical Kerr effect discussed in Topic 13C.

In addition to being useful laboratory tools, nonlinear optical materials are also finding many applications in the telecommunications industry, which is becoming ever more reliant on optical signals transmitted through optical fibres to carry voice and data. Judicious use of nonlinear phenomena leads to more ways in which the properties of optical signals, and hence the information they carry, can be manipulated.

## Checklist of concepts

- 1. The optical properties of molecular solids can be understood in terms of the formation and migration of **excitons**.
- 2. The spectroscopic properties of metallic conductors and semiconductors can be understood in terms of the photon-induced promotion of electrons from valence bands to conduction bands.
- 3. The unique electronic properties of p–n junctions between semiconductors can be put to good use in such optical devices as **light-emitting diodes** and **diode lasers**.
- 4. **Nonlinear optical phenomena** arise from changes in the optical properties of a material in the presence of intense electromagnetic radiation.

# CHAPTER 18 Solids

## TOPIC 18A Crystal structure

### Discussion questions

- 18A.1** Describe the relationship between the space lattice and unit cell.
- 18A.2** Explain how planes of lattice points are labelled.
- 18A.3** Describe the procedure for identifying the type and size of a cubic unit cell.

### Exercises

- 18A.1(a)** The orthorhombic unit cell of  $\text{NiSO}_4$  has the dimensions  $a = 634$  pm,  $b = 784$  pm, and  $c = 516$  pm, and the density of the solid is estimated as  $3.9$  g  $\text{cm}^{-3}$ . Determine the number of formula units per unit cell and calculate a more precise value of the density.
- 18A.1(b)** An orthorhombic unit cell of a compound of molar mass  $135.01$  g  $\text{mol}^{-1}$  has the dimensions  $a = 589$  pm,  $b = 822$  pm, and  $c = 798$  pm. The density of the solid is estimated as  $2.9$  g  $\text{cm}^{-3}$ . Determine the number of formula units per unit cell and calculate a more precise value of the density.
- 18A.2(a)** Find the Miller indices of the planes that intersect the crystallographic axes at the distances  $(2a, 3b, 2c)$  and  $(2a, 2b, \infty c)$ .
- 18A.2(b)** Find the Miller indices of the planes that intersect the crystallographic axes at the distances  $(-a, 2b, -c)$  and  $(a, 4b, -4c)$ .
- 18A.3(a)** Calculate the separations of the planes  $\{112\}$ ,  $\{110\}$ , and  $\{224\}$  in a crystal in which the cubic unit cell has side  $562$  pm.
- 18A.3(b)** Calculate the separations of the planes  $\{123\}$ ,  $\{222\}$ , and  $\{246\}$  in a crystal in which the cubic unit cell has side  $712$  pm.
- 18A.4(a)** The unit cells of  $\text{SbCl}_3$  are orthorhombic with dimensions  $a = 812$  pm,  $b = 947$  pm, and  $c = 637$  pm. Calculate the spacing,  $d$ , of the  $\{321\}$  planes.
- 18A.4(b)** An orthorhombic unit cell has dimensions  $a = 769$  pm,  $b = 891$  pm, and  $c = 690$  pm. Calculate the spacing,  $d$ , of the  $\{312\}$  planes.
- 18A.5(a)** The angle of a Bragg reflection from a set of crystal planes separated by  $99.3$  pm is  $20.85^\circ$ . Calculate the wavelength of the X-rays.
- 18A.5(b)** The angle of a Bragg reflection from a set of crystal planes separated by  $128.2$  pm is  $19.76^\circ$ . Calculate the wavelength of the X-rays.
- 18A.6(a)** What are the values of the angle  $\theta$  of the first three diffraction lines of bcc iron (atomic radius  $126$  pm) when the X-ray wavelength is  $72$  pm?
- 18A.6(b)** What are the values of the angle  $\theta$  of the first three diffraction lines of fcc gold (atomic radius  $144$  pm) when the X-ray wavelength is  $129$  pm?
- 18A.7(a)** Potassium nitrate crystals have orthorhombic unit cells of dimensions  $a = 542$  pm,  $b = 917$  pm, and  $c = 645$  pm. Calculate the values of  $\theta$  for the  $(100)$ ,  $(010)$ , and  $(111)$  reflections using radiation of wavelength  $154$  pm.
- 18A.7(b)** Calcium carbonate crystals in the form of aragonite have orthorhombic unit cells of dimensions  $a = 574.1$  pm,  $b = 796.8$  pm, and  $c = 495.9$  pm. Calculate the values of  $\theta$  for the  $(100)$ ,  $(010)$ , and  $(111)$  reflections using radiation of wavelength  $83.42$  pm.
- 18A.8(a)** Radiation from an X-ray source consists of two components of wavelengths  $154.433$  pm and  $154.051$  pm. Calculate the difference in glancing angles ( $2\theta$ ) of the diffraction lines arising from the two components in a diffraction pattern from planes of separation  $77.8$  pm.
- 18A.8(b)** Consider a source that emits X-radiation at a range of wavelengths, with two components of wavelengths  $93.222$  and  $95.123$  pm. Calculate the

**18A.4** Discuss what is meant by 'scattering factor'. How is it related to the number of electrons in the atoms scattering X-rays?

**18A.5** What is meant by a systematic absence? How do they arise?

**18A.6** Describe the consequences of the phase problem in determining structure factors and how the problem is overcome.

separation of the glancing angles ( $2\theta$ ) arising from the two components in a diffraction pattern from planes of separation  $82.3$  pm.

**18A.9(a)** What is the value of the scattering factor in the forward direction for  $\text{Br}^-$ ?

**18A.9(b)** What is the value of the scattering factor in the forward direction for  $\text{Mg}^{2+}$ ?

**18A.10(a)** The coordinates, in units of  $a$ , of the atoms in a primitive cubic unit cell are  $(0,0,0)$ ,  $(0,1,0)$ ,  $(0,0,1)$ ,  $(0,1,1)$ ,  $(1,0,0)$ ,  $(1,1,0)$ ,  $(1,0,1)$ , and  $(1,1,1)$ . Calculate the structure factors  $F_{hkl}$  when all the atoms are identical.

**18A.10(b)** The coordinates, in units of  $a$ , of the atoms in a body-centred cubic unit cell are  $(0,0,0)$ ,  $(0,1,0)$ ,  $(0,0,1)$ ,  $(0,1,1)$ ,  $(1,0,0)$ ,  $(1,1,0)$ ,  $(1,0,1)$ ,  $(1,1,1)$ , and  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ . Calculate the structure factors  $F_{hkl}$  when all the atoms are identical.

**18A.11(a)** Calculate the structure factors for a face-centred cubic structure (C) in which the scattering factors of the ions on the two faces are twice that of the ions at the corners of the cube.

**18A.11(b)** Calculate the structure factors for a body-centred cubic structure in which the scattering factor of the central ion is twice that of the ions at the corners of the cube.

**18A.12(a)** In an X-ray investigation, the following structure factors were determined (with  $F_{-h00} = F_{h00}$ ):

$h$	0	1	2	3	4	5	6	7	8	9
$F_{h00}$	10	-10	8	-8	6	-6	4	-4	2	-2

Construct the electron density along the corresponding direction.

**18A.12(b)** In an X-ray investigation, the following structure factors were determined (with  $F_{-h00} = F_{h00}$ ):

$h$	0	1	2	3	4	5	6	7	8	9
$F_{h00}$	10	10	4	4	6	6	8	8	10	10

Construct the electron density along the corresponding direction.

**18A.13(a)** Construct the Patterson synthesis from the information in Exercise 18A.12(a).

**18A.13(b)** Construct the Patterson synthesis from the information in Exercise 18A.12(b).

**18A.14(a)** In a Patterson synthesis, the spots correspond to the lengths and directions of the vectors joining the atoms in a unit cell. Sketch the pattern that would be obtained for a planar, triangular isolated  $\text{BF}_3$  molecule.

**18A.14(b)** In a Patterson synthesis, the spots correspond to the lengths and directions of the vectors joining the atoms in a unit cell. Sketch the pattern that would be obtained from the C atoms in an isolated benzene molecule.

**18A.15(a)** What speed should neutrons have if they are to have a wavelength of 65 pm?

**18A.15(b)** What speed should electrons have if they are to have a wavelength of 105 pm?

## Problems

**18A.1** Although the crystallization of large biological molecules may not be as readily accomplished as that of small molecules, their crystal lattices are no different. Tobacco seed globulin forms face-centred cubic crystals with unit cell dimension of 12.3 nm and a mass density of  $1.287 \text{ g cm}^{-3}$ . Determine its molar mass.

**18A.2** Show that the volume of a monoclinic unit cell is  $V = abc \sin \beta$ .

**18A.3** Derive an expression for the volume of a hexagonal unit cell.

**18A.4** Show that the volume of a triclinic unit cell of sides  $a$ ,  $b$ , and  $c$  and angles  $\alpha$ ,  $\beta$ , and  $\gamma$  is

$$V = abc(1 - \cos^2 \alpha - \cos^2 \beta - \cos^2 \gamma + 2 \cos \alpha \cos \beta \cos \gamma)^{1/2}$$

Use this expression to derive expressions for monoclinic and orthorhombic unit cells. For the derivation, it may be helpful to use the result from vector analysis that  $V = \mathbf{a} \cdot \mathbf{b} \times \mathbf{c}$  and to calculate  $V^2$  initially. The compound  $\text{Rb}_3\text{TlF}_6$  has a tetragonal unit cell with dimensions  $a = 651 \text{ pm}$  and  $c = 934 \text{ pm}$ . Calculate the volume of the unit cell.

**18A.5** The volume of a monoclinic unit cell is  $abc \sin \beta$  (see Problem 18A.2). Naphthalene has a monoclinic unit cell with two molecules per cell and sides in the ratio 1.377:1:1.436. The angle  $\beta$  is  $122.82^\circ$  and the mass density of the solid is  $1.152 \text{ g cm}^{-3}$ . Calculate the dimensions of the cell.

**18A.6** Fully crystalline polyethylene has its chains aligned in an orthorhombic unit cell of dimensions  $740 \text{ pm} \times 493 \text{ pm} \times 253 \text{ pm}$ . There are two repeating  $\text{CH}_2\text{CH}_2$  units per unit cell. Calculate the theoretical mass density of fully crystalline polyethylene. The actual density ranges from 0.92 to  $0.95 \text{ g cm}^{-3}$ .

**18A.7\*** B.A. Bovenzi and G.A. Pearse, Jr. (*J. Chem. Soc. Dalton Trans.*, 2793 (1997)) synthesized coordination compounds of the tridentate ligand pyridine-2,6-diamidoxime (1,  $\text{C}_7\text{H}_9\text{N}_5\text{O}_2$ ). The compound they isolated from the reaction of the ligand with  $\text{CuSO}_4(\text{aq})$  did not contain a  $[\text{Cu}(\text{C}_7\text{H}_9\text{N}_5\text{O}_2)_2]^{2+}$  complex cation as expected. Instead, X-ray diffraction analysis revealed a linear polymer of formula  $[\{\text{Cu}(\text{C}_7\text{H}_9\text{N}_5\text{O}_2)(\text{SO}_4)\} \cdot 2\text{H}_2\text{O}]_n$ , which features bridging sulfate groups. The unit cell was primitive monoclinic with  $a = 1.0427 \text{ nm}$ ,  $b = 0.8876 \text{ nm}$ ,  $c = 1.3777 \text{ nm}$ , and  $\beta = 93.254^\circ$ . The mass density of the crystals is  $2.024 \text{ g cm}^{-3}$ . How many monomer units are there in the unit cell?

### 1 Pyridine-2,6-diamidoxime

**18A.8\*** D. Sellmann et al. (*Inorg. Chem.* 36, 1397 (1997)) describe the synthesis and reactivity of the ruthenium nitrido compound  $[\text{N}(\text{C}_4\text{H}_9)_4][\text{Ru}(\text{N})(\text{S}_2\text{C}_6\text{H}_4)_2]$ . The ruthenium complex anion has the two 1,2-benzenedithiolate ligands (2) at the base of a rectangular pyramid and the nitrido ligand at the apex. Compute the mass density of the compound given that it crystallizes with an orthorhombic unit cell with  $a = 3.6881 \text{ nm}$ ,  $b = 0.9402 \text{ nm}$ , and  $c = 1.7652 \text{ nm}$  and eight formula units per cell. The replacement of the ruthenium with osmium results in a compound with the same crystal structure and a unit cell with a volume less than 1 per cent larger. Estimate the mass density of the osmium analogue.

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**18A.16(a)** Calculate the wavelength of neutrons that have reached thermal equilibrium by collision with a moderator at 350 K.

**18A.16(b)** Calculate the wavelength of electrons that have reached thermal equilibrium by collision with a moderator at 380 K.

### 2 1,2-Benzenedithiolate ion

**18A.9** Show that the separation of the  $\{hkl\}$  planes in an orthorhombic crystal with sides  $a$ ,  $b$ , and  $c$  is given by eqn 18A.1c.

**18A.10** In the early days of X-ray crystallography there was an urgent need to know the wavelengths of X-rays. One technique was to measure the diffraction angle from a mechanically ruled grating. Another method was to estimate the separation of lattice planes from the measured density of a crystal. The mass density of  $\text{NaCl}$  is  $2.17 \text{ g cm}^{-3}$  and the (100) reflection using radiation of a certain wavelength occurred at  $6.0^\circ$ . Calculate the wavelength of the X-rays.

**18A.11** The element polonium crystallizes in a cubic system. Bragg reflections, with X-rays of wavelength 154 pm, occur at  $\sin \theta = 0.225$ , 0.316, and 0.388 from the  $\{100\}$ ,  $\{110\}$ , and  $\{111\}$  sets of planes. The separation between the sixth and seventh lines observed in the diffraction pattern is larger than between the fifth and sixth lines. Is the unit cell primitive, body centred, or face centred? Calculate the unit cell dimension.

**18A.12** Elemental silver reflects X-rays of wavelength 154.18 pm at angles of  $19.076^\circ$ ,  $22.171^\circ$ , and  $32.256^\circ$ . However, there are no other reflections at angles of less than  $33^\circ$ . Assuming a cubic unit cell, determine its type and dimension. Calculate the mass density of silver.

**18A.13** In their book *X-rays and crystal structures* (which begins 'It is now two years since Dr. Laue conceived the idea...') the Braggs give a number of simple examples of X-ray analysis. For instance, they report that the reflection from  $\{100\}$  planes in  $\text{KCl}$  occurs at  $5.38^\circ$ , but for  $\text{NaCl}$  it occurs at  $6.00^\circ$  for X-rays of the same wavelength. If the side of the  $\text{NaCl}$  unit cell is 564 pm, what is the side of the  $\text{KCl}$  unit cell? The mass densities of  $\text{KCl}$  and  $\text{NaCl}$  are  $1.99 \text{ g cm}^{-3}$  and  $2.17 \text{ g cm}^{-3}$ , respectively. Do these values support the X-ray analysis?

**18A.14** Use mathematical software to draw a graph of the scattering factor  $f$  against  $(\sin \theta)/\lambda$  for an atom of atomic number  $Z$  for which  $\rho(r) = 3Z/4\pi R^3$  for  $0 \leq r \leq R$  and  $\rho(r) = 0$  for  $r > R$ , with  $R$  a parameter that represents the radius of the atom. Explore how  $f$  varies with  $Z$  and  $R$ .

**18A.15** The coordinates of the four I atoms in the unit cell of  $\text{KIO}_4$  are  $(0, 0, 0)$ ,  $(0, \frac{1}{2}, \frac{1}{2})$ ,  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ ,  $(\frac{1}{2}, 0, \frac{3}{4})$ . By calculating the phase of the I reflection in the structure factor, show that the I atoms contribute no net intensity to the (114) reflection.

**18A.16** The coordinates, as multiples of  $a$ , of the A atoms, with scattering factor  $f_A$ , in a cubic lattice are  $(0, 0, 0)$ ,  $(0, 1, 0)$ ,  $(0, 0, 1)$ ,  $(0, 1, 1)$ ,  $(1, 0, 0)$ ,  $(1, 1, 0)$ ,  $(1, 0, 1)$ , and  $(1, 1, 1)$ . There is also a B atom, with scattering factor  $f_B$ , at  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ . Calculate the structure factors  $F_{hkl}$  and predict the form of the diffraction pattern when (a)  $f_A = f$ ,  $f_B = 0$ , (b)  $f_B = \frac{1}{2} f_A$ , and (c)  $f_A = f_B = f$ .

**18A.17** Here we explore electron diffraction patterns. (a) Predict from the Wierl equation, eqn 18A.9, the positions of the first maximum and first minimum in the neutron and electron diffraction patterns of a  $\text{Br}_2$  molecule obtained with neutrons of wavelength 78 pm and electrons of wavelength 4.0 pm. (b) Use the Wierl equation to predict the appearance of the electron diffraction pattern of  $\text{CCl}_4$  with an (as yet) undetermined C—Cl bond length

but of known tetrahedral symmetry. Take  $f_{\text{Cl}} = 17f$  and  $f_{\text{C}} = 6f$  and note that  $R(\text{Cl}, \text{Cl}) = (8/3)^{1/2}R(\text{C}, \text{Cl})$ . Plot  $l/f^2$  against positions of the maxima occurred

at 3.17°, 5.37°, and 7.90° and minima occurred at 1.77°, 4.10°, 6.67°, and 9.17°. What is the C–Cl bond length in  $\text{CCl}_4$ ?

## TOPIC 18B Bonding in solids

### Discussion questions

**18B.1** In what respects is the hard-sphere model of metallic solids deficient?

**18B.2** Describe the caesium chloride and rock salt structures in terms of the occupation of holes in expanded close-packed lattices.

### Exercises

**18B.1(a)** Calculate the packing fraction for close-packed cylinders. (For a generalization of this Exercise, see Problem 18B.2.)

**18B.1(b)** Calculate the packing fraction for equilateral triangular rods stacked as shown in 3.

3

**18B.2(a)** Calculate the packing fractions of (i) a primitive cubic unit cell, (ii) a bcc unit cell, (iii) an fcc unit cell composed of identical hard spheres.

**18B.2(b)** Calculate the atomic packing factor for a face-centred (C) cubic unit cell.

**18B.3(a)** From the data in Table 18B.2 determine the radius of the smallest cation that can have (i) sixfold and (ii) eightfold coordination with the  $\text{Cl}^-$  ion.

**18B.3(b)** From the data in Table 18B.2 determine the radius of the smallest cation that can have (i) sixfold and (ii) eightfold coordination with the  $\text{Rb}^+$  ion.

**18B.4(a)** Does titanium expand or contract as it transforms from hcp to bcc? The atomic radius of titanium is 145.8 pm in hcp but 142.5 pm in bcc.

**18B.4(b)** Does iron expand or contract as it transforms from hcp to bcc? The atomic radius of iron is 126 pm in hcp but 122 pm in bcc.

**18B.5(a)** Calculate the lattice enthalpy of CaO from the following data:

	$\Delta H/(\text{kJ mol}^{-1})$
Sublimation of Ca(s)	+178
Ionization of Ca(g) to $\text{Ca}^{2+}(\text{g})$	+1735
Dissociation of $\text{O}_2(\text{g})$	+249
Electron attachment to O(g)	–141
Electron attachment to $\text{O}^-(\text{g})$	+844
Formation of CaO(s) from Ca(s) and $\text{O}_2(\text{g})$	–635

**18B.5(b)** Calculate the lattice enthalpy of  $\text{MgBr}_2$  from the following data:

	$\Delta H/(\text{kJ mol}^{-1})$
Sublimation of Mg(s)	+148
Ionization of Mg(g) to $\text{Mg}^{2+}(\text{g})$	+2187
Vaporization of $\text{Br}_2(\text{l})$	+31
Dissociation of $\text{Br}_2(\text{g})$	+193
Electron attachment to Br(g)	–331
Formation of $\text{MgBr}_2(\text{s})$ from Mg(s) and $\text{Br}_2(\text{l})$	–524

### Problems

**18B.1** Calculate the atomic packing factor for diamond.

**18B.2** Rods of elliptical cross-section with semi-minor and major axes  $a$  and  $b$  are close-packed as shown in 4. What is the packing fraction? Draw a graph of the packing fraction against the eccentricity  $\epsilon$  of the ellipse. For an ellipse with semi-major axis  $a$  and semi-minor axis  $b$ ,  $\epsilon = (1 - b^2/a^2)^{1/2}$ .

4

**18B.3** The carbon–carbon bond length in diamond is 154.45 pm. If diamond were considered to be a close-packed structure of hard spheres with radii equal to half the bond length, what would be its expected mass density? The diamond lattice is face-centred cubic and its actual mass density is  $3.516 \text{ g cm}^{-3}$ . Can you explain the discrepancy?

**18B.4** When energy levels in a band form a continuum, the density of states  $\rho(E)$ , the number of levels in an energy range divided by the width of the range, may be written as  $\rho(E) = dk/dE$ , where  $dk$  is the change in the quantum number  $k$  and  $dE$  is the energy change. (a) Use eqn 18B.1 to show that

$$\rho(E) = -\frac{(N+1)/2\pi\beta}{\left\{1 - \left(\frac{E-\alpha}{2\beta}\right)^2\right\}^{1/2}}$$

where  $k$ ,  $N$ ,  $\alpha$  and  $\beta$  have the meanings described in Topic 18B. (b) Use this expression to show that  $\rho(E)$  becomes infinite as  $E$  approaches  $\alpha \pm 2\beta$ . That is,

Figure 18.1 The variation of density of states in a three-dimensional solid.

show that the density of states increases towards the edges of the bands in a one-dimensional metallic conductor.

**18B.5** The treatment in Problem 18B.4 applies only to one-dimensional solids. In three dimensions, the variation of density of states is more like that shown in Fig. 18.1. Account for the fact that in a three-dimensional solid the greatest density of states is near the centre of the band and the lowest density is at the edges.

**18B.6** The energy levels of  $N$  atoms in the tight-binding Hückel approximation are the roots of a tridiagonal determinant (eqn 18B.1):

$$E_k = \alpha + 2\beta \cos \frac{k\pi}{N+1} \quad k=1,2,\dots,N$$

If the atoms are arranged in a ring, the solutions are the roots of a 'cyclic' determinant:

$$E_k = \alpha + 2\beta \cos \frac{2k\pi}{N} \quad k=0,\pm 1,\pm 2,\dots,\pm \frac{1}{2}N$$

(for  $N$  even). Discuss the consequences, if any, of joining the ends of an initially straight length of material.

Figure 18.2 Fragment of a two-dimensional lattice used as a model in Problem 18B.10.

**18B.7** Verify that the radius ratio for (a) sixfold coordination is 0.414, and (b) for eightfold coordination is 0.732.

**18B.8** Use the Born–Mayer equation for the lattice enthalpy and a Born–Haber cycle to show that formation of CaCl is an exothermic process (the sublimation enthalpy of Ca(s) is  $176 \text{ kJ mol}^{-1}$ ). Show that an explanation for the nonexistence of CaCl can be found in the reaction enthalpy for the reaction  $2 \text{ CaCl(s)} \rightarrow \text{Ca(s)} + \text{CaCl}_2$ .

**18B.9** Derive the Born–Mayer equation (eqn 18B.6) by calculating the energy at which  $d(E_p + E_p^*)/dd=0$ , with  $E_p$  and  $E_p^*$  given by eqns 18B.4 and 18B.5, respectively.

**18B.10** Suppose that ions are arranged in a (somewhat artificial) two-dimensional lattice like the fragment shown in Fig. 18.2. Calculate the Madelung constant for this array.

## TOPIC 18C Mechanical, electrical, and magnetic properties of solids

### Discussion questions

**18C.1** Describe the characteristics of the Fermi–Dirac distribution.

**18C.2** To what extent are the electric and magnetic properties of molecules analogous? How do they differ?

### Exercises

**18C.1(a)** Poisson's ratio for polyethene is 0.45. What change in volume takes place when a cube of polyethene of volume  $1.0 \text{ cm}^3$  is subjected to a uniaxial stress that produces a strain of 1.0 per cent?

**18C.1(b)** Poisson's ratio for lead is 0.41. What change in volume takes place when a cube of lead of volume  $1.0 \text{ dm}^3$  is subjected to a uniaxial stress that produces a strain of 2.0 per cent?

**18C.2(a)** Is arsenic-doped germanium a p-type or n-type semiconductor?

**18C.2(b)** Is gallium-doped germanium a p-type or n-type semiconductor?

**18C.3(a)** The magnitude of the magnetic moment of  $\text{CrCl}_3$  is  $3.81\mu_B$ . How many unpaired electrons does the Cr possess?

**18C.3(b)** The magnitude of the magnetic moment of  $\text{Mn}^{2+}$  in its complexes is typically  $5.3\mu_B$ . How many unpaired electrons does the ion possess?

**18C.4(a)** Calculate the molar susceptibility of benzene given that its volume susceptibility is  $-7.2 \times 10^{-7}$  and its mass density  $0.879 \text{ g cm}^{-3}$  at  $25^\circ\text{C}$ .

**18C.4(b)** Calculate the molar susceptibility of cyclohexane given that its volume susceptibility is  $-7.9 \times 10^{-7}$  and its mass density  $811 \text{ kg m}^{-3}$  at  $25^\circ\text{C}$ .

**18C.5(a)** Data on a single crystal of  $\text{MnF}_2$  give  $\chi_m = 0.1463 \text{ cm}^3 \text{ mol}^{-1}$  at  $294.53 \text{ K}$ . Determine the effective number of unpaired electrons in this compound and compare your result with the theoretical value.

**18C.5(b)** Data on a single crystal of  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$  give  $\chi_m = 6.00 \times 10^{-8} \text{ m}^3 \text{ mol}^{-1}$  at  $298 \text{ K}$ . Determine the effective number of unpaired electrons in this compound and compare your result with the theoretical value.

**18C.6(a)** Estimate the spin-only molar susceptibility of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  at  $25^\circ\text{C}$ .

**18C.6(b)** Estimate the spin-only molar susceptibility of  $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$  at  $298 \text{ K}$ .

## Problems

**18C.1** For an isotropic substance, the moduli and Poisson's ratio may be expressed in terms of two parameters  $\lambda$  and  $\mu$  called the *Lamé constants*:

$$E = \frac{\mu(3\lambda + 2\mu)}{\lambda + \mu} \quad K = \frac{3\lambda + 2\mu}{3} \quad G = \mu \quad \nu_P = \frac{\lambda}{2(\lambda + \mu)}$$

Use the Lamé constants to confirm the relations between  $G$ ,  $K$ , and  $E$  given in eqn 18C.3.

**18C.2** Refer to eqn 18C.6 and express  $f(E)$  as a function of the variables  $(E - \mu)/\mu$  and  $\mu/kT$ . Then, using mathematical software, display the set of curves shown in Fig. 18C.6 as a single surface.

**18C.3** In this and the following problem we explore further some of the properties of the Fermi–Dirac distribution, eqn 18C.6. For a three-dimensional solid of volume  $V$ , it turns out that  $\rho(E) = CE^{1/2}$ , with  $C = 4\pi V(2m_e/h^2)^{3/2}$ . Show that at  $T = 0$ ,

$$f(E) = 1 \text{ for } E < \mu \quad f(E) = 0 \text{ for } E > \mu$$

and deduce that  $\mu(0) = (3N/8\pi)^{2/3}(h^2/2m_e)$ , where  $N = N/V$ , the number density of electrons in the solid. Evaluate  $\mu(0)$  for sodium (where each atom contributes one electron).

**18C.4** By inspection of eqn 18C.6 and the expression for  $dN$  in eqn 18C.5 (and without attempting to evaluate integrals explicitly), show that in order for  $N$  to remain constant as the temperature is raised, the chemical potential must decrease in value from  $\mu(0)$ .

**18C.5** In an intrinsic semiconductor, the band gap is so small that the Fermi–Dirac distribution results in some electrons populating the conduction band. It follows from the exponential form of the Fermi–Dirac distribution that the conductance  $G$ , the inverse of the resistance (with units of siemens,  $1 \text{ S} = 1 \text{ } \Omega^{-1}$ ), of an intrinsic semiconductor should have an Arrhenius-like temperature dependence, shown in practice to have the form  $G = G_0 e^{-E_g/2kT}$ , where  $E_g$  is the band gap. The conductance of a sample of germanium varied with temperature as indicated below. Estimate the value of  $E_g$ .

$T/\text{K}$	312	354	420
$G/\text{S}$	0.0847	0.429	2.86

**18C.6** A transistor is a semiconducting device that is commonly used either as a switch or an amplifier of electrical signals. Prepare a brief report on

the design of a nanometre-sized transistor that uses a carbon nanotube as a component. A useful starting point is the work summarized by Tans, et al. (*Nature* 393, 49 (1998)).

**18C.7\*** J.J. Dannenberg et al. (*J. Phys. Chem.* 100, 9631 (1996)) carried out theoretical studies of organic molecules consisting of chains of unsaturated four-membered rings. The calculations suggest that such compounds have large numbers of unpaired spins, and that they should therefore have unusual magnetic properties. For example, the lowest-energy state of the compound shown as 5 is computed to have  $S = 3$ , but the energies of  $S = 2$  and  $S = 4$  structures are each predicted to be  $50 \text{ kJ mol}^{-1}$  higher in energy. Compute the molar magnetic susceptibility of these three low-lying levels at 298 K. Estimate the molar susceptibility at 298 K if each level is present in proportion to its Boltzmann factor (effectively assuming that the degeneracy is the same for all three of these levels).

5

**18C.8** An NO molecule has thermally accessible electronically excited states. It also has an unpaired electron, and so may be expected to be paramagnetic. However, its ground state is not paramagnetic because the magnetic moment of the orbital motion of the unpaired electron almost exactly cancels the spin magnetic moment. The first excited state (at  $121 \text{ cm}^{-1}$ ) is paramagnetic because the orbital magnetic moment adds to, rather than cancels, the spin magnetic moment. The upper state has a magnetic moment of magnitude  $2\mu_B$ . Because the upper state is thermally accessible, the paramagnetic susceptibility of NO shows a pronounced temperature dependence even near room temperature. Calculate the molar paramagnetic susceptibility of NO and plot it as a function of temperature.

**18C.9\*** P.G. Radaelli et al. (*Science* 265, 380 (1994)) reported the synthesis and structure of a material that becomes superconducting at temperatures below 45 K. The compound is based on a layered compound  $\text{Hg}_2\text{Ba}_2\text{YCu}_2\text{O}_{8-\delta}$ , which has a tetragonal unit cell with  $a = 0.38606 \text{ nm}$  and  $c = 2.8915 \text{ nm}$ ; each unit cell contains two formula units. The compound is made superconducting by partially replacing Y by Ca, accompanied by a change in unit cell volume by less than 1 per cent. Estimate the Ca content  $x$  in superconducting  $\text{Hg}_2\text{Ba}_2\text{Y}_{1-x}\text{Ca}_x\text{Cu}_2\text{O}_{7.55}$  given that the mass density of the compound is  $7.651 \text{ g cm}^{-3}$ .

## TOPIC 18D The optical properties of solids

### Discussion questions

**18D.1** Explain the origin of Davydov splitting in the exciton bands of a crystal.

**18D.2** Distinguish between light-emitting diodes and diode lasers.

### Exercises

**18D.1(a)** The promotion of an electron from the valence band into the conduction band in pure  $\text{TiO}_2$  by light absorption requires a wavelength of less than 350 nm. Calculate the energy gap in electronvolts between the valence and conduction bands.

**18D.1(b)** The band gap in silicon is 1.12 eV. Calculate the maximum wavelength of electromagnetic radiation that results in promotion of electrons from the valence to the conduction band.

## Problems

**18D.1** Here we investigate quantitatively the spectra of molecular solids. We begin by considering a dimer, with each monomer having a single transition with transition dipole moment  $\mu_{\text{mon}}$  and wavenumber  $\tilde{\nu}_{\text{mon}}$ . We assume that the ground state wavefunctions are not perturbed as a result of dimerization, and then write the dimer excited state wavefunctions  $\Psi_i$  as linear combinations of the excited state wavefunctions  $\psi_1$  and  $\psi_2$  of the monomer:  $\Psi_i = c_j \psi_j + c_k \psi_k$ . Now we write the hamiltonian matrix with diagonal elements set to the energy between the excited and ground state of the monomer (which, expressed as a wavenumber, is simply  $\tilde{\nu}_{\text{mon}}$ ), and off-diagonal elements correspond to the energy of interaction between the transition dipoles. Using the arrangement discussed in 1 of *Justification* 18D.1, we write this interaction energy (as a wavenumber) as:

$$\beta = \frac{\mu_{\text{mon}}^2}{4\pi\epsilon_0\hbar cr^3}(1-3\cos^2\theta)$$

It follows that the hamiltonian matrix is

$$\hat{H} = \begin{pmatrix} \tilde{\nu}_{\text{mon}} & \beta \\ \beta & \tilde{\nu}_{\text{mon}} \end{pmatrix}$$

The eigenvalues of the matrix are the dimer transition wavenumbers  $\tilde{\nu}_1$  and  $\tilde{\nu}_2$ . The eigenvectors are the wavefunctions for the excited states of the dimer and have the form  $\begin{pmatrix} c_j \\ c_k \end{pmatrix}$ . (a) The intensity of absorption of incident radiation is proportional to the square of the transition dipole moment (Topic 12A). The monomer transition dipole moment is  $\mu_{\text{mon}} = \int \psi_1^* \hat{\mu} \psi_0 d\tau = \int \psi_2^* \hat{\mu} \psi_0 d\tau$ ,

where  $\psi_0$  is the wavefunction of the monomer ground state. Assume that the dimer ground state may also be described by  $\psi_0$  and show that the transition dipole moment  $\mu_i$  of each dimer transition is given by  $\mu_i = \mu_{\text{mon}}(c_j + c_k)$ . (b) Consider a dimer of monomers with  $\mu_{\text{mon}} = 4.00 \text{ D}$ ,  $\tilde{\nu}_{\text{mon}} = 25000 \text{ cm}^{-1}$ , and  $r = 0.5 \text{ nm}$ . How do the transition wavenumbers  $\tilde{\nu}_1$  and  $\tilde{\nu}_2$  vary with the angle  $\theta$ ? The relative intensities of the dimer transitions may be estimated by calculating the ratio  $\mu_2^2 / \mu_1^2$ . How does this ratio vary with the angle  $\theta$ ? (c) Now expand the treatment given above to a chain of  $N$  monomers ( $N = 5, 10, 15$ , and  $20$ ), with  $\mu_{\text{mon}} = 4.00 \text{ D}$ ,  $\tilde{\nu}_{\text{mon}} = 25000 \text{ cm}^{-1}$ , and  $r = 0.5 \text{ nm}$ . For simplicity, assume that  $\theta = 0$  and that only nearest neighbours interact with interaction energy  $V$ . For example the hamiltonian matrix for the case  $N = 4$  is

$$\hat{H} = \begin{pmatrix} \tilde{\nu}_{\text{mon}} & V & 0 & 0 \\ V & \tilde{\nu}_{\text{mon}} & V & 0 \\ 0 & V & \tilde{\nu}_{\text{mon}} & V \\ 0 & 0 & V & \tilde{\nu}_{\text{mon}} \end{pmatrix}$$

How does the wavenumber of the lowest energy transition vary with size of the chain? How does the transition dipole moment of the lowest energy transition vary with the size of the chain?

**18D.2** Show that if a substance responds nonlinearly to two sources of radiation, one of frequency  $\omega_1$  and the other of frequency  $\omega_2$ , then it may give rise to radiation of the sum and difference of the two frequencies. This nonlinear optical phenomenon is known as *frequency mixing* and is used to expand the wavelength range of lasers in laboratory applications, such as spectroscopy and photochemistry.

## Integrated activities

**18.1** Calculate the thermal expansion coefficient,  $\alpha = (\partial V / \partial T)_p / V$ , of diamond given that the (111) reflection shifts from  $22.0403^\circ$  to  $21.9664^\circ$  on heating a crystal from 100 K to 300 K and  $154.0562 \text{ pm}$  X-rays are used.

**18.2** Calculate the scattering factor for a hydrogenic atom of atomic number  $Z$  in which the single electron occupies (a) the 1s orbital, (b) the 2s orbital. Plot

$f$  as a function of  $(\sin \theta) / \lambda$ . *Hint:* Interpret  $4\pi\rho(r)r^2$  as the radial distribution function  $P(r)$ .

**18.3** Explore how the scattering factor of Problem 18.2 changes when the actual 1s wavefunction of a hydrogenic atom is replaced by a Gaussian function.

## Mathematical background 7 Fourier series and Fourier transforms

Some of the most versatile mathematical functions are the trigonometric functions sine and cosine. As a result, it is often very helpful to express a general function as a linear combination of these functions and then to carry out manipulations on the resulting series. Because sines and cosines have the form of waves, the linear combinations often have a straightforward physical interpretation. Throughout this discussion, the function  $f(x)$  is real.

### MB7.1 Fourier series

A *Fourier series* is a linear combination of sines and cosines that replicates a periodic function:

$$f(x) = \frac{1}{2}a_0 + \sum_{n=1}^{\infty} \left\{ a_n \cos \frac{n\pi x}{L} + b_n \sin \frac{n\pi x}{L} \right\} \quad (\text{MB7.1})$$

A periodic function is one that repeats periodically, such that  $f(x+2L) = f(x)$  where  $2L$  is the period. Although it is perhaps not surprising that sines and cosines can be used to replicate continuous functions, it turns out that—with certain limitations—they can also be used to replicate discontinuous functions too. The coefficients in eqn MB7.1 are found by making use of the orthogonality of the sine and cosine functions

$$\int_{-L}^L \sin \frac{m\pi x}{L} \cos \frac{m\pi x}{L} dx = 0 \quad (\text{MB7.2a})$$

and the integrals

$$\int_{-L}^L \sin \frac{m\pi x}{L} \sin \frac{n\pi x}{L} dx = \int_{-L}^L \cos \frac{m\pi x}{L} \cos \frac{n\pi x}{L} dx = L\delta_{mn} \quad (\text{MB7.2b})$$

where  $\delta_{mn} = 1$  if  $m = n$  and 0 if  $m \neq n$ . Thus, multiplication of both sides of eqn MB7.1 by  $\cos(k\pi x/L)$  and integration from  $-L$  to  $L$  gives an expression for the coefficient  $a_k$ , and multiplication by  $\sin(k\pi x/L)$  and integration likewise gives an expression for  $b_k$ :

$$\begin{aligned} a_k &= \frac{1}{L} \int_{-L}^L f(x) \cos \frac{k\pi x}{L} dx \quad k=0,1,2,\dots \\ b_k &= \frac{1}{L} \int_{-L}^L f(x) \sin \frac{k\pi x}{L} dx \quad k=1,2,\dots \end{aligned} \quad (\text{MB7.3})$$

#### Brief illustration MB7.1 A square wave

Figure MB7.1 shows a graph of a square wave of amplitude  $A$  that is periodic between  $-L$  and  $L$ . The mathematical form of the wave is

$$f(x) = \begin{cases} -A & -L \leq x < 0 \\ +A & 0 \leq x < L \end{cases}$$

**Figure MB7.1** A square wave and two successive approximations by Fourier series ( $N=5$  and  $N=100$ ). The inset shows a magnification of the  $N=100$  approximation.

The coefficients  $a$  are all zero because  $f(x)$  is antisymmetric ( $f(-x) = -f(x)$ ) whereas all the cosine functions are symmetric ( $\cos(-x) = \cos(x)$ ) and so cosine waves make no contribution to the sum. The coefficients  $b$  are obtained from

$$\begin{aligned} b_k &= \frac{1}{L} \int_{-L}^L f(x) \sin \frac{k\pi x}{L} dx \\ &= \frac{1}{L} \int_{-L}^0 (-A) \sin \frac{k\pi x}{L} dx + \frac{1}{L} \int_0^L A \sin \frac{k\pi x}{L} dx \\ &= \frac{2A}{\pi} \frac{\{1 - (-1)^k\}}{k} \end{aligned}$$

The final expression has been formulated to acknowledge that the two integrals cancel when  $k$  is even but add together when  $k$  is odd. Therefore,

$$f(x) = \frac{2A}{\pi} \sum_{k=1}^N \frac{1 - (-1)^k}{k} \sin \frac{k\pi x}{L} = \frac{4A}{\pi} \sum_{n=1}^N \frac{1}{2n-1} \sin \frac{(2n-1)\pi x}{L}$$

with  $N \rightarrow \infty$ . The sum over  $n$  is the same as the sum over  $k$ ; in the latter, terms with  $k$  even are all zero. This function is plotted in Fig. MB7.1 for two values of  $N$  to show how the series becomes more faithful to the original function as  $N$  increases.

### MB7.2 Fourier transforms

The Fourier series in eqn MB7.1 can be expressed in a more succinct manner if we allow the coefficients to be complex numbers and make use of *de Moivre's relation*

$$e^{in\pi x/L} = \cos\left(\frac{n\pi x}{L}\right) + i \sin\left(\frac{n\pi x}{L}\right) \quad (\text{MB7.4})$$

for then we may write

$$f(x) = \sum_{n=-\infty}^{\infty} c_n e^{in\pi x/L} \quad c_n = \frac{1}{2L} \int_{-L}^L f(x) e^{-in\pi x/L} dx \quad (\text{MB7.5})$$

**Figure MB7.2** The formal definition of an integral as the sum of the value of a function at a series of infinitely spaced points multiplied by the separation of each point.

This complex formalism is well suited to the extension of this discussion to functions with periods that become infinite. If a period is infinite, then we are effectively dealing with a non-periodic function, such as the decaying exponential function  $e^{-x}$ .

We write  $\delta k = \pi/L$  and consider the limit as  $L \rightarrow \infty$  and therefore  $\delta k \rightarrow 0$ : that is, eqn MB7.5 becomes

$$\begin{aligned}
 f(x) &= \lim_{L \rightarrow \infty} \sum_{n=-\infty}^{\infty} \frac{1}{2L} \left\{ \int_{-L}^L f(x') e^{-in\pi x'/L} dx' \right\} e^{in\pi x/L} \\
 &= \lim_{\delta k \rightarrow 0} \sum_{n=-\infty}^{\infty} \frac{\delta k}{2\pi} \left\{ \int_{-\pi/\delta k}^{\pi/\delta k} f(x') e^{-in\delta k x'} dx' \right\} e^{in\delta k x/L} \\
 &= \lim_{\delta k \rightarrow 0} \sum_{n=-\infty}^{\infty} \frac{1}{2\pi} \left\{ \int_{-\infty}^{\infty} f(x') e^{-in\delta k(x'-x)} dx' \right\} \delta k \quad \text{(MB7.6)}
 \end{aligned}$$

In the last line we have anticipated that the limits of the integral will become infinite. At this point we should recognize that a formal definition of an integral is the sum of the value of a function at a series of infinitely spaced points multiplied by the separation of each point (Fig. MB7.2; see *Mathematical background 1*):

$$\int_a^b F(k) dk = \lim_{\delta k \rightarrow 0} \sum_{n=-\infty}^{\infty} F(n\delta k) \delta k \quad \text{(MB7.7)}$$

Exactly this form appears on the right-hand side of eqn MB7.6, so we can write that equation as

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}(k) e^{ikx} dk \quad \text{where } \tilde{f}(k) = \int_{-\infty}^{\infty} f(x') e^{-ikx'} dx' \quad \text{(MB7.8)}$$

At this stage we can drop the prime on  $x$  in the expression for  $\tilde{f}(k)$ . We call the function  $\tilde{f}(k)$  the *Fourier transform* of  $f(x)$ ; the original function  $f(x)$  is the *inverse Fourier transform* of  $\tilde{f}(k)$ .

**Brief illustration MB7.2** A Fourier transform

The Fourier transform of the symmetrical exponential function  $f(x) = e^{-a|x|}$  is

$$\begin{aligned}
 \tilde{f}(k) &= \int_{-\infty}^{\infty} f(x) e^{-ikx} dx = \int_{-\infty}^{\infty} e^{-a|x-ikx} dx \\
 &= \int_{-\infty}^0 e^{ax-ikx} dx + \int_0^{\infty} e^{-ax-ikx} dx \\
 &= \frac{1}{a-ik} + \frac{1}{a+ik} = \frac{2a}{a^2+k^2}
 \end{aligned}$$

The original function and its Fourier transform are drawn in Fig. MB7.3.

**Figure MB7.3** (a) The symmetrical exponential function  $f(x) = e^{-a|x|}$  and (b) its Fourier transform for two values of the decay constant  $a$ . Note how the function with the more rapid decay has a Fourier transform richer in short-wavelength (high  $k$ ) components.

The physical interpretation of eqn MB7.8 is that  $f(x)$  is expressed as a superposition of harmonic (sine and cosine) functions of wavelength  $\lambda = 2\pi/k$ , and that the weight of each constituent function is given by the Fourier transform at the corresponding value of  $k$ . This interpretation is consistent with the calculation in *Brief illustration MB7.2*. As we see from Fig. MB7.3, when the exponential function falls away rapidly with time, the Fourier transform is extended to high values of  $k$ , corresponding to a significant contribution from short-wavelength waves. When the exponential function decays only slowly, the most significant contributions to the superposition come from low-frequency components, which is reflected in the Fourier transform, with its predominance of small- $k$  contributions in this case. In general, a slowly varying function has a Fourier transform with significant contributions from small- $k$  components.

### MB7.3 The convolution theorem

A final point concerning the properties of Fourier transforms is the **convolution theorem**, which states that if a function is the 'convolution' of two other functions, that is if

$$F(x) = \int_{-\infty}^{\infty} f_1(x') f_2(x-x') dx' \quad (\text{MB7.9a})$$

then the Fourier transform of  $F(x)$  is the product of the Fourier transforms of its component functions:

$$\tilde{F}(k) = \tilde{f}_1(k) \tilde{f}_2(k) \quad (\text{MB7.9b})$$

#### Brief illustration MB7.3 Convolutions

Suppose that  $F(x)$  is the convolution of two Gaussian functions:

$$F(x) = \int_{-\infty}^{\infty} e^{-a^2 x'^2} e^{-b^2 (x-x')^2} dx'$$

The Fourier transform of a Gaussian function is itself a Gaussian function:

$$\tilde{f}(k) = \int_{-\infty}^{\infty} e^{-c^2 x^2} e^{-ikx} dx = \left(\frac{\pi}{c^2}\right)^{1/2} e^{-k^2/4c^2}$$

Therefore, the transform of  $F(x)$  is the product

$$\tilde{F}(k) = \left(\frac{\pi}{a^2}\right)^{1/2} e^{-k^2/4a^2} \left(\frac{\pi}{b^2}\right)^{1/2} e^{-k^2/4b^2} = \frac{\pi}{ab} e^{-(k^2/4)(1/a^2+1/b^2)}$$

# PART THREE

# Change

In Part 3 we consider the processes by which chemical change occurs and one form of matter is converted into another. We prepare the ground for a discussion of the rates of reactions by considering the motion of molecules in gases and in liquids. Then we establish the precise meaning of reaction rate and see how the overall rate, and the complex behaviour of some reactions, may be expressed in terms of elementary steps and the atomic events that take place when molecules meet. Of enormous importance in industry are reactions on solid surfaces, such as redox reactions at electrodes and various chemical transformations accelerated by solid catalysts. We discuss these processes in the final chapter of the text.

- 19 Molecules in motion
- 20 Chemical kinetics
- 21 Reaction dynamics
- 22 Processes on solid surfaces

# CHAPTER 19

## Molecules in motion

This chapter provides techniques for discussing the motion of all kinds of particles in all kinds of fluids. It makes extensive use of the kinetic theory of gases treated in Topic 1B.

### 19A Transport in gases

We set the scene by showing that molecular motion in fluids (both gases and liquids) shows a number of similarities. We concentrate on the ‘transport properties’ of a substance, its ability to transfer matter, energy, or some other property from one place to another. These properties include diffusion, thermal conduction, viscosity, and effusion and we see that their rates are expressed in terms of the kinetic theory of gases.

### 19B Motion in liquids

Molecular motion in liquids is different from that in gases on account of the intermolecular forces, which now play an important role and govern, for instance the viscosity. One way to probe motion in liquids is to drag ions through a solvent by applying an electric field, and we see how the conductivities and mobilities of ions give some insight into motion in liquids.

### 19C Diffusion

One very important type of motion in fluids is diffusion, and it turns out that it can be discussed in a uniform way by introducing the concept of a ‘thermodynamic force’. The spread of molecules can be explored by setting up and solving the ‘diffusion equation’, and that equation can be interpreted in terms of the molecules undergoing a random walk.

### What is the impact of this material?

A great deal of chemistry, chemical engineering, and biology depends on the ability of molecules and ions to migrate through media of various kinds. In *Impact* I19.1 we see how conductivity measurements are used to analyse the motion of nutrients and other matter through biological membranes.

### ► Why do you need to know this material?

The transport of properties by gas molecules plays an important role in the atmosphere. The Topic also extends the approach of kinetic theory, showing how to extract quantitative expressions from simple models.

### ► What is the key idea?

A molecule carries properties through space for about the distance of its mean free path.

### ► What do you need to know already?

This Topic builds on and extends the kinetic theory of gases (Topic 1B) and you need to be familiar with the expressions from that Topic for the mean speed of molecules and with the significance of the mean free path and its pressure-dependence.

Transport properties are commonly expressed in terms of a number of equations that are empirical summaries of experimental observations. These equations apply to all kinds of properties and media. In the following sections, we introduce

the equations for the general case and then show how to calculate the parameters that appear in them on the basis of a model of molecular behaviour in gases. A more general approach is taken in Topic 19C.

## 19A.1 The phenomenological equations

By a ‘phenomenological equation’, a term encountered commonly in the study of fluids, we mean an equation that summarizes empirical observations on phenomena without, initially at least, being based on an understanding of the molecular processes responsible for the property.

The rate of migration of a property is measured by its **flux**,  $J$ , the quantity of that property passing through a given area in a given time interval divided by the area and the duration of the interval. If matter is flowing (as in diffusion), we speak of a **matter flux** of so many molecules per square metre per second (number or amount  $\text{m}^{-2} \text{s}^{-1}$ ); if the property is energy (as in thermal conduction), then we speak of the **energy flux** and express it in joules per square metre per second ( $\text{J m}^{-2} \text{s}^{-1}$ ), and so on. To calculate the total quantity of each property transferred through a given area  $A$  in a given time interval  $\Delta t$ , we multiply the flux by the area and the time interval and form  $JA\Delta t$ .

Experimental observations on transport properties show that the flux of a property is usually proportional to the first derivative of some other related property. For example, the flux of matter diffusing parallel to the  $z$ -axis of a container is found to be proportional to the first derivative of the concentration:

$$J(\text{matter}) \propto \frac{d\mathcal{N}}{dz} \quad \text{Fick's first law of diffusion} \quad (19A.1)$$

where  $\mathcal{N}$  is the number density of particles with units number per metre cubed ( $\text{m}^{-3}$ ). The proportionality of the flux of matter to the concentration gradient is sometimes called **Fick's first law of diffusion**: the law implies that diffusion will be faster when the concentration varies steeply with position than when the concentration is nearly uniform. There is no net flux if the concentration is uniform ( $d\mathcal{N}/dz=0$ ). Similarly, the rate of thermal conduction (the flux of the energy associated with

**Figure 19A.1** The flux of particles down a concentration gradient. Fick's first law states that the flux of matter (the number of particles passing through an imaginary window in a given interval divided by the area of the window and the length of the interval) is proportional to the density gradient at that point.

thermal motion) is found to be proportional to the temperature gradient:

$$J(\text{energy of thermal motion}) \propto \frac{dT}{dz} \quad \text{Flux of energy} \quad (19A.2)$$

A positive value of  $J$  signifies a flux towards positive  $z$ ; a negative value of  $J$  signifies a flux towards negative  $z$ . Because matter flows down a concentration gradient, from high concentration to low concentration,  $J$  is positive if  $dN/dz$  is negative (Fig. 19A.1). Therefore, the coefficient of proportionality in eqn 19A.1 must be negative, and we write it  $-D$ :

$$J(\text{matter}) = -D \frac{dN}{dz} \quad \text{Fick's first law in terms of the diffusion coefficient} \quad (19A.3)$$

The constant  $D$  is called the **diffusion coefficient**; its SI units are metre squared per second ( $\text{m}^2 \text{s}^{-1}$ ). Energy migrates down a temperature gradient, and the same reasoning leads to

$$J(\text{energy of thermal motion}) = -\kappa \frac{dT}{dz} \quad \text{Flux of energy in terms of the coefficient of thermal conductivity} \quad (19A.4)$$

where  $\kappa$  is the **coefficient of thermal conductivity**. The SI units of  $\kappa$  are joules per kelvin per metre per second ( $\text{J K}^{-1} \text{m}^{-1} \text{s}^{-1}$ ) or, because  $1 \text{ J s}^{-1} = 1 \text{ W}$ , watts per kelvin per metre ( $\text{W K}^{-1} \text{m}^{-1}$ ). Some experimental values are given in Table 19A.1.

#### Brief illustration 19A.1 Energy flux

Suppose that there is a temperature difference of 10 K between two metal plates that are separated by 1.0 cm in air (for which  $\kappa = 24.1 \text{ mW K}^{-1} \text{m}^{-1}$ ). The temperature gradient is

$$\frac{dT}{dz} = -\frac{10 \text{ K}}{1.0 \times 10^{-2} \text{ m}} = -1.0 \times 10^3 \text{ K m}^{-1}$$

Therefore, because for air the energy flux is

$$J(\text{energy of thermal motion}) = -(24.1 \text{ mW K}^{-1} \text{m}^{-1}) \times (-1.0 \times 10^3 \text{ K m}^{-1}) = +24 \text{ W m}^{-2}$$

As a result, in 1.0 h (3600 s) the transfer of energy through an area of the opposite walls of  $1.0 \text{ cm}^2$  is

$$\text{Transfer} = (24 \text{ W m}^{-2}) \times (1.0 \times 10^{-4} \text{ m}^2) \times (3600 \text{ s}) = 8.6 \text{ J}$$

**Self-test 19A.1** The thermal conductivity of glass is  $0.92 \text{ W K}^{-1} \text{m}^{-1}$ . What is the rate of energy transfer through a window pane of thickness 0.50 cm and area  $1.0 \text{ m}^2$  when the room is at  $22^\circ\text{C}$  and the exterior is at  $0^\circ\text{C}$ ?

Answer: 2.8 Kw

**Table 19A.1\*** Transport properties of gases at 1 atm

	$\kappa/(\text{mW K}^{-1} \text{m}^{-1})$	$\eta/\mu\text{P}^\ddagger$

†  $1 \mu\text{P} = 10^{-7} \text{ kg m}^{-1} \text{s}^{-1}$ .

To see the connection between the flux of momentum and the viscosity, consider a fluid in a state of **Newtonian flow**, which can be imagined as occurring by a series of layers moving past one another (Fig. 19A.2). The layer next to the wall

**Figure 19A.2** The viscosity of a fluid arises from the transport of linear momentum. In this illustration the fluid is undergoing Newtonian (laminar) flow, and particles bring their initial momentum when they enter a new layer. If they arrive with high  $x$ -component of momentum they accelerate the layer; if with low  $x$ -component of momentum they retard the layer.

of the vessel is stationary, and the velocity of successive layers varies linearly with distance,  $z$ , from the wall. Molecules ceaselessly move between the layers and bring with them the  $x$ -component of linear momentum they possessed in their original layer. A layer is retarded by molecules arriving from a more slowly moving layer because they have a low momentum in the  $x$ -direction. A layer is accelerated by molecules arriving from a more rapidly moving layer. We interpret the net retarding effect as the fluid's viscosity.

Because the retarding effect depends on the transfer of the  $x$ -component of linear momentum into the layer of interest, the viscosity depends on the flux of this  $x$ -component in the  $z$ -direction. The flux of the  $x$ -component of momentum is proportional to  $d v_x / dz$  because there is no net flux when all the layers move at the same velocity. We can therefore write

$$J(\textit{x-component of momentum}) = -\eta \frac{d v_x}{dz}$$

Momentum flux in terms of the coefficient of viscosity (19A.5)

The constant of proportionality,  $\eta$ , is the **coefficient of viscosity** (or simply 'the viscosity'). Its units are kilograms per metre per second ( $\text{kg m}^{-1} \text{s}^{-1}$ ). Viscosities are often reported in poise (P), where  $1 \text{ P} = 10^{-1} \text{ kg m}^{-1} \text{ s}^{-1}$ . Some experimental values are given in Table 19A.1.

Although it is not strictly a transport property, closely related to diffusion is **effusion**, the escape of matter through a small hole. The essential empirical observations on effusion are summarized by **Graham's law of effusion**, which states that the rate of effusion is inversely proportional to the square root of the molar mass,  $M$ .

## 19A.2 The transport parameters

Here we derive expressions for the diffusion characteristics of a perfect gas on the basis of a model, the kinetic-molecular theory. All the expressions depend on knowing the **collision flux**,  $Z_w$ , the rate at which molecules strike a region in the gas (which may be an imaginary window in the gas, a part of a wall, or a hole in a wall) and specifically the number of collisions divided by the area of the region and the time interval. We show in the following *Justification* that the collision flux of molecules of mass  $m$  at a pressure  $p$  and temperature  $T$  is

$$Z_w = \frac{p}{(2\pi m k T)^{1/2}} \quad \text{Perfect gas} \quad \text{Collision flux} \quad (19A.6)$$

### Brief illustration 19A.2 The collision flux

The collision flux of  $\text{O}_2$  molecules, with  $m = M/N_A$  and  $M = 32.00 \text{ g mol}^{-1}$ , at  $25^\circ\text{C}$  and at  $1.00 \text{ bar}$  is

$$Z_w = \frac{1.00 \times 10^5 \overset{\text{kg m}^{-1} \text{ s}^{-2}}{\text{Pa}}}{\left\{ 2\pi \times \frac{32.00 \times 10^{-3} \text{ kg mol}^{-1}}{6.022 \times 10^{23} \text{ mol}^{-1}} \right.} \\ \left. \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K}) \right\}^{1/2}} \\ = 2.70 \times 10^{27} \text{ m}^{-2} \text{ s}^{-1}$$

This flux corresponds to  $2.70 \times 10^{23} \text{ cm}^{-2} \text{ s}^{-1}$ .

**Self-test 19A.2** Evaluate the collision flux of  $\text{H}_2$  molecules under the same conditions.

Answer:  $1.07 \times 10^{28} \text{ m}^{-2} \text{ s}^{-1}$

### Justification 19A.1 The collision flux

Consider a wall of area  $A$  perpendicular to the  $x$ -axis (Fig. 19A.3). If a molecule has  $v_x > 0$  (that is, it is travelling in the direction of positive  $x$ ), then it will strike the wall within an interval  $\Delta t$  if it lies within a distance  $v_x \Delta t$  of the wall. Therefore, all molecules in the volume  $A v_x \Delta t$ , and with positive  $x$ -component of velocities, will strike the wall in the interval  $\Delta t$ . The total number of collisions in this interval is therefore the volume  $A v_x \Delta t$  multiplied by the number density,  $\mathcal{N}$ , of molecules. However, to take account of the presence of a range of velocities in the sample, we must sum the result over all the positive values of  $v_x$  weighted by the probability distribution of velocities given in *Justification 1B.2*:

$$f(v_x) = \left( \frac{m}{2\pi k T} \right)^{1/2} e^{-m v_x^2 / 2k T}$$

That is,

$$\text{Number of collisions} = \mathcal{N} A \Delta t \int_0^\infty v_x f(v_x) dv_x$$

The collision flux is the number of collisions divided by  $A$  and  $\Delta t$ , so

$$Z_w = \mathcal{N} \int_0^\infty v_x f(v_x) dv_x$$

**Figure 19A.3** A molecule will reach the wall on the right within an interval  $\Delta t$  if it is within a distance  $v_x \Delta t$  of the wall and travelling to the right.

Then, because

$$\int_0^{\infty} v_x f(v_x) dv_x = \left( \frac{m}{2\pi kT} \right)^{1/2} \int_0^{\infty} v_x e^{-mv_x^2/2kT} dv_x \stackrel{\text{Integral G.2}}{=} \left( \frac{kT}{2\pi m} \right)^{1/2}$$

it follows that

$$Z_w = \mathcal{N} \left( \frac{kT}{2\pi m} \right)^{1/2}$$

Substitution of  $\mathcal{N} = p/kT$  then gives eqn 19A.6.

According to eqn 19A.6, the collision flux increases with pressure, because the rate of collisions on the region of interest increases with pressure. The flux decreases with increasing mass of the molecules because heavy molecules move more slowly than light molecules. Caution, however, is needed with the interpretation of the role of temperature, for it is wrong to conclude that because  $T^{1/2}$  appears in the denominator that the collision flux decreases with increasing temperature. If the system has constant volume, the pressure increases with temperature ( $p \propto T$ ), so the collision flux is in fact proportional to  $T/T^{1/2} = T^{1/2}$ , and increases with temperature (because the molecules are moving faster).

### (a) The diffusion coefficient

Consider the arrangement depicted in Fig. 19A.4. The molecules passing through the area  $A$  at  $z=0$  have travelled an average of about one mean free path  $\lambda$  since their last collision. Therefore, the number density where they originated is  $\mathcal{N}(z)$  evaluated at  $z = -\lambda$ . This number density is approximately

$$\mathcal{N}(-\lambda) = \mathcal{N}(0) - \lambda \left( \frac{d\mathcal{N}}{dz} \right)_0 \quad (19A.7a)$$

where we have used a Taylor expansion of the form  $f(x) = f(0) + (df/dx)_0 x + \dots$  truncated after the second term (see

**Figure 19A.4** The calculation of the rate of diffusion of a gas considers the net flux of molecules through a plane of area  $A$  as a result of arrivals from an average distance  $\lambda$  away in each direction, where  $\lambda$  is the mean free path.

*Mathematical Background 1*). Similarly, the number density at an equal distance on the other side of the area is

$$\mathcal{N}(\lambda) = \mathcal{N}(0) + \lambda \left( \frac{d\mathcal{N}}{dz} \right)_0 \quad (19A.7b)$$

The average number of impacts on the imaginary region of area  $A_0$  during an interval  $\Delta t$  is  $Z_w A_0 \Delta t$ , where  $Z_w$  is the collision flux. Therefore, the flux from left to right,  $J(L \rightarrow R)$ , arising from the supply of molecules on the left, is

$$J(L \rightarrow R) = \frac{\overbrace{\frac{1}{4} \mathcal{N}(-\lambda) v_{\text{mean}} A_0 \Delta t}^{Z_w}}{A_0 \Delta t} = \frac{1}{4} \mathcal{N}(-\lambda) v_{\text{mean}} \quad (19A.8a)$$

There is also a flux of molecules from right to left. On average, the molecules making the journey have originated from  $z = +\lambda$  where the number density is  $\mathcal{N}(\lambda)$ . Therefore,

$$J(L \leftarrow R) = \frac{1}{4} \mathcal{N}(\lambda) v_{\text{mean}} \quad (19A.8b)$$

The net flux from left to right is

$$\begin{aligned} J_z &= J(L \rightarrow R) - J(L \leftarrow R) \\ &= \frac{1}{4} v_{\text{mean}} \{ \mathcal{N}(-\lambda) - \mathcal{N}(\lambda) \} \\ &= \frac{1}{4} v_{\text{mean}} \left\{ \left[ \mathcal{N}(0) - \lambda \left( \frac{d\mathcal{N}}{dz} \right)_0 \right] - \left[ \mathcal{N}(0) + \lambda \left( \frac{d\mathcal{N}}{dz} \right)_0 \right] \right\} \end{aligned}$$

That is,

$$J_z = -\frac{1}{2} v_{\text{mean}} \lambda \left( \frac{d\mathcal{N}}{dz} \right)_0 \quad (19A.9)$$

This equation shows that the flux is proportional to the first derivative of the concentration, in agreement with Fick's law, eqn 19A.1.

At this stage it looks as though we can pick out a value of the diffusion coefficient by comparing eqns 19A.9 and 19A.3, so obtaining  $D = \frac{1}{2} \lambda v_{\text{mean}}$ . It must be remembered, however, that the calculation is quite crude, and is little more than an assessment of the order of magnitude of  $D$ . One aspect that has not been taken into account is illustrated in Fig. 19A.5, which shows that although a molecule may have begun its journey very close to the window, it could have a long flight before it gets there. Because the path is long, the molecule is likely to collide before reaching the window, so it ought to be added to the graveyard of other molecules that have collided. To take this effect into account involves a lot of work, but the end result is the appearance of a factor of  $\frac{2}{3}$  representing the lower flux. The modification results in

$$D = \frac{2}{3} \lambda v_{\text{mean}} \quad \text{Diffusion coefficient} \quad (19A.10)$$

**Figure 19A.5** One approximation ignored in the simple treatment is that some particles might make a long flight to the plane even though they are only a short perpendicular distance away, and therefore they have a higher chance of colliding during their journey.

### Brief illustration 19A.3 The diffusion coefficient

In *Brief illustration 1B.4* of Topic 1B it is established that the mean free path of  $N_2$  molecules in a gas at 1.0 bar is 95 nm; in *Example 1B.1* of the same Topic it is calculated that the mean speed of  $N_2$  molecules at 25 °C is 475 m s<sup>-1</sup>. Therefore, the diffusion coefficient for  $N_2$  molecules under these conditions is

$$D = \frac{1}{3} \times (9.5 \times 10^{-8} \text{ m}) \times 475 \text{ m s}^{-1} = 1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$$

The experimental value (for  $N_2$  in  $O_2$ ) is  $2.0 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ .

**Self-test 19A.3** Evaluate  $D$  for  $H_2$  under the same conditions.

Answer:  $9.0 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$

There are three points to note about eqn 19A.10:

- The mean free path,  $\lambda$ , decreases as the pressure is increased (eqn 1B.13 of Topic 1B,  $\lambda = kT/\sigma p$ ), so  $D$  decreases with increasing pressure and, as a result, the gas molecules diffuse more slowly.
- The mean speed,  $v_{\text{mean}}$ , increases with the temperature (eqn 1B.8 of Topic 1B,  $v_{\text{mean}} = (8RT/\pi M)^{1/2}$ ), so  $D$  also increases with temperature. As a result, molecules in a hot sample diffuse more quickly than those in a cool sample (for a given concentration gradient).
- Because the mean free path increases when the collision cross-section  $\sigma$  of the molecules decreases (eqn 1B.13 again,  $\lambda = kT/\sigma p$ ), the diffusion coefficient is greater for small molecules than for large molecules.

Physical interpretation

### (b) Thermal conductivity

According to the equipartition theorem (*Foundations C*), each molecule carries an average energy  $\varepsilon = \nu kT$ , where  $\nu$  is a number of the order of 1. For atoms,  $\nu = \frac{3}{2}$ . When one molecule passes through the imaginary window, it transports that average energy. We suppose that the number density is uniform but that the temperature is not. Molecules arrive from the left after

travelling a mean free path from their last collision in a hotter region, and therefore with a higher energy. Molecules also arrive from the right after travelling a mean free path from a cooler region. The two opposing energy fluxes are therefore

$$J(L \leftarrow R) = \frac{1}{4} \overbrace{\mathcal{N} v_{\text{mean}} \varepsilon(-\lambda)}^{Z_w} \quad J(L \leftarrow R) = \frac{1}{4} \overbrace{\mathcal{N} v_{\text{mean}} \varepsilon(\lambda)}^{Z_w} \quad (19A.11)$$

and the net flux is

$$\begin{aligned} J_z &= J(L \rightarrow R) - J(L \leftarrow R) \\ &= \frac{1}{4} v_{\text{mean}} \mathcal{N} \{ \varepsilon(-\lambda) - \varepsilon(\lambda) \} \\ &= \frac{1}{4} v_{\text{mean}} \mathcal{N} \left\{ \left[ \varepsilon(0) - \lambda \left( \frac{d\varepsilon}{dz} \right)_0 \right] - \left[ \varepsilon(0) + \lambda \left( \frac{d\varepsilon}{dz} \right)_0 \right] \right\} \end{aligned}$$

That is,

$$J_z = -\frac{1}{2} v_{\text{mean}} \lambda \mathcal{N} \left( \frac{d\varepsilon}{dz} \right)_0 = -\frac{1}{2} v v_{\text{mean}} \lambda \mathcal{N} k \left( \frac{dT}{dz} \right)_0 \quad (19A.12)$$

The energy flux is proportional to the temperature gradient, as we wanted to show. As before, we multiply by  $\frac{2}{3}$  to take long flight paths into account, and after comparison of this equation with eqn 19A.4 arrive at

$$\kappa = \frac{1}{3} v v_{\text{mean}} \lambda \mathcal{N} k \quad \text{Thermal conductivity} \quad (19A.13a)$$

If we now identify  $\mathcal{N} = n N_A / V = [J] N_A$ , where  $[J]$  is the molar concentration of the carrier particles  $J$  and  $N_A$  is Avogadro's constant, and identify  $\nu k N_A$  as the molar constant-volume heat capacity of a perfect gas (which follows from  $C_{V,m} = N_A (\partial \varepsilon / \partial T)_v$ ), this expression becomes

$$\kappa = \frac{1}{3} v_{\text{mean}} \lambda [J] C_{V,m} \quad \text{Thermal conductivity} \quad (19A.13b)$$

Yet another form is found by recognizing that  $\mathcal{N} = p/kT$  and the expression for  $D$  in eqn 19A.10, for then

$$\kappa = \frac{\nu p D}{T} \quad \text{Thermal conductivity} \quad (19A.13c)$$

### Brief illustration 19A.4 The thermal conductivity

In *Brief illustration 19A.3* we calculated  $D = 1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$  for  $N_2$  molecules at 25 °C. To use eqn 19A.13c note that for  $N_2$  molecules  $\nu = \frac{5}{2}$  (there are three translational modes and two rotational modes). Therefore, at 1.0 bar

$$\kappa = \frac{\frac{5}{2} \times (1.0 \times 10^5 \overbrace{\text{Pa}}^{\text{J m}^{-3}}) \times (1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1})}{298 \text{ K}} = 1.3 \times 10^{-2} \text{ J K}^{-1} \text{ m}^{-1} \text{ s}^{-1}$$

or  $13 \text{ mW K}^{-1} \text{ m}^{-1}$ . The experimental value is  $26 \text{ mW K}^{-1} \text{ m}^{-1}$ .

**Self-test 19A.4** Estimate the thermal conductivity of argon gas at  $25^\circ\text{C}$  and  $1.0 \text{ bar}$ .

Answer:  $8 \text{ mW K}^{-1} \text{ m}^{-1}$

To interpret eqn 19A.13, we note that:

- Because  $\lambda$  is inversely proportional to the pressure (eqn 1B.13 of Topic 1B,  $\lambda = kT/\sigma p$ ), and hence inversely proportional to the molar concentration of the gas, and  $\mathcal{N}$  is proportional to the pressure ( $\mathcal{N} = p/kT$ ), the thermal conductivity, which is proportional to the product  $\lambda p$ , is independent of the pressure.
- The thermal conductivity is greater for gases with a high heat capacity (eqn 19A.13b) because a given temperature gradient then corresponds to a greater energy gradient.

Physical interpretation

The physical reason for the pressure independence of the thermal conductivity is that it can be expected to be large when many molecules are available to transport the energy, but the presence of so many molecules limits their mean free path and they cannot carry the energy over a great distance. These two effects balance. The thermal conductivity is indeed found experimentally to be independent of the pressure, except when the pressure is very low, when  $\kappa \propto p$ . At low pressures  $\lambda$  exceeds the dimensions of the apparatus, and the distance over which the energy is transported is determined by the size of the container and not by collisions with the other molecules present. The flux is still proportional to the number of carriers, but the length of the journey no longer depends on  $\lambda$ , so  $\kappa \propto [A]$ , which implies that  $\kappa \propto p$ .

### (c) Viscosity

Molecules travelling from the right in Fig. 19A.6 (from a fast layer to a slower one) transport a momentum  $mv_x(\lambda)$  to their new layer at  $z=0$ ; those travelling from the left transport  $mv_x(-\lambda)$  to it. If it is assumed that the density is uniform, the collision flux is  $\frac{1}{4}\mathcal{N}\bar{v}_{\text{mean}}$ . Those arriving from the right on average carry a momentum

$$mv_x(\lambda) = mv_x(0) + m\lambda \left( \frac{dv_x}{dz} \right)_0 \quad (19A.14a)$$

Those arriving from the left bring a momentum

$$mv_x(-\lambda) = mv_x(0) - m\lambda \left( \frac{dv_x}{dz} \right)_0 \quad (19A.14b)$$

The net flux of  $x$ -momentum in the  $z$ -direction is therefore

**Figure 19A.6** The calculation of the viscosity of a gas examines the net  $x$ -component of momentum brought to a plane from faster and slower layers on average a mean free path away in each direction.

$$J_z = \frac{1}{4}\bar{v}_{\text{mean}}\mathcal{N} \left\{ \left[ mv_x(0) - m\lambda \left( \frac{dv_x}{dz} \right)_0 \right] - \left[ mv_x(0) + m\lambda \left( \frac{dv_x}{dz} \right)_0 \right] \right\} = -\frac{1}{2}\bar{v}_{\text{mean}}\lambda m\mathcal{N} \left( \frac{dv_x}{dz} \right)_0 \quad (19A.15)$$

The flux is proportional to the velocity gradient, as we wished to show. Comparison of this expression with eqn 19A.5, and multiplication by  $\frac{2}{3}$  in the normal way, leads to

$$\eta = \frac{1}{3}\bar{v}_{\text{mean}}\lambda m\mathcal{N} \quad \text{Viscosity} \quad (19A.16a)$$

Two alternative forms of this expression (after using  $mN_A = M$ ) are

$$\eta = MD[J] \quad \text{Viscosity} \quad (19A.16b)$$

$$\eta = \frac{pMD}{RT} \quad \text{Viscosity} \quad (19A.16c)$$

where  $[J]$  is the molar concentration of the gas molecules and  $M$  is their molar mass.

#### Brief illustration 19A.5 The viscosity

We have already calculated  $D = 1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$  for  $\text{N}_2$  at  $25^\circ\text{C}$ . Because  $M = 28.02 \text{ g mol}^{-1}$ , for the gas at  $1.0 \text{ bar}$ , eqn 19A.17c gives

$$\eta = \frac{(1.0 \times 10^5 \text{ Pa}) \times (28.02 \times 10^{-3} \text{ kg mol}^{-1}) \times (1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1})}{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = 1.7 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$$

or  $171 \mu\text{P}$ . The experimental value is  $176 \mu\text{P}$ .

**Self-test 19A.5** Evaluate the viscosity of benzene vapour at 0.10 bar and 25°C.

Answer: 140 μP

We can interpret eqn 19A.16a as follows:

- Because  $\lambda \propto 1/p$  (eqn 1B.13,  $\lambda = kT/\sigma p$ ) and  $[A] \propto p$ , it follows that  $\eta \propto \lambda N$  is independent of  $p$ . That is, the viscosity is independent of the pressure.
- Because  $v_{\text{mean}} \propto T^{1/2}$  (eqn 1B.8),  $\eta \propto T^{1/2}$ . That is, the viscosity of a gas *increases* with temperature.

Physical interpretation

The physical reason for the pressure independence of the viscosity is the same as for the thermal conductivity: more molecules are available to transport the momentum, but they carry it less far on account of the decrease in mean free path. The increase of viscosity with temperature is explained when we remember that at high temperatures the molecules travel more quickly, so the flux of momentum is greater. By contrast, as discussed in Topic 19B, the viscosity of a liquid *decreases* with increase in temperature because intermolecular interactions must be overcome.

#### (d) Effusion

Because the mean speed of molecules is inversely proportional to  $M^{1/2}$ , the rate at which they strike the area of the hole through which they are effusing is also inversely proportional to  $M^{1/2}$ , in accord with Graham's law. However, by using the expression for the collision flux, we can obtain a more detailed expression for the rate of effusion and hence use effusion data more effectively.

When a gas at a pressure  $p$  and temperature  $T$  is separated from a vacuum by a small hole, the rate of escape of its molecules is equal to the rate at which they strike the area of the hole, which is the product of the collision flux and the area of the hole,  $A_0$ :

$$\begin{aligned} \text{Rate of effusion} &= Z_{\text{W}} A_0 \\ &= \frac{p A_0}{(2\pi m k T)^{1/2}} \stackrel{\substack{m=M/N_A \\ k=R/N_A}}{\cong} \frac{p A_0 N_A}{(2\pi M R T)^{1/2}} \end{aligned} \quad \text{Rate of effusion} \quad (19A.17)$$

This rate is inversely proportional to  $M^{1/2}$ , in accord with Graham's law. Do not conclude from eqn 19A.17, however, that

effusion is slower at high temperatures than at low. Because  $p \propto T$ , the rate is in fact proportional to  $T^{1/2}$  and increases with temperature.

Equation 19A.17 is the basis of the **Knudsen method** for the determination of the vapour pressures of liquids and solids, particularly of substances with very low vapour pressures. Thus, if the vapour pressure of a sample is  $p$ , and it is enclosed in a cavity with a small hole, then the rate of loss of mass from the container is proportional to  $p$ .

#### Example 19A.1 Calculating the vapour pressure from a mass loss

Caesium (m.p. 29°C, b.p. 686°C) was introduced into a container and heated to 500°C. When a hole of diameter 0.50 mm was opened in the container for 100 s, a mass loss of 385 mg was measured. Calculate the vapour pressure of liquid caesium at 500 K.

**Method** The pressure of vapour is constant inside the container despite the effusion of atoms because the hot liquid metal replenishes the vapour. The rate of effusion is therefore constant, and given by eqn 19A.17. To express the rate in terms of mass, multiply the number of atoms that escape by the mass of each atom.

**Answer** The mass loss  $\Delta m$  in an interval  $\Delta t$  is related to the collision flux by

$$\Delta m = Z_{\text{W}} A_0 m \Delta t$$

where  $A_0$  is the area of the hole and  $m$  is the mass of one atom. It follows that

$$Z_{\text{W}} = \frac{\Delta m}{A_0 m \Delta t}$$

Because  $Z_{\text{W}}$  is related to the pressure by eqn 19A.17, we can write

$$p = \left( \frac{2\pi R T}{M} \right)^{1/2} \frac{\Delta m}{A_0 \Delta t}$$

Because  $M = 132.9 \text{ g mol}^{-1}$ , substitution of the data gives  $p = 8.7 \text{ kPa}$  (using  $1 \text{ Pa} = 1 \text{ N m}^{-2} = 1 \text{ J m}^{-1}$ ), or 65 Torr.

**Self-test 19A.6** How long would it take 1.0 g of Cs atoms to effuse out of the oven under the same conditions?

Answer: 260 s

## Checklist of concepts

1. **Flux** is the quantity of a property passing through a given area in a given time interval divided by the area and the duration of the interval.
2. **Diffusion** is the migration of matter down a concentration gradient.

- 3. **Fick's first law of diffusion** states that the flux of matter is proportional to the concentration gradient.
- 4. **Thermal conduction** is the migration of energy down a temperature gradient and the flux of energy is proportional to the temperature gradient.
- 5. **Viscosity** is the migration of linear momentum down a velocity gradient and the flux of momentum is proportional to the velocity gradient.
- 6. **Effusion** is the emergence of a gas from a container through a small hole.
- 7. **Graham's law of effusion** states that the rate of effusion is inversely proportional to the square root of the molar mass.
- 8. The coefficients of diffusion, thermal conductivity, and viscosity of a perfect gas are proportional to the product of the mean free path and mean speed.

## Checklist of equations

Property	Equation	Comment	Equation number
Fick's first law of diffusion	$J = -D \frac{dN}{dz}$		19A.3
Flux of energy of thermal motion	$J = -\kappa \frac{dT}{dz}$		19A.4
Flux of momentum	$J = -\eta \frac{dv_x}{dz}$		19A.5
Diffusion coefficient of a perfect gas	$D = \frac{1}{3} \lambda v_{\text{mean}}$	KMT*	19A.10
Coefficient of thermal conductivity of a perfect gas	$\kappa = \frac{1}{3} v_{\text{mean}} \lambda [J] C_{V,m}$	KMT and equipartition	19A.13b
Coefficient of viscosity of a perfect gas	$\eta = \frac{1}{3} v_{\text{mean}} \lambda m \mathcal{N}$	KMT	19A.16a
Rate of effusion	Rate $\propto 1/M^{1/2}$	Graham's law	19A.17

\* KMT indicates that the equation is based on the kinetic theory of gases.

### ► Why do you need to know this material?

Liquids are central to chemical reactions, and it is important to know how the mobility of their molecules and solutes in them varies with the conditions. Ionic motion is a way of exploring this motion as forces to move them can be applied electrically. From electrical measurements the properties of diffusing neutral molecules may also be inferred.

### ► What is the key idea?

The viscosity of a liquid decreases with increasing temperature; ions reach a terminal velocity when the electrical force on them is balanced by the drag due to the viscosity of the solvent.

### ► What do you need to know already?

The discussion of viscosity starts with the definition of viscosity coefficient introduced in Topic 19A. One derivation uses the same argument about flux as was used in Topic 19A. The final section quotes the relation between the drift speed and a generalized force acting on a solute particle, which is derived in Topic 19C. You need to be aware of several concepts from electrostatics, which are introduced in *Foundations B*.

In this Topic we consider two aspects of motion in liquids. First, we deal with pure liquids, and examine how the mobilities of their molecules, as measured by their viscosity, varies with temperature. Then we consider the motion of solutes. A particularly simple and to some extent controllable type of motion through a liquid, is that of an ion, and we shall see that the information that motion provides can be used to infer the behaviour of uncharged species too.

## 19B.1 Experimental results

The motion of molecules in liquids can be studied experimentally by a variety of methods. Relaxation time measurements in NMR (Topic 14C) and EPR can be interpreted in terms of the mobilities of the molecules, and have been used to show that big molecules in viscous fluids typically rotate in a series of small (about 5°) steps, whereas small molecules in non-viscous fluids typically jump through about 1 radian (57°) in each step. Another important technique is **inelastic neutron scattering**, in which the energy neutrons collect or discard as they pass through a sample is interpreted in terms of the motion of its particles. The same technique is used to examine the internal dynamics of macromolecules.

### (a) Liquid viscosity

The coefficient of viscosity,  $\eta$  (eta), is introduced in Topic 19A as a phenomenological coefficient, the constant of proportionality between the flux of linear momentum and the velocity gradient in a fluid:

$$J_z(x\text{-component of momentum}) = -\eta \frac{dv_x}{dz} \quad \text{Viscosity} \quad (19B.1)$$

(This is eqn 19A.5 of Topic 19A.) Some values for liquids are given in Table 19B.1. The SI units of viscosity are kilograms per metre per second ( $\text{kg m}^{-1} \text{s}^{-1}$ ), but they may also be reported in the equivalent units of pascal seconds (Pa s). The non-SI unit poise (P) and centipoise (cP) are still widely encountered:  $1 \text{ P} = 10^{-1} \text{ Pa s}$  and so  $1 \text{ cP} = 1 \text{ mPa s}$ .

Unlike in a gas, for a molecule to move in a liquid it must acquire at least a minimum energy (an 'activation energy' in the language of Topic 20D) to escape from its neighbours. The probability that a molecule has at least an energy  $E_a$  is proportional to  $e^{-E_a/RT}$ , so the mobility of the molecules in the liquid

Table 19B.1\* Viscosities of liquids at 298 K,  $\eta/(10^{-3} \text{ kg m}^{-1} \text{ s}^{-1})$ 

	$\eta/(10^{-3} \text{ kg m}^{-1} \text{ s}^{-1})$
Benzene	0.601
Mercury	1.55
Pentane	0.224
Water <sup>‡</sup>	0.891

\* More values are given in the Resource section.

‡ The viscosity of water corresponds to 0.891 cP.

should follow this type of temperature dependence. Because the coefficient of viscosity is inversely proportional to the mobility of the particles, we should expect that

$$\eta = \eta_0 e^{E_a/RT} \quad \text{Temperature dependence of viscosity (liquid)} \quad (19B.2)$$

(Note the positive sign of the exponent, because the viscosity is *inversely* proportion to the mobility.) This expression implies that the viscosity should decrease sharply with increasing temperature. Such a variation is found experimentally, at least over reasonably small temperature ranges (Fig. 19B.1). The activation energy typical of viscosity is comparable to the mean potential energy of intermolecular interactions.

One problem with the interpretation of viscosity measurements is that the change in density of the liquid as it is heated makes a pronounced contribution to the temperature variation of the viscosity. Thus, the temperature dependence of viscosity at constant volume, when the density is constant, is much less than that at constant pressure. The intermolecular interactions between the molecules of the liquid govern the magnitude of  $E_a$ , but the problem of calculating it is immensely difficult and still largely unsolved. At low temperatures, the viscosity of water decreases as the pressure is increased. This behaviour is consistent with the need to rupture hydrogen bonds for migration to occur.

Figure 19B.1 The experimental temperature dependence of the viscosity of water. As the temperature is increased, more molecules are able to escape from the potential wells provided by their neighbours, and so the liquid becomes more fluid.

### Brief illustration 19B.1 Liquid viscosity

The viscosity of water at 25 °C and 50 °C is 0.890 mPa s and 0.547 mPa s, respectively. It follows from eqn 19B.2 that the activation energy for molecular migration is the solution of

$$\frac{\eta(T_2)}{\eta(T_1)} = e^{(E_a/R)(1/T_2 - 1/T_1)}$$

which is

$$E_a = \frac{R \ln\{\eta(T_2)/\eta(T_1)\}}{1/T_2 - 1/T_1} = \frac{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \ln(0.547/0.890)}{1/320 \text{ K} - 1/298 \text{ K}}$$

or 17.5 kJ mol<sup>-1</sup>. That value is comparable to the strength of a hydrogen bond.

**Self-test 19B.1** The corresponding values of the viscosity of benzene are 0.604 mPa s and 0.436 mPa s. Evaluate the activation energy for viscosity.

Answer: 11.7 kJ mol<sup>-1</sup>

## (b) Electrolyte solutions

Further insight into the nature of molecular motion can be obtained by studying the net transport of charged species through solution, for ions can be dragged through the solvent by the application of a potential difference between two electrodes immersed in the sample. By studying the transport of charge through electrolyte solutions it is possible to build up a picture of the events that occur in them and, in some cases, to extrapolate the conclusions to species that have zero charge; that is, to neutral molecules.

The fundamental measurement used to study the motion of ions is that of the electrical resistance,  $R$ , of the solution. The **conductance**,  $G$ , of a solution is the inverse of its resistance  $R$ :  $G = 1/R$ . As resistance is expressed in ohms,  $\Omega$ , the conductance of a sample is expressed in  $\Omega^{-1}$ . The reciprocal ohm used to be called the mho, but its SI designation is now the siemens, S, and  $1 \text{ S} = 1 \text{ } \Omega^{-1} = 1 \text{ C V}^{-1} \text{ s}^{-1}$ . It is found that the conductance of a sample decreases with its length  $l$  and increases with its cross-sectional area  $A$ . We therefore write

$$G = \kappa \frac{A}{l} \quad \text{Definition of } \kappa \quad \text{Conductivity} \quad (19B.3)$$

where  $\kappa$  (kappa) is the electrical **conductivity**. With the conductance in siemens and the dimensions in metres, it follows that the SI units of  $\kappa$  are siemens per metre ( $\text{S m}^{-1}$ ).

The conductivity of a solution depends on the number of ions present, and it is normal to introduce the **molar conductivity**,  $A_m$ , which is defined as

$$A_m = \frac{\kappa}{c} \quad \text{Definition} \quad \text{Molar conductivity} \quad (19B.4)$$

where  $c$  is the molar concentration of the added electrolyte. The SI unit of molar conductivity is siemens metre-squared per mole ( $\text{S m}^2 \text{mol}^{-1}$ ), and typical values are about  $10 \text{ mS m}^2 \text{mol}^{-1}$  (where  $1 \text{ mS} = 10^{-3} \text{ S}$ ).

The values of the molar conductivity as calculated by eqn 19B.4 are found to vary with the concentration. One reason for this variation is that the number of ions in the solution might not be proportional to the nominal concentration of the electrolyte. For instance, the concentration of ions in a solution of a weak electrolyte depends on the concentration of the solute in a complicated way, and doubling the concentration of the solute added does not double the number of ions. Secondly, because ions interact strongly with one another, the conductivity of a solution is not exactly proportional to the number of ions present.

In an extensive series of measurements during the nineteenth century, Friedrich Kohlrausch established the **Kohlrausch law**, that at low concentrations the molar conductivities of strong electrolytes vary linearly with the square root of the concentration:

$$A_m = A_m^\circ - \mathcal{K}c^{1/2} \quad \text{Kohlrausch law} \quad (19\text{B.5})$$

He also established that  $A_m^\circ$ , the **limiting molar conductivity**, the molar conductivity in the limit of zero concentration, is the sum of contributions from its individual ions. If the limiting molar conductivity of the cations is denoted  $\lambda_+$ , and that of the anions  $\lambda_-$ , then his **law of the independent migration of ions** states that

$$A_m^\circ = \nu_+ \lambda_+ + \nu_- \lambda_- \quad \text{Limiting law} \quad \text{Law of the independent migration of ions} \quad (19\text{B.6})$$

where  $\nu_+$  and  $\nu_-$  are the numbers of cations and anions per formula unit of electrolyte. For example,  $\nu_+ = \nu_- = 1$  for HCl, NaCl, and  $\text{CuSO}_4$ , but  $\nu_+ = 1$ ,  $\nu_- = 2$  for  $\text{MgCl}_2$ .

### Example 19B.1 Determining the limiting molar conductivity

The conductivity of  $\text{KCl}(\text{aq})$  at  $25^\circ\text{C}$  is  $14.668 \text{ mS m}^{-1}$  when  $c = 1.0000 \text{ mmol dm}^{-3}$  and  $71.740 \text{ mS m}^{-1}$  when  $c = 5.0000 \text{ mmol dm}^{-3}$ . Determine the values of the limiting molar conductivity  $A_m^\circ$  and the Kohlrausch constant  $\mathcal{K}$ .

**Method** Use eqn 19B.4 to determine the molar conductivities at the two concentrations, then use the Kohlrausch law, eqn 19B.5, in the form

$$A_m(c_2) - A_m(c_1) = \mathcal{K}(c_1^{1/2} - c_2^{1/2})$$

to determine  $\mathcal{K}$ . Then find  $A_m^\circ$  from the law in the form

$$A_m^\circ = A_m + \mathcal{K}c^{1/2}$$

With more data available, a better procedure is to perform a linear regression.

**Answer** It follows that the molar conductivity of  $\text{KCl}$  when  $c = 1.0000 \text{ mmol dm}^{-3}$  (which is the same as  $1.0000 \text{ mol m}^{-3}$ ) is

$$A_m = \frac{14.688 \text{ mS m}^{-1}}{1.0000 \text{ mol m}^{-3}} = 14.688 \text{ mS m}^2 \text{mol}^{-1}$$

Similarly, when  $c = 5.0000 \text{ mol dm}^{-3}$  the molar conductivity is  $14.348 \text{ mS m}^2 \text{mol}^{-1}$ . It then follows that

$$\begin{aligned} \mathcal{K} &= \frac{A_m(c_2) - A_m(c_1)}{c_1^{1/2} - c_2^{1/2}} \\ &= \frac{(14.348 - 14.688) \text{ mS m}^2 \text{mol}^{-1}}{(0.0010000^{1/2} - 0.0050000^{1/2}) (\text{mol dm}^{-3})^{1/2}} \\ &= 8.698 \text{ mS m}^2 \text{mol}^{-1} / (\text{mol dm}^{-3})^{1/2} \end{aligned}$$

(It is best to keep this awkward but convenient array of units as they are rather than converting them to the equivalent  $10^{-3/2} \text{ S m}^{7/2} \text{mol}^{-3/2}$ .) Now we find the limiting value from the data for  $c = 0.0100 \text{ mol dm}^{-3}$ :

$$\begin{aligned} A_m^\circ &= 14.688 \text{ mS m}^2 \text{mol}^{-1} + 8.698 \frac{\text{mS m}^2 \text{mol}^{-1}}{(\text{mol dm}^{-3})^{1/2}} \\ &\quad \times (0.0010000 \text{ mol dm}^{-3})^{1/2} = 14.963 \text{ mS m}^2 \text{mol}^{-1} \end{aligned}$$

**Self-test 19B.2** The conductivity of  $\text{KClO}_4(\text{aq})$  at  $25^\circ\text{C}$  is  $13.780 \text{ mS m}^{-1}$  when  $c = 1.000 \text{ mmol dm}^{-3}$  and  $67.045 \text{ mS m}^{-1}$  when  $c = 5.000 \text{ mmol dm}^{-3}$ . Determine the values of the limiting molar conductivity  $A_m^\circ$  and the Kohlrausch constant  $\mathcal{K}$  for this system.

$$\text{Answer: } \mathcal{K} = 9.491 \text{ mS m}^2 \text{mol}^{-1} / (\text{mol dm}^{-3})^{1/2}, \quad A_m^\circ = 14.08 \text{ mS m}^2 \text{mol}^{-1}$$

## 19B.2 The mobilities of ions

To interpret conductivity measurements we need to know why ions move at different rates, why they have different molar conductivities, and why the molar conductivities of strong electrolytes decrease with the square root of the molar concentration. The central idea in this section is that although the motion of an ion remains largely random, the presence of an electric field biases its motion, and the ion undergoes net migration through the solution.

### (a) The drift speed

When the potential difference between two planar electrodes a distance  $l$  apart is  $\Delta\phi$ , the ions in the solution between them experience a uniform electric field of magnitude

$$E = \frac{\Delta\phi}{l} \quad (19\text{B.7})$$

In such a field, an ion of charge  $ze$  experiences a force of magnitude

$$F = zeE = \frac{ze\Delta\phi}{l} \quad \text{Electric force} \quad (19B.8)$$

where here and throughout this section we disregard the sign of the charge number and so avoid notational complications.

A cation responds to the application of the field by accelerating towards the negative electrode and an anion responds by accelerating towards the positive electrode. However, this acceleration is short lived. As the ion moves through the solvent it experiences a frictional retarding force,  $F_{\text{fric}}$ , proportional to its speed. For a spherical particle of radius  $a$  travelling at a speed  $s$ , this force is given by **Stokes' law**, which was derived by considering the hydrodynamics of the passage of a sphere through a continuous fluid:

$$F_{\text{fric}} = fs \quad f = 6\pi\eta a \quad \text{Stokes' law} \quad (19B.9)$$

where  $\eta$  is the viscosity. In writing eqn 19B.9, we have assumed that it applies on a molecular scale, and independent evidence from magnetic resonance suggests that it often gives at least the right order of magnitude.

The two forces act in opposite directions, and the ions quickly reach a terminal speed, the **drift speed**, when the accelerating force is balanced by the viscous drag. The net force is zero when  $fs = zeE$ , or

$$s = \frac{zeE}{f} \quad \text{Drift speed} \quad (19B.10)$$

It follows that the drift speed of an ion is proportional to the strength of the applied field. We write

$$s = uE \quad \text{Definition of } u \quad \text{Mobility} \quad (19B.11)$$

where  $u$  is called the **mobility** of the ion (Table 19B.2). Comparison of the last two equations shows that

$$u = \frac{ze}{f} = \frac{ze}{6\pi\eta a} \quad \text{Mobility} \quad (19B.12)$$

**Table 19B.2\*** Ionic mobilities in water at 298 K,  $u/(10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1})$

	$u/(10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1})$		$u/(10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1})$
H <sup>+</sup>	36.23	OH <sup>-</sup>	20.64
Na <sup>+</sup>	5.19	Cl <sup>-</sup>	7.91
K <sup>+</sup>	7.62	Br <sup>-</sup>	8.09
Zn <sup>2+</sup>	5.47	SO <sub>4</sub> <sup>2-</sup>	8.29

\* More values are given in the *Resource section*.

### Brief illustration 19B.2 Ion mobility

For an order of magnitude estimate we can take  $z=1$  and  $a$  the radius of an ion such as Cs<sup>+</sup> (which might be typical of a smaller ion plus its hydration sphere), which is 170 pm. For the viscosity, we use  $\eta=1.0$  cP (1.0 mPa s, Table 19B.1). Then

$$u = \frac{1.6 \times 10^{-19} \overset{\text{JV}^{-1}}{\text{C}}}{6\pi \times \left( 1.0 \times 10^{-3} \frac{\text{Pa s}}{\text{J m}^{-3}} \right) \times (170 \times 10^{-12} \text{ m})} \\ = 5.0 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$$

This value means that when there is a potential difference of 1 V across a solution of length 1 cm (so  $E=100 \text{ V m}^{-1}$ ), the drift speed is typically about  $5 \mu\text{m s}^{-1}$ . That speed might seem slow, but not when expressed on a molecular scale, for it corresponds to an ion passing about  $10^4$  solvent molecules per second.

**Self-test 19B.3** The mobility of an SO<sub>4</sub><sup>2-</sup> ion in water at 25 °C is  $8.29 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ . What is its effective radius?

Answer: 205 pm

Because the drift speed governs the rate at which charged species are transported, we might expect the conductivity to decrease with increasing solution viscosity and ion size. Experiments confirm these predictions for bulky ions (such as R<sub>4</sub>N<sup>+</sup> and RCO<sub>2</sub><sup>-</sup>) but not for small ions. For example, the mobilities of the alkali metal ions in water increase from Li<sup>+</sup> to Cs<sup>+</sup> (Table 19B.2) even though the ionic radii increase. The paradox is resolved when we realize that the radius  $a$  in the Stokes formula is the **hydrodynamic radius** (or 'Stokes radius') of the ion, its effective radius in the solution taking into account all the H<sub>2</sub>O molecules it carries in its hydration shell. Small ions give rise to stronger electric fields than large ones (the electric field at the surface of a sphere of radius  $r$  is proportional to  $ze/r^2$  and it follows that the smaller the radius the stronger the field), so small ions are more extensively solvated than big ions. Thus, an ion of small ionic radius may have a large hydrodynamic radius because it drags many solvent molecules through the solution as it migrates. The hydrating H<sub>2</sub>O molecules are often very labile, however, and NMR and isotope studies have shown that the exchange between the coordination sphere of the ion and the bulk solvent is very rapid for ions of low charge but may be slow for ions of high charge.

The proton, although it is very small, has a very high mobility (Table 19B.2)! Proton and <sup>17</sup>O-NMR show that the times characteristic of protons hopping from one molecule to the next are about 1.5 ps, which is comparable to the time that inelastic neutron scattering shows it takes a water molecule to

Figure 19B.2 A highly schematic diagram showing the effective motion of a proton in water.

reorient through about 1 radian (1 to 2 ps). According to the **Grotthuss mechanism**, there is an effective motion of a proton that involves the rearrangement of bonds in a group of water molecules (Fig. 19B.2). However, the actual mechanism is still highly contentious. The mobility of  $\text{NH}_4^+$  in liquid ammonia is also anomalous and presumably occurs by an analogous mechanism.

### (b) Mobility and conductivity

Ionic mobilities provide a link between measurable and theoretical quantities. As a first step we establish in the following *Justification* the relation between an ion's mobility and its molar conductivity:

$$\lambda = zuF \quad \text{Ion conductivity} \quad (19B.13)$$

where  $F$  is Faraday's constant ( $F = N_A e$ ).

#### Justification 19B.1 The relation between ionic mobility and molar conductivity

To keep the calculation simple, we ignore signs in the following, and concentrate on the magnitudes of quantities.

Consider a solution of a fully dissociated strong electrolyte at a molar concentration  $c$ . Let each formula unit give rise to  $\nu_+$  cations of charge  $z_+e$  and  $\nu_-$  anions of charge  $z_-e$ . The molar concentration of each type of ion is therefore  $\nu c$  (with  $\nu = \nu_+$  or  $\nu_-$ ), and the number density of each type is  $\nu c N_A$ . The number of ions of one kind that pass through an imaginary window of area  $A$  during an interval  $\Delta t$  is equal to the number within the distance  $s\Delta t$  (Fig. 19B.3), and therefore to the number in the volume  $s\Delta t A$ . (The same sort of argument is used in Topic 19A in the discussion of the transport properties of gases.) The number of ions of that kind in this volume is equal to  $s\Delta t A \nu c N_A$ . The flux through the window (the number of this type of ion passing through the window divided by the area of the window and the duration of the interval) is therefore

$$J(\text{ions}) = \frac{s\Delta t A \nu c N_A}{\Delta t A} = \nu c N_A$$

Figure 19B.3 In the calculation of the current, all the cations within a distance  $s_+\Delta t$  (that is, those in the volume  $s_+A\Delta t$ ) will pass through the area  $A$ . The anions in the corresponding volume the other side of the window will also contribute to the current similarly.

Each ion carries a charge  $ze$ , so the flux of charge is

$$J(\text{charge}) = zsvceN_A = zsvcF$$

Because  $s = uE$ , the flux is

$$J(\text{charge}) = zuvcFE$$

The current,  $I$ , through the window due to the ions we are considering is the charge flux times the area:

$$I = JA = zuvcFEA$$

Because the electric field is the potential gradient (eqn 19B.7,  $E = \Delta\phi/l$ ), we can write

$$I = \frac{zuvcFA\Delta\phi}{l}$$

Current and potential difference are related by Ohm's law,  $\Delta\phi = IR$ , so it follows that

$$I = \frac{\Delta\phi}{R} = G\Delta\phi = \frac{\kappa A \Delta\phi}{l}$$

where we have used eqn 19B.3 in the form  $\kappa = G/lA$ . Comparison of the last two expressions gives  $\kappa = zuvcF$ . Division by the molar concentration of ions,  $\nu c$ , then results in eqn 19B.13.

Equation 19B.13 applies to the cations and to the anions. Therefore, for the solution itself in the limit of zero concentration (when there are no ionic interactions),

$$\Lambda_m^\circ = (z_+u_+\nu_+ + z_-u_-\nu_-)F \quad (19B.14a)$$

For a symmetrical  $z:z$  electrolyte (for example,  $\text{CuSO}_4$  with  $z=2$ ), this equation simplifies to

$$\Lambda_m^\circ = z(u_+ + u_-)F \quad (19B.14b)$$

**Brief illustration 19B.3** Ionic conductivity

Earlier, we estimated the typical ionic mobility as  $5.0 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ ; so, with  $z=1$  for both the cation and anion, we can estimate that a typical limiting molar conductivity should be about

$$l = (5.0 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}) \times (9.648 \times 10^4 \text{ C mol}^{-1}) \\ = 4.8 \times 10^{-3} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1} \text{ C mol}^{-1}$$

But  $1 \text{ V C}^{-1} \text{ s} = 1 \text{ S}$  (see the remark preceding eqn 19B.3), so  $\lambda \approx 5 \text{ mS m}^2 \text{ mol}^{-1}$ , and about twice that value for  $\Lambda_{\text{m}}^{\circ}$ , in accord with experiment. The experimental value for KCl, for instance, is  $15 \text{ mS m}^2 \text{ mol}^{-1}$ .

**Self-test 19B.4** Estimate the ionic conductivity of an  $\text{SO}_4^{2-}$  ion in water at  $25^\circ \text{C}$  from its mobility (Table 19B.2).

Answer:  $16 \text{ mS m}^2 \text{ mol}^{-1}$

**(c) The Einstein relations**

An important relation between the drift speed  $s$  and a force  $F$  of any kind acting on a particle is derived in Topic 19C:

$$s = \frac{DF}{RT} \quad \text{Drift speed} \quad (19B.15)$$

where  $D$  is the diffusion coefficient for the species (Table 19B.3). We have seen that an ion in solution has a drift speed  $s = uE$  when it experiences a force  $N_A e z E$  from an electric field of strength  $E$ . Therefore, substituting these known values into eqn 19B.15 and using  $N_A e = F$  gives  $uE = DFzE/RT$  and hence, on cancelling the  $E$ , we obtain the **Einstein relation**:

$$u = \frac{zDF}{RT} \quad \text{Einstein relation} \quad (19B.16)$$

The Einstein relation provides a link between the molar conductivity of an electrolyte and the diffusion coefficients of its ions. First, by using eqns 19B.13 and 19B.16 we write

$$\lambda = zuF = \frac{z^2 DF^2}{RT} \quad (19B.17)$$

for each type of ion. Then, from  $\Lambda_{\text{m}}^{\circ} = \nu_+ \lambda_+ + \nu_- \lambda_-$ , the limiting molar conductivity is

$$\Lambda_{\text{m}}^{\circ} = (\nu_+ z_+^2 D_+ + \nu_- z_-^2 D_-) \frac{F^2}{RT} \quad \text{Nernst-Einstein equation} \quad (19B.18)$$

which is the **Nernst-Einstein equation**. An application of this equation is to the determination of ionic diffusion coefficients

**Table 19B.3\*** Diffusion coefficients at 298 K,  $D/(10^{-9} \text{ m}^2 \text{ s}^{-1})$ 

Molecules in liquids	Ions in water

\* More values are given in the *Resource section*.

from conductivity measurements; another is to the prediction of conductivities using models of ionic diffusion.

Equations 19B.12 ( $u = ze/f$ ) and 19B.16 ( $u = zDF/RT$  in the form  $u = zDe/kT$ ) relate the mobility of an ion to the frictional force and to the diffusion coefficient, respectively. We can combine the two expressions and cancel the  $ze$  and obtain the **Stokes-Einstein equation**:

$$D = \frac{kT}{f} \quad \text{Stokes-Einstein equation} \quad (19B.19a)$$

If the frictional force is described by Stokes' law, then we also obtain a relation between the diffusion coefficient and the viscosity of the medium:

$$D = \frac{kT}{6\pi\eta a} \quad \text{Stokes-Einstein equation} \quad (19B.19b)$$

An important feature of eqn 19B.19b is that it makes no reference to the charge of the diffusing species. Therefore, the equation also applies in the limit of vanishingly small charge; that is, it also applies to neutral molecules. This feature is taken further in Topic 19C. It must not be forgotten, however, that both equations depend on the assumption that the viscous drag is proportional to the speed.

**Brief illustration 19B.4** Mobility and diffusion

From Table 19B.2, the mobility of  $\text{SO}_4^{2-}$  is  $8.29 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ . It follows from eqn 19B.16 in the form  $D = uRT/zF$  that the diffusion coefficient for the ion in water at  $25^\circ \text{C}$  is

$$D = \frac{(8.29 \times 10^{-8} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{2 \times \left( 9.649 \times 10^4 \frac{\text{C}}{\text{V}} \text{ mol}^{-1} \right)} \\ = 1.06 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$$

**Self-test 19B.5** Repeat the calculation for the  $\text{NH}_4^+$  ion.

Answer:  $1.96 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$

## Checklist of concepts

- 1. The **viscosity of a liquid** decreases with increasing temperature.
- 2. The **conductance**,  $G$ , of a solution is the inverse of its resistance.
- 3. **Kohlrausch's law** states that at low concentrations the molar conductivities of strong electrolytes vary linearly with the square root of the concentration.
- 4. The **law of the independent migration of ions** states the molar conductivity in the limit of zero concentration, is the sum of contributions from its individual ions.
- 5. An ion reaches a **drift speed** when the acceleration due to the electrical force is balanced by the viscous drag.
- 6. The **hydrodynamic radius** of an ion may be greater than its geometrical radius due to solvation.
- 7. The high mobility of a proton in water is explained by the **Grotthuss mechanism**.

## Checklist of equations

Property	Equation	Comment	Equation number
Viscosity of a liquid	$\eta = \eta_0 e^{E_a/RT}$	Narrow temperature range	19B.2
Conductivity	$\kappa = G/A$ , $G = 1/R$	Definition	19B.3
Molar conductivity	$\Lambda_m = \kappa/c$	Definition	19B.4
Kohlrausch's law	$\Lambda_m = \Lambda_m^\circ - Kc^{1/2}$	Empirical observation	19B.5
Law of independent migration of ions	$\Lambda_m^\circ = \nu_+ \lambda_+ + \nu_- \lambda_-$	Limiting law	19B.6
Stokes' law	$F_{\text{fric}} = f s$ $f = 6\pi\eta a$	Hydrodynamic radius	19B.9
Drift speed	$s = uE$	Defines $u$	19B.11
Ion mobility	$u = ze/6\pi\eta a$	Assumes Stokes' law	19B.12
Conductivity and mobility	$\lambda = zuF$		19B.13
Molar conductivity and mobility	$\Lambda_m^\circ = (\nu_+ u_+ \nu_- u_-)F$		19B.14a
Drift speed	$s = DF/RT$		19B.15
Einstein relation	$u = zDF/RT$		19B.16
Nernst–Einstein relation	$\Lambda_m^\circ = (\nu_+ z_+^2 D_+ + \nu_- z_-^2 D_-)(F^2/RT)$		19B.18
Stokes–Einstein relation	$D = kT/f$		19B.19a

### ► Why do you need to know this material?

Diffusion is a hugely important process both in the atmosphere and in solution, and it is important to be able to predict the spread of one material through another when discussing reactions in solution and the spread of substances into the environment. The interpretation of diffusion in terms of a random walk also gives insight into the molecular basis of the process.

### ► What is the key idea?

Particles tend to spread and achieve a uniform distribution.

### ► What do you need to know already?

This Topic draws on arguments relating to flux that are treated in Topic 19A, particularly the way to calculate the flux of particles through a window of given area. This Topic goes into more detail about the diffusion coefficient, which was introduced in Topic 19A and used in Topic 19B. It uses the concept of chemical potential (Topic 5A) to discuss the direction of spontaneous change. One of the *Justifications* develops the random walk model introduced in Topic 17A.

That solutes in gases, liquids, and solids have a tendency to spread can be discussed from three points of view. One viewpoint is from the Second Law of thermodynamics and the tendency for entropy to increase or, if the temperature and pressure are constant, for the Gibbs energy to decrease. When this law is applied to solutes it appears that there is a force acting to disperse the solute. That force is illusory, but it provides an interesting and useful approach to discussing diffusion. The second approach is to set up a differential equation for the change in concentration in a region by considering the flux of material through its boundaries. The resulting ‘diffusion equation’ can then be solved (in principle, at least) for various configurations of the system, including taking into account the shape of a reaction vessel. The third approach is more mechanistic, and is to imagine diffusion as taking place in a series of random small steps.

## 19C.1 The thermodynamic view

It is established in Topic 3C that, at constant temperature and pressure, the maximum non-expansion work that can be done per mole when a substance moves from one location to another differing in molar Gibbs energy by  $dG_m$  is  $dw_e = dG_m$ . In terms of the chemical potentials of the substance in the two locations (its partial molar Gibbs energy),  $dw_e = d\mu$ . In a system in which the chemical potential depends on the position  $x$ ,

$$dw = d\mu = \left( \frac{\partial \mu}{\partial x} \right)_{T,p} dx$$

It is also shown in Topic 2A that in general work can always be expressed in terms of an opposing force (which here we write  $F$ ), and that  $dw = -Fdx$ . By comparing these two expressions for  $dw$  we see that the slope of the chemical potential with respect to position can be interpreted as an effective force per mole of molecules. We write this **thermodynamic force** as

$$F = - \left( \frac{\partial \mu}{\partial x} \right)_{T,p} \quad \text{Thermodynamic force} \quad (19C.1)$$

There is not necessarily a real force pushing the particles down the slope of the chemical potential. As we shall see, the force may represent the spontaneous tendency of the molecules to disperse as a consequence of the Second Law and the hunt for maximum entropy.

In a solution in which the activity of the solute is  $a$ , the chemical potential is  $\mu = \mu^\ominus + RT \ln a$ . If the solution is not uniform the activity depends on the position and we can write

$$\mathcal{F} = -RT \left( \frac{\partial \ln a}{\partial x} \right)_{T,p} \quad (19C.2a)$$

If the solution is ideal,  $a$  may be replaced by the molar concentration  $c$ , and then

$$\mathcal{F} = -RT \left( \frac{\partial \ln c}{\partial x} \right)_{T,p} \stackrel{d \ln y / dx = (1/y)(dy/dx)}{\cong} -\frac{RT}{c} \left( \frac{\partial c}{\partial x} \right)_{T,p} \quad (19C.2b)$$

### Brief illustration 19C.1 The thermodynamic force

Suppose a linear concentration gradient is set up across a container at 25 °C, with points separated by 1.0 cm differing in concentration by 0.10 mol dm<sup>-3</sup> around a mean value of 1.0 mol dm<sup>-3</sup>. According to eqn 19C.2b, the solute experiences a thermodynamic force of magnitude

$$|\mathcal{F}| = \frac{(8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{1.0 \text{ mol dm}^{-3}} \times \frac{0.10 \text{ mol dm}^{-3}}{1.0 \times 10^{-2} \text{ m}} \\ = 2.5 \times 10^4 \text{ J m}^{-1} \text{ mol}^{-1}$$

or 25 kN mol<sup>-1</sup>. Note that the thermodynamic force is a molar quantity.

**Self-test 19C.1** Suppose that the concentration of a solute decreases exponentially as  $c(x) = c_0 e^{-x/\lambda}$ . Derive an expression for the thermodynamic force.

Answer:  $\mathcal{F} = RT/\lambda$

In Topic 19A it is established that Fick's first law of diffusion, which we write here in the form

$$J(\text{number}) = -D \frac{dN}{dx} \quad \text{Fick's first law} \quad (19C.3)$$

can be deduced from the kinetic model of gases. Here we generalize that result and show that it applies to the diffusion of species in condensed phases too. To do so, we suppose that the flux of diffusing particles is a response to a thermodynamic force due to a concentration gradient. The diffusing particles reach a steady 'drift speed',  $s$ , when the thermodynamic force,  $\mathcal{F}$ , is matched by the drag due to the viscosity of the medium. This drift speed is proportional to the thermodynamic force, and we write  $s \propto \mathcal{F}$ . However, the particle flux,  $J$ , is proportional to the drift speed, and the thermodynamic force is proportional to the concentration gradient,  $dc/dx$ . The chain of proportionalities

( $J \propto s$ ,  $s \propto \mathcal{F}$ , and  $\mathcal{F} \propto dc/dx$ ) implies that  $J \propto dc/dx$ , which is the content of Fick's law.

If we divide both sides of eqn 19C.3 by Avogadro's constant, so converting numbers into amounts (numbers of moles), noting that  $\mathcal{N}/N_A = (N/V)/N_A = (nN_A/V)/N_A = n/V = c$ , the molar concentration, then Fick's law becomes

$$J(\text{amount}) = -D \frac{dc}{dx} \quad (19C.4)$$

In this expression,  $D$  is the diffusion coefficient and  $dc/dx$  is the slope of the molar concentration. The flux is related to the drift speed by

$$J(\text{amount}) = sc \quad (19C.5)$$

This relation follows from the argument used in Topic 19A. Thus, all particles within a distance  $s\Delta t$ , and therefore in a volume  $s\Delta tA$ , can pass through a window of area  $A$  in an interval  $\Delta t$ . Hence, the amount of substance that can pass through the window in that interval is  $s\Delta tAc$ . The particle flux is this quantity divided by the area  $A$  and the time interval  $\Delta t$ , and is therefore simply  $sc$ .

By combining the last two equations for  $J(\text{amount})$  and using eqn 19C.2b

$$sc = -D \frac{dc}{dx} = \frac{Dc\mathcal{F}}{RT} \quad \text{or} \quad s = \frac{D\mathcal{F}}{RT} \quad (19C.6)$$

Therefore, once we know the effective force and the diffusion coefficient,  $D$ , we can calculate the drift speed of the particles (and vice versa) whatever the origin of the force. This equation is used in Topic 19B, where the force is applied electrically to an ion.

### Brief illustration 19C.2 The thermodynamic force and the drift speed

Laser measurements showed that a molecule has a drift speed of 1.0 μm s<sup>-1</sup> in water at 25 °C, with diffusion coefficient 5.0 × 10<sup>-9</sup> m<sup>2</sup> s<sup>-1</sup>. The corresponding thermodynamic force from eqn 19C.6 in the form  $\mathcal{F} = sRT/D$  is

$$\mathcal{F} = \frac{(1.0 \times 10^{-6} \text{ m s}^{-1}) \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{(5.0 \times 10^{-9} \text{ m}^2 \text{ s}^{-1})} \\ = 5.0 \times 10^5 \text{ J m}^{-1} \text{ mol}^{-1}$$

or about 500 kN mol<sup>-1</sup>.

**Self-test 19C.2** What thermodynamic force would achieve a drift speed of 10 μm s<sup>-1</sup> in water at 25 °C?

Answer: 5.0 MN mol<sup>-1</sup>

## 19C.2 The diffusion equation

We now turn to the discussion of time-dependent diffusion processes, where we are interested in the spreading of inhomogeneities with time. One example is the temperature of a metal bar that has been heated at one end: if the source of heat is removed, then the bar gradually settles down into a state of uniform temperature. When the source of heat is maintained and the bar can radiate, it settles down into a steady state of non-uniform temperature. Another example (and one more relevant to chemistry) is the concentration distribution in a solvent to which a solute is added. We shall focus on the description of the diffusion of particles, but similar arguments apply to the diffusion of physical properties, such as temperature. Our aim is to obtain an equation for the rate of change of the concentration of particles in an inhomogeneous region.

### (a) Simple diffusion

The central equation of this section is the **diffusion equation**, also called ‘Fick’s second law of diffusion’, which relates the rate of change of concentration at a point to the spatial variation of the concentration at that point:

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \quad \text{Diffusion equation} \quad (19C.7)$$

We show in the following *Justification* that the diffusion equation follows from Fick’s first law of diffusion.

#### Justification 19C.1 The diffusion equation

Consider a thin slab of cross-sectional area  $A$  that extends from  $x$  to  $x + \lambda$  (Fig. 19C.1). Let the concentration at  $x$  be  $c$  at the time  $t$ . The rate at which the amount (in moles) of particles

**Figure 19C.1** The net flux in a region is the difference between the flux entering from the region of high concentration (on the left) and the flux leaving to the region of low concentration (on the right).

enter the slab is  $JA$ , so the rate of increase in molar concentration inside the slab (which has volume  $A\lambda$ ) on account of the flux from the left is

$$\frac{\partial c}{\partial t} = \frac{JA}{A\lambda} = \frac{J}{\lambda}$$

There is also an outflow through the right-hand window. The flux through that window is  $J'$ , and the rate of change of concentration that results is

$$\frac{\partial c}{\partial t} = -\frac{J'}{\lambda}$$

The net rate of change of concentration is therefore

$$\frac{\partial c}{\partial t} = \frac{J - J'}{\lambda}$$

Each flux is proportional to the concentration gradient at the respective window. So, by using Fick’s first law, we can write

$$J - J' = -D \frac{\partial c}{\partial x} + D \frac{\partial c'}{\partial x}$$

The concentration at the right-hand window is related to that on the left by

$$c' = c + \left( \frac{\partial c}{\partial x} \right) \lambda$$

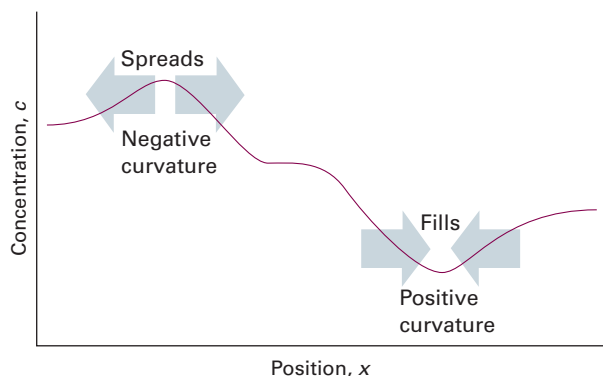

which implies that

$$J - J' = -D \frac{\partial c}{\partial x} + D \frac{\partial}{\partial x} \left\{ c + \left( \frac{\partial c}{\partial x} \right) \lambda \right\} = D \lambda \frac{\partial^2 c}{\partial x^2}$$

When this relation is substituted into the expression for the rate of change of concentration in the slab, we get eqn 19C.7.

The diffusion equation shows that the rate of change of concentration is proportional to the curvature (more precisely, to the second derivative) of the concentration with respect to distance. If the concentration changes sharply from point to point (i.e. if the distribution is highly wrinkled), then the concentration changes rapidly with time. Where the curvature is positive (a dip, Fig. 19C.2), the change in concentration is positive; the dip tends to fill. Where the curvature is negative (a heap), the change in concentration is negative; the heap tends to spread. If the curvature is zero, then the concentration is constant in time. If the concentration decreases linearly with distance, then the concentration at any point is constant because the inflow of particles is exactly balanced by the outflow.

The diffusion equation can be regarded as a mathematical formulation of the intuitive notion that there is a natural tendency for the wrinkles in a distribution to disappear. More succinctly: Nature abhors a wrinkle.

**Figure 19C.2** Nature abhors a wrinkle. The diffusion equation tells us that peaks in a distribution (regions of negative curvature) spread and troughs (regions of positive curvature) fill in.

### Brief illustration 19C.3 The diffusion equation

If a concentration falls linearly across a small region of space, in the sense that  $c = c_0 - ax$  then  $\partial^2 c / \partial x^2 = 0$  and consequently  $\partial c / \partial t = 0$ . The concentration in the region is constant because the inward flow through one window is matched by the outward flow through the other window (Fig. 19C.3a). If the concentration varies as  $c = c_0 - \frac{1}{2}ax^2$  then  $\partial^2 c / \partial x^2 = -a$  and consequently  $\partial c / \partial t = -Da$ . Now the concentration decreases, because there is a greater outward flow than inward flow (Fig. 19C.3b).

**Figure 19C.3** The two instances treated in *Brief illustration 19C.3*: (a) linear concentration gradient, (b) parabolic concentration gradient.

**Self-test 19C.3** What is the change in concentration when the concentration falls exponentially across a region? Take  $c = c_0 e^{-x/\lambda}$ .

Answer:  $\partial c / \partial t = -(D/\lambda^2)c$

### (b) Diffusion with convection

The transport of particles arising from the motion of a streaming fluid is called **convection**. If for the moment we ignore diffusion,

then the flux of particles through an area  $A$  in an interval  $\Delta t$  when the fluid is flowing at a velocity  $v$  can be calculated in the way we have used several times elsewhere (such as in Topic 19A, by counting the particles within a distance  $v\Delta t$ ), and is

$$J_{\text{conv}} = \frac{cA v \Delta t}{A \Delta t} = cv \quad \text{Convective flux} \quad (19C.8)$$

This  $J$  is called the **convective flux**. The rate of change of concentration in a slab of thickness  $l$  and area  $A$  is, by the same argument as before and assuming that the velocity does not depend on the position,

$$\frac{\partial c}{\partial t} = \frac{J_{\text{conv}} - J'_{\text{conv}}}{\lambda} = \frac{cv}{\lambda} - \left\{ c + \left( \frac{\partial c}{\partial x} \right) \lambda \right\} \frac{v}{\lambda} = - \left( \frac{\partial c}{\partial x} \right) v \quad \text{Convection} \quad (19C.9)$$

When both diffusion and convection occur, the total change of concentration in a region is the sum of the two effects, and the **generalized diffusion equation** is

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} - v \frac{\partial c}{\partial x} \quad \text{Generalized diffusion equation} \quad (19C.10)$$

A further refinement, which is important in chemistry, is the possibility that the concentrations of particles may change as a result of reaction. When reactions are included in eqn 19C.10 (which we do in Topic 21B) we get a powerful differential equation for discussing the properties of reacting, diffusing, convecting systems, which is the basis of reactor design in chemical industry and of the utilization of resources in living cells.

### Brief illustration 19C.4 Convection

Here we continue the discussion of the systems treated in *Brief illustration 19C.3* and suppose that there is a convective flow  $v$ . If the concentration falls linearly across a small region of space, in the sense that  $c = c_0 - ax$  then  $\partial c / \partial x = -a$  and the change in concentration in the region is  $\partial c / \partial t = av$ . There is now an increase in the region because the inward convective flow outweighs the outward flow, and there is no diffusion. If  $a = 0.010 \text{ mol dm}^{-3} \text{ m}^{-1}$  and  $v = +1.0 \text{ mm s}^{-1}$ ,

$$\begin{aligned} \frac{\partial c}{\partial t} &= (0.010 \text{ mol dm}^{-3} \text{ m}^{-1}) \times (1.0 \times 10^{-3} \text{ m s}^{-1}) \\ &= 1.0 \times 10^{-5} \text{ mol dm}^{-3} \text{ s}^{-1} \end{aligned}$$

and the concentration increases at the rate of  $10 \mu\text{mol dm}^{-3} \text{ s}^{-1}$ .

**Self-test 19C.4** What rate of flow is needed to replenish the concentration when the concentration varies exponentially as  $c = c_0 e^{-x/\lambda}$  across the region?

Answer:  $v = D/\lambda$

### (c) Solutions of the diffusion equation

The diffusion equation is a second-order differential equation with respect to space and a first-order differential equation with respect to time. Therefore, we must specify two boundary conditions for the spatial dependence and a single initial condition for the time dependence (see *Mathematical background 4* following Chapter 8).

As an illustration, consider a solvent in which the solute is initially coated on one surface of the container (for example, a layer of sugar on the bottom of a deep beaker of water). The single initial condition is that at  $t=0$  all  $N_0$  particles are concentrated on the  $yz$ -plane (of area  $A$ ) at  $x=0$ . The two boundary conditions are derived from the requirements (1) that the concentration must everywhere be finite and (2) that the total amount (number of moles) of particles present is  $n_0$  (with  $n_0=N_0/N_A$ ) at all times. These requirements imply that the flux of particles is zero at the top and bottom surfaces of the system. Under these conditions it is found that

$$c(x,t) = \frac{n_0}{A(\pi Dt)^{1/2}} e^{-x^2/4Dt} \quad \text{One-dimensional diffusion} \quad (19C.11)$$

as may be verified by direct substitution. Figure 19C.4 shows the shape of the concentration distribution at various times, and it is clear that the concentration spreads and tends to uniformity.

Another useful result is for a localized concentration of solute in a three-dimensional solvent (a sugar lump suspended in a large flask of water). The concentration of diffused solute is spherically symmetrical, and at a radius  $r$  is

$$c(x,t) = \frac{n_0}{8(\pi Dt)^{3/2}} e^{-r^2/4Dt} \quad \text{Three-dimensional diffusion} \quad (19C.12)$$

**Figure 19C.4** The concentration profiles above a plane from which a solute is diffusing. The curves are plots of eqn 19C.11 and are labelled with different values of  $Dt$ . The units of  $Dt$  and  $x$  are arbitrary, but are related so that  $Dt/x^2$  is dimensionless. For example, if  $x$  is in metres,  $Dt$  would be in metres<sup>2</sup>; so, for  $D=10^{-9}$  m<sup>2</sup> s<sup>-1</sup>,  $Dt=0.1$  m<sup>2</sup> corresponds to  $t=10^8$  s.

Other chemically (and physically) interesting arrangements, such as transport of substances across biological membranes can be treated. In many cases the solutions are more cumbersome.

The solutions of the diffusion equation are useful for experimental determinations of diffusion coefficients. In the **capillary technique**, a capillary tube, open at one end and containing a solution, is immersed in a well-stirred larger quantity of solvent, and the change of concentration in the tube is monitored. The solute diffuses from the open end of the capillary at a rate that can be calculated by solving the diffusion equation with the appropriate boundary conditions, so  $D$  may be determined. In the **diaphragm technique**, the diffusion occurs through the capillary pores of a sintered glass diaphragm separating the well-stirred solution and solvent. The concentrations are monitored and then related to the solutions of the diffusion equation corresponding to this arrangement. Diffusion coefficients may also be measured by a number of techniques, including NMR spectroscopy.

The solutions of the diffusion equation can be used to predict the concentration of particles (or the value of some other physical quantity, such as the temperature in a non-uniform system) at any location. We can also use them to calculate the average displacement of the particles in a given time.

#### Example 19C.1 Calculating the average displacement

Calculate the average displacement of particles in a time  $t$  in a one-dimensional system if they have a diffusion constant  $D$ .

**Method** We need to calculate the probability that a particle will be found at a certain distance from the origin, and then calculate the average by weighting each distance by that probability.

**Answer** The number of particles in a slab of thickness  $dx$  and area  $A$  at  $x$ , where the molar concentration is  $c$ , is  $cAN_A dx$ . The probability that any of the  $N_0=n_0N_A$  particles is in the slab is therefore  $cAN_A dx/N_0$ . If the particle is in the slab, it has travelled a distance  $x$  from the origin. Therefore, the average displacement of all the particles is the sum of each  $x$  weighted by the probability of its occurrence:

$$\langle x \rangle = \int_0^\infty x \frac{c(x,t)AN_A}{N_0} dx = \frac{1}{(\pi Dt)^{1/2}} \int_0^\infty x e^{-x^2/4Dt} dx \stackrel{\text{Integral G.2}}{=} 2 \left( \frac{Dt}{\pi} \right)^{1/2}$$

The average displacement varies as the square root of the lapsed time.

**Self-test 19C.5** Derive an expression for the root-mean-square distance travelled by diffusing particles in a time  $t$  in a one-dimensional system. You will need Integral G.3 from the *Resource section*.

Answer:  $\langle x^2 \rangle^{1/2} = (2Dt)^{1/2}$

**Figure 19C.5** The root-mean-square distance covered by particles with  $D=5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ . Note the great slowness of diffusion.

As shown in *Example 19C.1*, the average displacement of a diffusing particle in a time  $t$  in a one-dimensional system is

$$x = 2 \left( \frac{Dt}{\pi} \right)^{1/2} \quad \text{One dimension} \quad \text{Mean displacement} \quad (19C.13)$$

and the root-mean-square displacement in the same time is

$$\langle x^2 \rangle^{1/2} = (2Dt)^{1/2} \quad \text{One dimension} \quad \text{Root-mean-square displacement} \quad (19C.14)$$

The latter is a valuable measure of the spread of particles when they can diffuse in both directions from the origin (for then  $\langle x \rangle = 0$  at all times). The root-mean-square displacement of particles with a typical diffusion coefficient in a liquid ( $D = 5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ ) is illustrated in Fig. 19C.5, which shows how long it takes for diffusion to increase the net distance travelled on average to about 1 cm in an unstirred solution. The graph shows that diffusion is a very slow process (which is why solutions are stirred, to encourage mixing by convection). The diffusion of pheromones in still air is also very slow, and greatly accelerated by convection.

### 19C.3 The statistical view

An intuitive picture of diffusion is of the particles moving in a series of small steps and gradually migrating from their original positions. We explore this idea by using a model in which the particles can jump through a distance  $\lambda$  in a time  $\tau$ . The total distance travelled by a particle in a time  $t$  is therefore  $t\lambda/\tau$ . However, the particle will not necessarily be found at that distance from the origin. The direction of each step may be different, and the net distance travelled must take the changing directions into account.

If we simplify the discussion by allowing the particles to travel only along a straight line (the  $x$ -axis), and for each step (to the left or the right) to be through the same distance  $\lambda$ , then we obtain the **one-dimensional random walk**. The same model can be used to discuss the random coil structures of denatured polymers (Topic 17B).

We show in the following *Justification* that the probability of a particle being at a distance  $x$  from the origin after a time  $t$  is

$$P(x, t) = \left( \frac{2\tau}{\pi t} \right)^{1/2} e^{-x^2\tau/2t\lambda^2} \quad \text{One dimension} \quad \text{Probability} \quad (19C.15)$$

#### Justification 19C.2 The one-dimensional random walk

The starting point for this calculation is the expression derived in *Justification 17A.1*, with steps in place of the bonds treated there, for the probability that the net distance  $n\lambda$  reached from the origin with  $n = N_R - N_L$  after  $N$  steps each of length  $\lambda$ , with  $N_R$  steps to the right and  $N_L$  to the left is

$$P(n\lambda) = \frac{N!}{(N - N_R)! N_R! 2^N}$$

As in *Justification 17A.1*, this expression can be developed by making use of Stirling's approximation (Topic 15A) in the form

$$\ln x! \approx \ln(2\pi)^{1/2} + \left(x + \frac{1}{2}\right) \ln x - x$$

but here we use the parameter

$$\mu = \frac{N_R}{N} - \frac{1}{2} \ll 1$$

which is small because almost half the steps are to the right. The smallness of  $\mu$  allows us to use the expansion

$$\ln\left(\frac{1}{2} \pm \mu\right) = -\ln 2 \pm 2\mu - 2\mu^2 + \dots$$

and retain terms through  $O(\mu^2)$  in the overall expression for  $\ln P(n\lambda)$ . The final result, after quite a lot of algebra (see Problem 19C.11) is

$$P(n\lambda) = \frac{2^{N+1} e^{-2N\mu^2}}{2^N (2\pi N)^{1/2}} = \frac{2e^{-2N\mu^2}}{(2\pi N)^{1/2}}$$

At this point we recognize that

$$N\mu^2 = \frac{(2N_R - N)^2}{4N} = \frac{(N_R - N_L)^2}{4N} = \frac{n^2}{4N}$$

The net distance from the origin is  $x = n\lambda$  and the number of steps taken in a time  $t$  is  $N = t/\tau$ , so  $N\mu^2 = \pi x^2/4t\lambda^2$ . Substitution of these quantities into the expression for  $P$  gives eqn 19C.15.

The differences of detail between eqns 19C.11 (for one-dimensional diffusion) and 19C.15 arises from the fact that in the present calculation the particles can migrate in either direction from the origin. Moreover, they can be found only at discrete points separated by  $\lambda$  instead of being anywhere on a continuous line. The fact that the two expressions are so similar suggests that diffusion can indeed be interpreted as the outcome of a large number of steps in random directions.

We can now relate the coefficient  $D$  to the step length  $\lambda$  and the rate at which the jumps occur. Thus, by comparing the two exponents in eqn 19C.11 and eqn 19C.15 we can immediately write down the **Einstein–Smoluchowski equation**:

$$D = \frac{\lambda^2}{2\tau} \quad \text{Einstein–Smoluchowski equation} \quad (19C.16)$$

#### Brief illustration 19C.5 Random walk

Suppose an  $\text{SO}_4^{2-}$  ion jumps through its own diameter each time it makes a move in an aqueous solution, then because  $D = 1.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  and  $a = 250 \text{ pm}$  (as deduced from mobility measurements, Topic 19B), it follows from  $\lambda = 2a$  that

$$\tau = \frac{(2a)^2}{2D} = \frac{2a^2}{D} = \frac{2 \times (250 \times 10^{-12} \text{ pm})^2}{1.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}} = 1.1 \times 10^{-10} \text{ s}$$

or  $\tau = 110 \text{ ps}$ . Because  $\tau$  is the time for one jump, the ion makes about  $1 \times 10^{10}$  jumps per second.

**Self-test 19C.6** What would be the diffusion constant for a similar ion that is 50 per cent larger than  $\text{SO}_4^{2-}$  and leaps through its own diameter at only 30 per cent of the rate?

Answer:  $2.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$

The Einstein–Smoluchowski equation is the central connection between the microscopic details of particle motion and the macroscopic parameters relating to diffusion. It also brings us back full circle to the properties of the perfect gas treated in Topic 19A. For if we interpret  $\lambda/\tau$  as  $v_{\text{mean}}$ , the mean speed of the molecules, and interpret  $\lambda$  as a mean free path, then we can recognize in the Einstein–Smoluchowski equation essentially the same expression as we obtained from the kinetic model of gases (eqn 19A.10 of Topic 19A,  $D = \frac{1}{3} \lambda v_{\text{mean}}$ ). That is, the diffusion of a perfect gas is a random walk with an average step size equal to the mean free path.

## Checklist of concepts

- 1. A **thermodynamic force** represents the spontaneous tendency of the molecules to disperse as a consequence of the Second Law and the hunt for maximum entropy.
- 2. The **diffusion equation** (Fick's second law; see below) can be regarded as a mathematical formulation of the notion that there is a natural tendency for concentration to become uniform.
- 3. **Convection** is the transport of particles arising from the motion of a streaming fluid.
- 4. An intuitive picture of diffusion is of the particles moving in a series of small steps, a **random walk**, and gradually migrating from their original positions.

## Checklist of equations

Property	Equation	Comment	Equation number
Thermodynamic force	$\mathcal{F} = -(\partial\mu/\partial x)_{T,p}$	Definition	19C.1
Fick's first law	$J(\text{amount}) = -Ddc/dx$		19C.4
Convective flux	$J = sc$		19C.5
Drift speed	$s = D\mathcal{F}/RT$		19C.6
Diffusion equation	$\partial c/\partial t = D\partial^2 c/\partial x^2$	One dimension	19C.7
Generalized diffusion equation	$\partial c/\partial t = D\partial^2 c/\partial x^2 - v\partial c/\partial x$	One dimension	19C.10

---

Property	Equation	Comment	Equation number
Mean displacement	$\langle x \rangle = 2(Dt/\pi)^{1/2}$	One-dimensional diffusion	19C.13
Root-mean-square displacement	$\langle x^2 \rangle^{1/2} = (2Dt)^{1/2}$	One-dimensional diffusion	19C.14
Probability of displacement	$P(x, t) = (2\tau/\pi t)^{1/2} e^{-x^2/2\tau\lambda^2}$	One-dimensional random walk	19C.15
Einstein–Smoluchowski equation	$D = \lambda^2/2\tau$	One-dimensional random walk	19C.16

---

# CHAPTER 19 Molecules in motion

## TOPIC 19A Transport properties of a perfect gas

### Discussion questions

**19A.1** Explain how Fick's first law arises from the concentration gradient of gas molecules.

**19A.2** Provide molecular interpretations for the dependencies of the diffusion constant and the viscosity on the temperature, pressure, and size of gas molecules.

**19A.3** What might be the effect of molecular interactions on the transport properties of a gas?

### Exercises

**19A.1(a)** Calculate the thermal conductivity of argon ( $C_{V,m} = 12.5 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $\sigma = 0.36 \text{ nm}^2$ ) at 298 K.

**19A.1(b)** Calculate the thermal conductivity of nitrogen ( $C_{V,m} = 20.8 \text{ J K}^{-1} \text{ mol}^{-1}$ ,  $\sigma = 0.43 \text{ nm}^2$ ) at 298 K.

**19A.2(a)** Calculate the diffusion constant of argon at 20 °C and (i) 1.00 Pa, (ii) 100 kPa, (iii) 10.0 MPa. If a pressure gradient of  $1.0 \text{ bar m}^{-1}$  is established in a pipe, what is the flow of gas due to diffusion?

**19A.2(b)** Calculate the diffusion constant of nitrogen at 20 °C and (i) 100.0 Pa, (ii) 100 kPa, (iii) 20.0 MPa. If a pressure gradient of  $1.20 \text{ bar m}^{-1}$  is established in a pipe, what is the flow of gas due to diffusion?

**19A.3(a)** Calculate the flux of energy arising from a temperature gradient of  $10.5 \text{ K m}^{-1}$  in a sample of argon in which the mean temperature is 280 K.

**19A.3(b)** Calculate the flux of energy arising from a temperature gradient of  $8.5 \text{ K m}^{-1}$  in a sample of hydrogen in which the mean temperature is 290 K.

**19A.4(a)** Use the experimental value of the thermal conductivity of neon (Table 19A.2) to estimate the collision cross-section of Ne atoms at 273 K.

**19A.4(b)** Use the experimental value of the thermal conductivity of nitrogen (Table 19A.2) to estimate the collision cross-section of  $\text{N}_2$  molecules at 273 K.

**19A.5(a)** In a double-glazed window, the panes of glass are separated by 1.0 cm. What is the rate of transfer of heat by conduction from the warm room (28 °C) to the cold exterior (−15 °C) through a window of area  $1.0 \text{ m}^2$ ? What power of heater is required to make good the loss of heat?

**19A.5(b)** Two sheets of copper of area  $2.00 \text{ m}^2$  are separated by 5.00 cm in air. What is the rate of transfer of heat by conduction from the warm sheet (70 °C) to the cold sheet (0 °C).

**19A.6(a)** Use the experimental value of the coefficient of viscosity for neon (Table 19A.1) to estimate the collision cross-section of Ne atoms at 273 K.

**19A.6(b)** Use the experimental value of the coefficient of viscosity for nitrogen (Table 19A.1) to estimate the collision cross-section of the molecules at 273 K.

**19A.7(a)** Calculate the viscosity of air at (i) 273 K, (ii) 298 K, (iii) 1000 K. Take  $\sigma \approx 0.40 \text{ nm}^2$ . (The experimental values are  $173 \mu\text{P}$  at 273 K,  $182 \mu\text{P}$  at 20 °C, and  $394 \mu\text{P}$  at 600 °C.)

**19A.7(b)** Calculate the viscosity of benzene vapour at (i) 273 K, (ii) 298 K, (iii) 1000 K. Take  $\sigma \approx 0.88 \text{ nm}^2$ .

**19A.8(a)** A solid surface with dimensions  $2.5 \text{ mm} \times 3.0 \text{ mm}$  is exposed to argon gas at 90 Pa and 500 K. How many collisions do the Ar atoms make with this surface in 15 s?

**19A.8(b)** A solid surface with dimensions  $3.5 \text{ mm} \times 4.0 \text{ cm}$  is exposed to helium gas at 111 Pa and 1500 K. How many collisions do the He atoms make with this surface in 10 s?

**19A.9(a)** An effusion cell has a circular hole of diameter 2.50 mm. If the molar mass of the solid in the cell is  $260 \text{ g mol}^{-1}$  and its vapour pressure is 0.835 Pa at 400 K, by how much will the mass of the solid decrease in a period of 2.00 h?

**19A.9(b)** An effusion cell has a circular hole of diameter 3.00 mm. If the molar mass of the solid in the cell is  $300 \text{ g mol}^{-1}$  and its vapour pressure is 0.224 Pa at 450 K, by how much will the mass of the solid decrease in a period of 24.00 h?

**19A.10(a)** A solid compound of molar mass  $100 \text{ g mol}^{-1}$  was introduced into a container and heated to 400 °C. When a hole of diameter 0.50 mm was opened in the container for 400 s, a mass loss of 285 mg was measured. Calculate the vapour pressure of the compound at 400 °C.

**19A.10(b)** A solid compound of molar mass  $200 \text{ g mol}^{-1}$  was introduced into a container and heated to 300 °C. When a hole of diameter 0.50 mm was opened in the container for 500 s, a mass loss of 277 mg was measured. Calculate the vapour pressure of the compound at 300 °C.

**19A.11(a)** A manometer was connected to a bulb containing carbon dioxide under slight pressure. The gas was allowed to escape through a small pinhole, and the time for the manometer reading to drop from 75 cm to 50 cm was 52 s. When the experiment was repeated using nitrogen (for which  $M = 28.02 \text{ g mol}^{-1}$ ) the same fall took place in 42 s. Calculate the molar mass of carbon dioxide.

**19A.11(b)** A manometer was connected to a bulb containing nitrogen under slight pressure. The gas was allowed to escape through a small pinhole, and the time for the manometer reading to drop from 65.1 cm to 42.1 cm was 18.5 s. When the experiment was repeated using a fluorocarbon gas, the same fall took place in 82.3 s. Calculate the molar mass of the fluorocarbon.

**19A.12(a)** A space vehicle of internal volume  $3.0 \text{ m}^3$  is struck by a meteor and a hole of radius 0.10 mm is formed. If the oxygen pressure within the vehicle is initially 80 kPa and its temperature 298 K, how long will the pressure take to fall to 70 kPa?

**19A.12(b)** A container of internal volume  $22.0 \text{ m}^3$  was punctured, and a hole of radius 0.050 mm was formed. If the nitrogen pressure within the container is initially 122 kPa and its temperature 293 K, how long will the pressure take to fall to 105 kPa?

### Problems

**19A.1\*** A. Feghhour et al. (*J. Phys. Chem. Ref. Data* **24**, 1649 (1995)) compiled an extensive table of viscosity coefficients for ammonia in the liquid and

vapour phases. Deduce the effective molecular diameter of  $\text{NH}_3$  based on each of the following vapour-phase viscosity coefficients: (a)  $\eta = 9.08 \times 10^{-6} \text{ kg m}^{-1} \text{ s}^{-1}$  at 270 K and 1.00 bar; (b)  $\eta = 1.749 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$  at 490 K and 10.0 bar.

\* These problems were provided by Charles Trapp and Carmen Giunta.

**19A.2** Calculate the ratio of the thermal conductivities of gaseous hydrogen at 300 K to gaseous hydrogen at 10 K. Be circumspect, and think about the modes of motion that are thermally active at the two temperatures.

**19A.3** Interstellar space is quite different from the gaseous environments we commonly encounter on Earth. For instance, a typical density of the medium is about  $1 \text{ atom cm}^{-3}$  and that atom is typically H; the effective temperature due to stellar background radiation is about 10 kK. Estimate the diffusion coefficient and thermal conductivity of H under these conditions. *Comment:* Energy is in fact transferred much more effectively by radiation.

**19A.4** A Knudsen cell was used to determine the vapour pressure of germanium at 1000 °C. During an interval of 7200 s the mass loss through a hole of radius 0.50 mm amounted to 43  $\mu\text{g}$ . What is the vapour pressure of germanium at 1000 °C? Assume the gas to be monatomic.

**19A.5** An atomic beam is designed to function with (a) cadmium, (b) mercury. The source is an oven maintained at 380 K, there being a small slit of dimensions  $1.0 \text{ cm} \times 1.0 \times 10^{-3} \text{ cm}$ . The vapour pressure of cadmium is 0.13 Pa and that of mercury is 12 Pa at this temperature. What is the atomic current (the number of atoms per second) in the beams?

**19A.6** Derive an expression that shows how the pressure of a gas inside an effusion oven (a heated chamber with a small hole in one wall) varies with time if the oven is not replenished as the gas escapes. Then show that  $t_{1/2}$ , the time required for the pressure to decrease to half its initial value, is independent of the initial pressure. *Hint.* Begin by setting up a differential equation relating  $dp/dt$  to  $p = NkT/V$ , and then integrating it.

## TOPIC 19B Motion in liquids

### Discussion questions

**19B.1** Discuss the difference between the hydrodynamic radius of an ion and its ionic radius and explain why a small ion can have a large hydrodynamic radius.

**19B.2** Discuss the mechanism of proton conduction in water. How could the model be tested?

**19B.3** Why is a proton less mobile in liquid ammonia than in water?

### Exercises

**19B.1(a)** The viscosity of water at 20 °C is 1.002 cP and 0.7975 cP at 30 °C. What is the energy of activation for the transport process?

**19B.1(b)** The viscosity of mercury at 20 °C is 1.554 cP and 1.450 cP at 40 °C. What is the energy of activation for the transport process?

**19B.2(a)** The mobility of a chloride ion in aqueous solution at 25 °C is  $7.91 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ . Calculate the molar ionic conductivity.

**19B.2(b)** The mobility of an acetate ion in aqueous solution at 25 °C is  $4.24 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ . Calculate the molar ionic conductivity.

**19B.3(a)** The mobility of a  $\text{Rb}^+$  ion in aqueous solution is  $7.92 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$  at 25 °C. The potential difference between two electrodes placed in the solution is 25.0 V. If the electrodes are 7.00 mm apart, what is the drift speed of the  $\text{Rb}^+$  ion?

**19B.3(b)** The mobility of a  $\text{Li}^+$  ion in aqueous solution is  $4.01 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$  at 25 °C. The potential difference between two electrodes placed in the solution is 24.0 V. If the electrodes are 5.0 mm apart, what is the drift speed of the ion?

**19B.4(a)** The limiting molar conductivities of NaI,  $\text{NaNO}_3$ , and  $\text{AgNO}_3$  are  $12.69 \text{ mS m}^2 \text{ mol}^{-1}$ ,  $12.16 \text{ mS m}^2 \text{ mol}^{-1}$  and  $13.34 \text{ mS m}^2 \text{ mol}^{-1}$ , respectively (all at 25 °C). What is the limiting molar conductivity of  $\text{AgI}$  at this temperature?

**19B.4(b)** The limiting molar conductivities of KF,  $\text{KCH}_3\text{CO}_2$ , and  $\text{Mg}(\text{CH}_3\text{CO}_2)_2$  are  $12.89 \text{ mS m}^2 \text{ mol}^{-1}$ ,  $11.44 \text{ mS m}^2 \text{ mol}^{-1}$  and  $18.78 \text{ mS m}^2 \text{ mol}^{-1}$ , respectively (all at 25 °C). What is the limiting molar conductivity of  $\text{MgF}_2$  at this temperature?

**19B.5(a)** At 25 °C the molar ionic conductivities of  $\text{Li}^+$ ,  $\text{Na}^+$ , and  $\text{K}^+$  are  $3.87 \text{ mS m}^2 \text{ mol}^{-1}$ ,  $5.01 \text{ mS m}^2 \text{ mol}^{-1}$ , and  $7.35 \text{ mS m}^2 \text{ mol}^{-1}$ , respectively. What are their mobilities?

**19B.5(b)** At 25 °C the molar ionic conductivities of  $\text{F}^-$ ,  $\text{Cl}^-$ , and  $\text{Br}^-$  are  $5.54 \text{ mS m}^2 \text{ mol}^{-1}$ ,  $7.635 \text{ mS m}^2 \text{ mol}^{-1}$ , and  $7.81 \text{ mS m}^2 \text{ mol}^{-1}$ , respectively. What are their mobilities?

**19B.6(a)** Estimate the effective radius of a sucrose molecule in water at 25 °C given that its diffusion coefficient is  $5.2 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$  and that the viscosity of water is 1.00 cP.

**19B.6(b)** Estimate the effective radius of a glycine molecule in water at 25 °C given that its diffusion coefficient is  $1.055 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  and that the viscosity of water is 1.00 cP.

**19B.7(a)** The mobility of a  $\text{NO}_3^-$  ion in aqueous solution at 25 °C is  $7.40 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ . Calculate its diffusion coefficient in water at 25 °C.

**19B.7(b)** The mobility of a  $\text{CH}_3\text{CO}_2^-$  ion in aqueous solution at 25 °C is  $4.24 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ . Calculate its diffusion coefficient in water at 25 °C.

### Problems

**19B.1** The viscosity of benzene varies with temperature as shown in the following table. Use the data to infer the activation energy for viscosity.

$\theta/\text{°C}$	10	20	30	40	50	60	70
$\eta/\text{cP}$	0.758	0.652	0.564	0.503	0.442	0.392	0.358

**19B.2** An empirical expression that reproduces the viscosity of water in the range 20–100 °C is

$$\log \frac{\eta}{\eta_{20}} = \frac{1.3272(20 - \theta/\text{°C}) - 0.001053(20 - \theta/\text{°C})^2}{\theta/\text{°C} + 105}$$

where  $\eta_{20}$  is the viscosity at 20 °C. Explore (by using mathematical software) the possibility of fitting an exponential curve to this expression and hence identifying an activation energy for the viscosity.

**19B.3** The conductivity of aqueous ammonium chloride at a series of concentrations is listed in the following table. Deduce the molar conductivity and determine the parameters that occur in Kohlrausch's law.

$c/(\text{mol dm}^{-3})$	1.334	1.432	1.529	1.672	1.725
$\kappa/(\text{mS cm}^{-1})$	131	139	147	156	164

**19B.4** Conductivities are often measured by comparing the resistance of a cell filled with the sample to its resistance when filled with some standard solution, such as aqueous potassium chloride. The conductivity of water is  $76 \text{ mS m}^{-1}$  at  $25^\circ\text{C}$  and the conductivity of  $0.100 \text{ mol dm}^{-3}$   $\text{KCl(aq)}$  is  $1.1639 \text{ S m}^{-1}$ . A cell had a resistance of  $33.21 \Omega$  when filled with  $0.100 \text{ mol dm}^{-3}$   $\text{KCl(aq)}$  and  $300.0 \Omega$  when filled with  $0.100 \text{ mol dm}^{-3}$   $\text{CH}_3\text{COOH(aq)}$ . What is the molar conductivity of acetic acid at that concentration and temperature?

**19B.5** The resistances of a series of aqueous  $\text{NaCl}$  solutions, formed by successive dilution of a sample, were measured in a cell with cell constant (the constant  $C$  in the relation  $\kappa=C/R$ ) equal to  $0.2063 \text{ cm}^{-1}$ . The following values were found:

$c/(\text{mol dm}^{-3})$	0.00050	0.0010	0.0050	0.010	0.020	0.050
$R/\Omega$	3314	1669	342.1	174.1	89.08	37.14

Verify that the molar conductivity follows Kohlrausch's law and find the limiting molar conductivity. Determine the coefficient  $\mathcal{K}$ . Use the value of  $\mathcal{K}$  (which should depend only on the nature, not the identity, of the ions) and the information that  $\lambda(\text{Na}^+) = 5.01 \text{ mS m}^2 \text{ mol}^{-1}$  and  $\lambda(\text{I}^-) = 7.68 \text{ mS m}^2 \text{ mol}^{-1}$  to predict (a) the molar conductivity, (b) the conductivity, (c) the resistance it would show in the cell of  $0.010 \text{ mol dm}^{-3}$   $\text{NaI(aq)}$  at  $25^\circ\text{C}$ .

**19B.6** What are the drift speeds of  $\text{Li}^+$ ,  $\text{Na}^+$ , and  $\text{K}^+$  in water when a potential difference of  $100 \text{ V}$  is applied across a  $5.00 \text{ cm}$  conductivity cell? How

long would it take an ion to move from one electrode to the other? In conductivity measurements it is normal to use alternating current: what are the displacements of the ions in (a) centimetres, (b) solvent diameters, about  $300 \text{ pm}$ , during a half cycle of  $2.0 \text{ kHz}$  applied potential difference?

**19B.7\*** G. Bakale, et al. (*J. Phys. Chem.* **100**, 12477 (1996)) measured the mobility of singly charged  $\text{C}_{60}^-$  ions in a variety of nonpolar solvents. In cyclohexane at  $22^\circ\text{C}$ , the mobility is  $1.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ . Estimate the effective radius of the  $\text{C}_{60}^-$  ion. The viscosity of the solvent is  $0.93 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ . Suggest a reason why there is a substantial difference between this number and the van der Waals radius of neutral  $\text{C}_{60}$ .

**19B.8** Estimate the diffusion coefficients and the effective hydrodynamic radii of the alkali metal cations in water from their mobilities at  $25^\circ\text{C}$ . Estimate the approximate number of water molecules that are dragged along by the cations. Ionic radii are given Table 18B.2.

**19B.9** Nuclear magnetic resonance can be used to determine the mobility of molecules in liquids. A set of measurements on methane in carbon tetrachloride showed that its diffusion coefficient is  $2.05 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  at  $0^\circ\text{C}$  and  $2.89 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  at  $25^\circ\text{C}$ . Deduce what information you can about the mobility of methane in carbon tetrachloride.

**19B.10\*** A dilute solution of a weak (1,1)-electrolyte contains both neutral ion pairs and ions in equilibrium ( $\text{AB} \rightleftharpoons \text{A}^+ + \text{B}^-$ ). Prove that molar conductivities are related to the degree of ionization by the equations:

$$\frac{1}{\Lambda_m} = \frac{1}{\Lambda_m(\alpha)} + \frac{(1-\alpha)\Lambda_m^\circ}{\alpha^2 \Lambda_m(\alpha)^2}, \quad \Lambda_m(\alpha) = \Lambda_m^\circ - \mathcal{K}(\alpha)^{1/2}$$

where  $\Lambda_m^\circ$  is the molar conductivity at infinite dilution and  $\mathcal{K}$  is the constant in Kohlrausch's law.

## TOPIC 19C Diffusion

### Discussion questions

**19C.1** Describe the origin of the thermodynamic force. To what extent can it be regarded as an actual force?

**19C.2** Account physically for the form of the diffusion equation.

### Exercises

**19C.1(a)** The diffusion coefficient of glucose in water at  $25^\circ\text{C}$  is  $6.73 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ . Estimate the time required for a glucose molecule to undergo a root-mean-square displacement of  $5.0 \text{ mm}$ .

**19C.1(b)** The diffusion coefficient of  $\text{H}_2\text{O}$  in water at  $25^\circ\text{C}$  is  $2.26 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . Estimate the time required for an  $\text{H}_2\text{O}$  molecule to undergo a root-mean-square displacement of  $1.0 \text{ cm}$ .

**19C.2(a)** A layer of  $20.0 \text{ g}$  of sucrose is spread uniformly over a surface of area  $5.0 \text{ cm}^2$  and covered in water to a depth of  $20 \text{ cm}$ . What will be the molar concentration of sucrose molecules at  $10 \text{ cm}$  above the original layer at (i)  $10 \text{ s}$ , (ii)  $24 \text{ h}$ ? Assume diffusion is the only transport process and take  $D = 5.216 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ .

**19C.2(b)** A layer of  $10.0 \text{ g}$  of iodine is spread uniformly over a surface of area  $10.0 \text{ cm}^2$  and covered in hexane to a depth of  $10 \text{ cm}$ . What will be the molar concentration of sucrose molecules at  $5.0 \text{ cm}$  above the original layer at (i)  $10 \text{ s}$ , (ii)  $24 \text{ h}$ ? Assume diffusion is the only transport process and take  $D = 4.05 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ .

**19C.3(a)** Suppose the concentration of a solute decays linearly along the length of a container. Calculate the thermodynamic force on the solute at  $25^\circ\text{C}$  and  $10 \text{ cm}$  and  $20 \text{ cm}$  given that the concentration falls to half its value in  $10 \text{ cm}$ .

**19C.3(b)** Suppose the concentration of a solute increases as  $x^2$  along the length of a container. Calculate the thermodynamic force on the solute at  $25^\circ\text{C}$  and  $8 \text{ cm}$  and  $16 \text{ cm}$  given that the concentration falls to half its value in  $8 \text{ cm}$ .

**19C.4(a)** Suppose the concentration of a solute follows a Gaussian distribution (proportional to  $e^{-x^2}$ ) along the length of a container. Calculate the thermodynamic force on the solute at  $20^\circ\text{C}$  and  $5.0 \text{ cm}$  given that the concentration falls to half its value in  $5.0 \text{ cm}$ .

**19C.4(b)** Suppose the concentration of a solute follows a Gaussian distribution (proportional to  $e^{-x^2}$ ) along the length of a container. Calculate the thermodynamic force on the solute at  $18^\circ\text{C}$  and  $10.0 \text{ cm}$  given that the concentration falls to half its value in  $10.0 \text{ cm}$ .

**19C.5(a)** The diffusion coefficient of  $\text{CCl}_4$  in heptane at  $25^\circ\text{C}$  is  $3.17 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . Estimate the time required for a  $\text{CCl}_4$  molecule to have a root-mean-square displacement of  $5.0 \text{ mm}$ .

**19C.5(b)** The diffusion coefficient of  $\text{I}_2$  in hexane at  $25^\circ\text{C}$  is  $4.05 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . Estimate the time required for an iodine molecule to have a root-mean-square displacement of  $1.0 \text{ cm}$ .

**19C.6(a)** Estimate the effective radius of a sucrose molecule in water  $25^\circ\text{C}$  given that its diffusion coefficient is  $5.2 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$  and that the viscosity of water is  $1.00 \text{ cP}$ .

**19C.6(b)** Estimate the effective radius of a glycine molecule in water at 25 °C given that its diffusion coefficient is  $1.055 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  and that the viscosity of water is 1.00 cP.

**19C.7(a)** The diffusion coefficient for molecular iodine in benzene is  $2.13 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . How long does a molecule take to jump through about one molecular diameter (approximately the fundamental jump length for translational motion)?

## Problems

**19C.1** A dilute solution of potassium permanganate in water at 25 °C was prepared. The solution was in a horizontal tube of length 10 cm, and at first there was a linear gradation of intensity of the purple solution from the left (where the concentration was  $0.100 \text{ mol dm}^{-3}$ ) to the right (where the concentration was  $0.050 \text{ mol dm}^{-3}$ ). What is the magnitude and sign of the thermodynamic force acting on the solute (a) close to the left face of the container, (b) in the middle, (c) close to the right face? Give the force per mole and force per molecule in each case.

**19C.2** A dilute solution of potassium permanganate in water at 25 °C was prepared. The solution was in a horizontal tube of length 10 cm, and at first there was a Gaussian distribution of concentration around the centre of the tube at  $x=0$ ,  $c(x) = c_0 e^{-ax^2}$ , with  $c_0 = 0.100 \text{ mol dm}^{-3}$  and  $a = 0.10 \text{ cm}^{-2}$ . Determine the thermodynamic force acting on the solute as a function of location,  $x$ , and plot the result. Give the force per mole and force per molecule in each case. What do you expect to be the consequence of the thermodynamic force?

**19C.3** Instead of a Gaussian ‘heap’ of solute, as in Problem 19C.2, suppose that there is a Gaussian dip, a distribution of the form  $c(x) = c_0(1 - e^{-ax^2})$ . Repeat the calculation in Problem 19C.2 and its consequences.

**19C.4** A lump of sucrose of mass 10.0 g is suspended in the middle of a spherical flask of water of radius 10 cm at 25 °C. What is the concentration of sucrose at the wall of the flask after (a) 1.0 h, (b) 1.0 week? Take  $D = 5.22 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ .

**19C.5** Confirm that eqn 19C.11 is a solution of the diffusion equation with the correct initial value.

**19C.6** Confirm that

$$c(x) = \frac{c_0}{(4\pi Dt)^{1/2}} e^{-(x-x_0-vt)^2/4Dt}$$

is a solution of the diffusion equation with convection (eqn 19C.10) with all the solute concentrated at  $x = x_0$  at  $t = 0$  and plot the concentration profile at a series of times to show how the distribution spreads and its centroid drifts.

**19C.7** Calculate the relation between  $\langle x^2 \rangle^{1/2}$  and  $\langle x^4 \rangle^{1/4}$  for diffusing particles at a time  $t$  if they have a diffusion constant  $D$ .

**19C.7(b)** The diffusion coefficient for  $\text{CCl}_4$  in heptane is  $3.17 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . How long does a molecule take to jump through about one molecular diameter (approximately the fundamental jump length for translational motion)?

**19C.8(a)** What are the root-mean-square distances travelled by an iodine molecule in benzene and by a sucrose molecule in water at 25 °C in 1.0 s?

**19C.8(b)** About how long, on average, does it take for the molecules in Exercise 19C.8(a) to drift to a point (i) 1.0 mm, (ii) 1.0 cm from their starting points?

**19C.8** The thermodynamic force has a direction as well as a magnitude, and in a three-dimensional ideal system eqn 19C.7 becomes  $\mathcal{F} = -RT\Delta(\ln c)$ . What is the thermodynamic force acting to bring about the diffusion summarized by eqn 19C.12 (that of a solute initially suspended at the centre of a flask of solvent)? *Hint:* Use  $\nabla = i\partial/\partial x + j\partial/\partial y + k\partial/\partial z$ .

**19C.9** The diffusion equation is valid when many elementary steps are taken in the time interval of interest, but the random walk calculation lets us discuss distributions for short times as well as for long. Use the expression  $P(n\lambda) = N!/(N - N_R)!N_R!2^N$  to calculate the probability of being six paces from the origin (that is, at  $x = 6\lambda$ ) after (a) four, (b) six, (c) twelve steps.

**19C.10** Use mathematical software to calculate  $P(n\lambda)$  in a one-dimensional random walk, and evaluate the probability of being at  $x = n\lambda$  for  $n = 6, 10, 14, \dots, 60$ . Compare the numerical value with the analytical value in the limit of a large number of steps. At what value of  $n$  is the discrepancy no more than 0.1 per cent? Use  $n = 6$  and  $N = 6, 8, \dots, 180$ .

**19C.11** Supply the intermediate mathematical steps in *Justification* 19C.2.

**19C.12** The diffusion coefficient of a particular kind of t-RNA molecule is  $D = 1.0 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$  in the medium of a cell interior. How long does it take molecules produced in the cell nucleus to reach the walls of the cell at a distance 1.0  $\mu\text{m}$ , corresponding to the radius of the cell?

**19C.13\*** In this problem, we examine a model for the transport of oxygen from air in the lungs to blood. First, show that, for the initial and boundary conditions  $c(x,t) = c(x,0) = c_0$ , ( $0 < x < \infty$ ) and  $c(0,t) = c_s$  ( $0 \leq t \leq \infty$ ) where  $c_0$  and  $c_s$  are constants, the concentration,  $c(x,t)$ , of a species is given by

$$c(x,t) = c_0 + (c_s - c_0)\{1 - \text{erf}(\xi)\}$$

where  $\text{erf}(\xi)$  is the error function (see the collection of integrals in the *Resource section*) and the concentration  $c(x,t)$  evolves by diffusion from the  $yz$ -plane of constant concentration, such as might occur if a condensed phase is absorbing a species from a gas phase. Now draw graphs of concentration profiles at several different times of your choice for the diffusion of oxygen into water at 298 K (when  $D = 2.10 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ ) on a spatial scale comparable to passage of oxygen from lungs through alveoli into the blood. Use  $c_0 = 0$  and set  $c_s$  equal to the solubility of oxygen in water. *Hint:* Use mathematical software.

---

## Integrated activities

**19.1** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book to generate a family of curves similar to that shown in Fig. 19C.4 but by using eqn 19C.14, which describes diffusion in three dimensions.

**19.2** In Topic 20D it is shown that a general expression for the activation energy of a chemical reaction is  $E_a = RT^2(d \ln k/dT)$ . Confirm that the same

expression may be used to extract the activation energy from eqn 19B.2 for the viscosity and then apply the expression to deduce the temperature-dependence of the activation energy when the viscosity of water is given by the empirical expression in Problem 19B.2. Plot this activation energy as a function of temperature. Suggest an explanation of the temperature dependence of  $E_a$ .

# CHAPTER 20

## Chemical kinetics

This chapter introduces the principles of ‘chemical kinetics’, the study of reaction rates. The rate of a chemical reaction might depend on variables under our control, such as the pressure, the temperature, and the presence of a catalyst, and we may be able to optimize the rate by the appropriate choice of conditions. Here we begin to see how such manipulations are possible. In the remaining chapters of the text we develop this material in more detail and apply it to more complicated or more specialized cases.

### 20A The rates of chemical reactions

This Topic discusses the definition of reaction rate and outlines the techniques for its measurement. The results of such measurements show that reaction rates depend on the concentration of reactants (and products) and ‘rate constants’ that are characteristic of the reaction. This dependence can be expressed in terms of differential equations known as ‘rate laws’.

### 20B Integrated rate laws

‘Integrated rate laws’ are the solutions of the differential equations that describe rate laws. They are used to predict the concentrations of species at any time after the start of the reaction and to provide procedures for measuring rate constants. This Topic explores simple yet very useful integrated rate laws that appear throughout the chapter.

### 20C Reactions approaching equilibrium

In this Topic we see that in general the rate laws must take into account both the forward and reverse reactions and that they

give rise to expressions that describe the approach to equilibrium, when the forward and reverse rates are equal. A result of the analysis is a useful relation, which can be explored experimentally, between the equilibrium constant of the overall process and the rate constants of the forward and reverse reactions in the proposed mechanism.

### 20D The Arrhenius equation

The rate constants of most reactions increase with increasing temperature. In this Topic we see that the ‘Arrhenius equation’ captures this temperature dependence by using only two parameters that can be determined experimentally.

### 20E Reaction mechanisms

The study of reaction rates also leads to an understanding of the ‘mechanisms’ of reactions, their analysis into a sequence of elementary steps. In this Topic we see how to construct rate laws from a proposed mechanism. The elementary steps themselves have simple rate laws which can be combined together by invoking the concept of the ‘rate-determining step’ of a reaction or making either the ‘steady-state approximation’ or the existence of a ‘pre-equilibrium’.

### 20F Examples of mechanisms

This Topic develops two examples of reaction mechanisms. The first describes a special class of reactions in the gas phase that depend on the collisions between reactants. The second gives insight into the formation of polymers and shows how the kinetics of their formation affects their properties.

## 20G Photochemistry

'Photochemistry' is the study of reactions that are initiated by light. In this Topic we explore mechanisms of photochemical reactions, with special emphasis on electron and energy transfer processes.

## 20H Enzymes

In this Topic we discuss the general mechanism of action of 'enzymes', which are biological catalysts. We show how to assemble expressions for their influence on the rate of reactions and the effect of substances that inhibit their function.

## What is the impact of this material?

Plants, algae, and some species of bacteria evolved apparatus that perform 'photosynthesis', the capture of visible and near-infrared radiation for the purpose of synthesizing complex molecules in the cell. In *Impact* I20.1 we explore plant photosynthesis in detail.

### ► Why do you need to know this material?

Studies of the rates of disappearance of reactants and appearance of products allow us to predict how quickly a reaction mixture approaches equilibrium. Furthermore, studies of reaction rates lead to detailed descriptions of the molecular events that transform reactants into products.

### ► What is the key idea?

Reaction rates can be expressed mathematically in terms of the concentrations of reactants and, in some cases, products.

### ► What do you need to know already?

This introductory Topic is the foundation of a sequence: all you need to be aware of initially is the significance of stoichiometric numbers (Topic 2C). For more background on the spectroscopic determination of concentration, refer to Topic 12A.

This Topic introduces the principles of **chemical kinetics**, the study of reaction rates, by showing how the rates of reactions are defined and measured. The results of such measurements show that reaction rates depend on the concentration of reactants (and products) in characteristic ways that can be expressed in terms of differential equations known as rate laws.

## 20A.1 Monitoring the progress of a reaction

The first steps in the kinetic analysis of reactions are to establish the stoichiometry of the reaction and identify any side reactions. The basic data of chemical kinetics are then the concentrations of the reactants and products at different times after a reaction has been initiated.

### (a) General considerations

The rates of most chemical reactions are sensitive to the temperature (as described in Topic 20D), so in conventional experiments the temperature of the reaction mixture must be held constant throughout the course of the reaction. This requirement puts severe demands on the design of an experiment. Gas-phase reactions, for instance, are often carried out in a vessel held in contact with a substantial block of metal. Liquid-phase reactions, including flow reactions, must be carried out in an efficient thermostat. Special efforts have to be made to study reactions at low temperatures, as in the study of the kinds of reactions that take place in interstellar clouds. Thus, supersonic expansion of the reaction gas can be used to attain temperatures as low as 10 K. For work in the liquid-phase and the solid-phase, very low temperatures are often reached by flowing cold liquid or cold gas around the reaction vessel. Alternatively, the entire reaction vessel is immersed in a thermally insulated container filled with a cryogenic liquid, such as liquid helium (for work at around 4 K) or liquid nitrogen (for work at around 77 K). Non-isothermal conditions are sometimes employed. For instance, the shelf life of an expensive pharmaceutical may be explored by slowly raising the temperature of a single sample.

Spectroscopy is widely applicable to the study of reaction kinetics, and is especially useful when one substance in the reaction mixture has a strong characteristic absorption in a

conveniently accessible region of the electromagnetic spectrum. For example, the progress of the reaction

can be followed by measuring the absorption of visible light by bromine. A reaction that changes the number or type of ions present in a solution may be followed by monitoring the electrical conductivity of the solution. The replacement of neutral molecules by ionic products can result in dramatic changes in the conductivity, as in the reaction

If hydrogen ions are produced or consumed, the reaction may be followed by monitoring the pH of the solution.

Other methods of determining composition include emission spectroscopy (Topic 13B), mass spectrometry (Topic 17D), gas chromatography, nuclear magnetic resonance (Topics 14B and 14C), and electron paramagnetic resonance (for reactions involving radicals or paramagnetic d-metal ions; see Topic 14D). A reaction in which at least one component is a gas might result in an overall change in pressure in a system of constant volume, so its progress may be followed by recording the variation of pressure with time.

### Example 20A.1 Monitoring the variation in pressure

Predict how the total pressure varies during the gas-phase decomposition  $2\text{N}_2\text{O}_5(\text{g}) \rightarrow 4\text{NO}_2(\text{g}) + \text{O}_2(\text{g})$  in a constant-volume container.

**Method** The total pressure (at constant volume and temperature and assuming perfect gas behaviour) is proportional to the number of gas-phase molecules. Therefore, because each mole of  $\text{N}_2\text{O}_5$  gives rise to  $\frac{5}{2}$  mol of gas molecules, we can expect the pressure to rise to  $\frac{5}{2}$  times its initial value. To confirm this conclusion, express the progress of the reaction in terms of the fraction,  $\alpha$ , of  $\text{N}_2\text{O}_5$  molecules that have reacted.

**Answer** Let the initial pressure be  $p_0$  and the initial amount of  $\text{N}_2\text{O}_5$  molecules present be  $n$ . When a fraction  $\alpha$  of the  $\text{N}_2\text{O}_5$  molecules has decomposed, the amounts of the components in the reaction mixture are:

	$\text{N}_2\text{O}_5$	$\text{NO}_2$	$\text{O}_2$	Total
Amount:	$n(1-\alpha)$	$2\alpha n$	$\frac{1}{2}\alpha n$	$n(1+\frac{3}{2}\alpha)$

When  $\alpha=0$  the pressure is  $p_0$ , so at any stage the total pressure is

$$p = (1 + \frac{3}{2}\alpha)p_0$$

When the reaction is complete ( $\alpha=1$ ), the pressure will have risen to  $\frac{5}{2}$  times its initial value.

**Self-test 20A.1** Repeat the calculation for  $2\text{NOBr}(\text{g}) \rightarrow 2\text{NO}(\text{g}) + \text{Br}_2(\text{g})$ .

$$\text{Answer: } p = (1 + \frac{1}{2}\alpha)p_0$$

## (b) Special techniques

The method used to monitor concentrations depends on the species involved and the rapidity with which their concentrations change. Many reactions reach equilibrium over periods of minutes or hours, and several techniques may then be used to follow the changing concentrations. In a **real-time analysis** the composition of the system is analysed while the reaction is in progress. Either a small sample is withdrawn or the bulk solution is monitored. In the **flow method** the reactants are mixed as they flow together in a chamber (Fig. 20A.1). The reaction continues as the thoroughly mixed solutions flow through the outlet tube, and observation of the composition at different positions along the tube is equivalent to the observation of the reaction mixture at different times after mixing. The disadvantage of conventional flow techniques is that a large volume of reactant solution is necessary. This requirement makes the study of fast reactions particularly difficult because to spread the reaction over a length of tube the flow must be rapid. This disadvantage is avoided by the **stopped-flow technique**, in which the reagents are mixed very quickly in a small chamber fitted with a syringe instead of an outlet tube (Fig. 20A.2). The flow ceases when the plunger of the syringe reaches a stop and the reaction continues in the mixed solutions. Observations, commonly using spectroscopic techniques such as ultraviolet-visible absorption, circular dichroism, and fluorescence emission (all introduced in Topics 13A and 13B), are made on the sample as a function of time. The technique allows for the study

**Figure 20A.1** The arrangement used in the flow technique for studying reaction rates. The reactants are injected into the mixing chamber at a steady rate. The location of the spectrometer corresponds to different times after initiation.

**Figure 20A.2** In the stopped-flow technique the reagents are driven quickly into the mixing chamber by the driving pistons and then the time-dependence of the concentrations is monitored.

of reactions that occur on the millisecond to second timescale. The suitability of the stopped-flow method to the study of small samples means that it is appropriate for many biochemical reactions; it has been widely used to study the kinetics of protein folding and enzyme action.

Very fast reactions can be studied by **flash photolysis**, in which the sample is exposed to a brief flash of light that initiates the reaction and then the contents of the reaction chamber are monitored. The apparatus used for flash photolysis studies is based on the experimental design for time-resolved spectroscopy, in which reactions occurring on a picosecond or femtosecond timescale may be monitored by using electronic absorption or emission, infrared absorption, or Raman scattering (Topic 13C).

In contrast to real-time analysis, **quenching methods** are based on quenching, or stopping, the reaction after it has been allowed to proceed for a certain time. In this way the composition is analysed at leisure and reaction intermediates may be trapped. These methods are suitable only for reactions that are slow enough for there to be little reaction during the time it takes to quench the mixture. In the **chemical quench flow method**, the reactants are mixed in much the same way as in the flow method but the reaction is quenched by another reagent, such as solution of acid or base, after the mixture has travelled along a fixed length of the outlet tube. Different reaction times can be selected by varying the flow rate along the outlet tube. An advantage of the chemical quench flow method over the stopped-flow method is that spectroscopic fingerprints are not needed in order to measure the concentration of reactants and products. Once the reaction has been quenched, the solution may be examined by 'slow' techniques, such as gel electrophoresis, mass spectrometry, and chromatography. In the **freeze quench method**, the reaction is quenched by cooling the mixture within milliseconds and the concentrations of reactants, intermediates, and products are measured spectroscopically.

## 20A.2 The rates of reactions

Reaction rates depend on the composition and the temperature of the reaction mixture. The next few sections look at these observations in more detail.

### (a) The definition of rate

Consider a reaction of the form  $A + 2B \rightarrow 3C + D$ , in which at some instant the molar concentration of a participant J is  $[J]$  and the volume of the system is constant. The instantaneous **rate of consumption** of one of the reactants at a given time is  $-d[R]/dt$ , where R is A or B. This rate is a positive quantity (Fig. 20A.3). The **rate of formation** of one of the products (C or D),

**Figure 20A.3** The definition of (instantaneous) rate as the slope of the tangent drawn to the curve showing the variation of concentration of (a) products, (b) reactants with time. For negative slopes, the sign is changed when reporting the rate, so all reaction rates are positive.

which we denote P) is  $d[P]/dt$  (note the difference in sign). This rate is also positive.

It follows from the stoichiometry of the reaction  $A + 2B \rightarrow 3C + D$  that

$$\frac{d[D]}{dt} = \frac{1}{3} \frac{d[C]}{dt} = -\frac{d[A]}{dt} = -\frac{1}{2} \frac{d[B]}{dt}$$

so there are several rates connected with the reaction. The undesirability of having different rates to describe the same reaction is avoided by using the extent of reaction,  $\xi$  (xi, the quantity introduced in Topic 6A):

$$\xi = \frac{n_J - n_{J,0}}{\nu_J} \quad \text{Definition} \quad \text{Extent of reaction} \quad (20A.1)$$

where  $\nu_J$  is the stoichiometric number of species J (Topic 2C; remember that  $\nu_J$  is negative for reactants and positive for products), and defining the unique **rate of reaction**,  $\nu$ , as the rate of change of the extent of reaction:

$$\nu = \frac{1}{V} \frac{d\xi}{dt} \quad \text{Definition} \quad \text{Rate of reaction} \quad (20A.2)$$

where  $V$  is the volume of the system. It follows that

$$\nu = \frac{1}{\nu_J} \times \frac{1}{V} \frac{dn_J}{dt} \quad (20A.3a)$$

For a homogeneous reaction in a constant-volume system the volume  $V$  can be taken inside the differential and we use  $[J] = n_J/V$  to write

$$\nu = \frac{1}{\nu_J} \frac{d[J]}{dt} \quad (20A.3b)$$

For a heterogeneous reaction we use the (constant) surface area,  $A$ , occupied by the species in place of  $V$  and then use  $\sigma_j = n_j/A$  to write

$$v = \frac{1}{\nu_j} \frac{d\sigma_j}{dt} \quad (20A.3c)$$

In each case there is now a single rate for the entire reaction (for the chemical equation as written). With molar concentrations in moles per cubic decimetre and time in seconds, reaction rates of homogeneous reactions are reported in moles per cubic decimetre per second ( $\text{mol dm}^{-3} \text{s}^{-1}$ ) or related units. For gas-phase reactions, such as those taking place in the atmosphere, concentrations are often expressed in molecules per cubic centimetre ( $\text{molecules cm}^{-3}$ ) and rates in molecules per cubic centimetre per second ( $\text{molecules cm}^{-3} \text{s}^{-1}$ ). For heterogeneous reactions, rates are expressed in moles per square metre per second ( $\text{mol m}^{-2} \text{s}^{-1}$ ) or related units.

#### Brief illustration 20A.1 Reaction rates from balanced chemical equations

If the rate of formation of NO in the reaction  $2 \text{NOBr(g)} \rightarrow 2 \text{NO(g)} + \text{Br}_2(\text{g})$  is reported as  $0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$ , we use  $\nu_{\text{NO}} = +2$  to report that  $v = 0.080 \text{ mmol dm}^{-3} \text{s}^{-1}$ . Because  $\nu_{\text{NOBr}} = -2$  it follows that  $d[\text{NOBr}]/dt = -0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$ . The rate of consumption of NOBr is therefore  $0.16 \text{ mmol dm}^{-3} \text{s}^{-1}$ , or  $9.6 \times 10^{16} \text{ molecules cm}^{-3} \text{s}^{-1}$ .

**Self-test 20A.2** The rate of change of molar concentration of  $\text{CH}_3$  radicals in the reaction  $2 \text{CH}_3(\text{g}) \rightarrow \text{CH}_3\text{CH}_3(\text{g})$  was reported as  $d[\text{CH}_3]/dt = -1.2 \text{ mol dm}^{-3} \text{s}^{-1}$  under particular conditions. What is (a) the rate of reaction and (b) the rate of formation of  $\text{CH}_3\text{CH}_3$ ?

Answer: (a)  $0.60 \text{ mol dm}^{-3} \text{s}^{-1}$ , (b)  $0.60 \text{ mol dm}^{-3} \text{s}^{-1}$

### (b) Rate laws and rate constants

The rate of reaction is often found to be proportional to the concentrations of the reactants raised to a power. For example, the rate of a reaction may be proportional to the molar concentrations of two reactants A and B, so we write

$$v = k_r [\text{A}][\text{B}] \quad (20A.4)$$

with each concentration raised to the first power. The coefficient  $k_r$  is called the **rate constant** for the reaction. The rate constant is independent of the concentrations but depends on the temperature. An experimentally determined equation of this kind is called the **rate law** of the reaction. More formally, a rate law is an equation that expresses the rate of reaction as a function of the concentrations of all the species present in

the overall chemical equation for the reaction at the time of interest:

$$v = f([\text{A}], [\text{B}], \dots) \quad \begin{array}{l} \text{General} \\ \text{form} \end{array} \quad \begin{array}{l} \text{Rate law} \\ \text{in terms of} \\ \text{concentrations} \end{array} \quad (20A.5a)$$

For homogeneous gas-phase reactions, it is often more convenient to express the rate law in terms of partial pressures, which are related to molar concentrations by  $p_j = RT[J]$ . In this case, we write

$$v = f(p_{\text{A}}, p_{\text{B}}, \dots) \quad \begin{array}{l} \text{General} \\ \text{form} \end{array} \quad \begin{array}{l} \text{Rate law in} \\ \text{terms of partial} \\ \text{pressures} \end{array} \quad (20A.5b)$$

The rate law of a reaction is determined experimentally, and cannot in general be inferred from the chemical equation for the reaction. The reaction of hydrogen and bromine, for example, has a very simple stoichiometry,  $\text{H}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow 2 \text{HBr}(\text{g})$ , but its rate law is complicated:

$$v = \frac{k_a [\text{H}_2][\text{Br}_2]^{3/2}}{[\text{Br}_2] + k_b [\text{HBr}]} \quad (20A.6)$$

In certain cases the rate law does reflect the stoichiometry of the reaction; but that is either a coincidence or reflects a feature of the underlying reaction mechanism (see Topic 20E).

*A note on good (or, at least, our) practice* We denote a general rate constant  $k_r$  to distinguish it from the Boltzmann constant  $k$ . In some texts  $k$  is used for the former and  $k_B$  for the latter. When expressing the rate constants in a more complicated rate law, such as that in eqn 20A.6, we use  $k_a$ ,  $k_b$ , and so on.

The units of  $k_r$  are always such as to convert the product of concentrations into a rate expressed as a change in concentration divided by time. For example, if the rate law is the one shown in eqn 20A.4, with concentrations expressed in  $\text{mol dm}^{-3}$ , then the units of  $k_r$  will be  $\text{dm}^3 \text{mol}^{-1} \text{s}^{-1}$  because

$$\text{dm}^3 \text{mol}^{-1} \text{s}^{-1} \times \text{mol dm}^{-3} \times \text{mol dm}^{-3} = \text{mol dm}^{-3} \text{s}^{-1}$$

In gas-phase studies, including studies of the processes taking place in the atmosphere, concentrations are commonly expressed in molecules  $\text{cm}^{-3}$ , so the rate constant for the reaction above would be expressed in  $\text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$ . We can use the approach just developed to determine the units of the rate constant from rate laws of any form. For example, the rate constant for a reaction with rate law of the form  $k_r[\text{A}]$  is commonly expressed in  $\text{s}^{-1}$ .

#### Brief illustration 20A.2 The units of rate constants

The rate constant for the reaction  $\text{O}(\text{g}) + \text{O}_3(\text{g}) \rightarrow 2 \text{O}_2(\text{g})$  is  $8.0 \times 10^{-15} \text{ cm}^3 \text{molecule}^{-1} \text{s}^{-1}$  at 298 K. To express this rate constant in  $\text{dm}^3 \text{mol}^{-1} \text{s}^{-1}$ , we make use of the two relations

1 cm = 10<sup>-1</sup> dm and 1 molecule = (1 mol)/(6.022 × 10<sup>23</sup>). It follows that

$$\begin{aligned} k_r &= 8.0 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \\ &= 8.0 \times 10^{-15} (10^{-1} \text{ dm})^3 \left( \frac{1 \text{ mol}}{6.022 \times 10^{23}} \right)^{-1} \text{ s}^{-1} \\ &= 8.0 \times 10^{-15} \times 10^{-3} \times 6.022 \times 10^{23} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} \\ &= 4.8 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} \end{aligned}$$

**Self-test 20A.3** A reaction has a rate law of the form  $k_r[A]^2[B]$ . What are the units of the rate constant if the reaction rate is measured in mol dm<sup>-3</sup> s<sup>-1</sup>?

Answer: dm<sup>6</sup> mol<sup>-2</sup> s<sup>-1</sup>

A practical application of a rate law is that once we know the law and the value of the rate constant, we can predict the rate of reaction from the composition of the mixture. Moreover, as demonstrated in Topic 20B, by knowing the rate law, we can go on to predict the composition of the reaction mixture at a later stage of the reaction. Moreover, a rate law is a guide to the mechanism of the reaction, for any proposed mechanism must be consistent with the observed rate law. This application is developed in Topic 20E.

### (c) Reaction order

Many reactions are found to have rate laws of the form

$$v = k_r[A]^a[B]^b \dots \quad (20A.7)$$

The power to which the concentration of a species (a product or a reactant) is raised in a rate law of this kind is the **order** of the reaction with respect to that species. A reaction with the rate law in eqn 20A.4 is first order in A and first order in B. The **overall order** of a reaction with a rate law like that in eqn 20A.7 is the sum of the individual orders,  $a + b + \dots$ . The rate law in eqn 20A.4 is therefore second order overall.

A reaction need not have an integral order, and many gas-phase reactions do not. For example, a reaction having the rate law

$$v = k_r[A]^{1/2}[B] \quad (20A.8)$$

is half order in A, first order in B, and three-halves order overall.

#### Brief illustration 20A.3 The interpretation of rate laws

The experimentally determined rate law for the gas-phase reaction  $\text{H}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow 2 \text{HBr}(\text{g})$  is given by eqn 20A.6. Although the reaction is first-order in  $\text{H}_2$ , it has an indefinite

order with respect to both  $\text{Br}_2$  and  $\text{HBr}$  and an indefinite order overall.

**Self-test 20A.4** Repeat this analysis for a typical rate law for the action of an enzyme E on a substrate S:  $v = k_r[E][S]/([S] + K_M)$ , where  $K_M$  is a constant.

Answer: First order in E; no specific order with respect to S

Some reactions obey a zero-order rate law, and therefore have a rate that is independent of the concentration of the reactant (so long as some is present). Thus, the catalytic decomposition of phosphine ( $\text{PH}_3$ ) on hot tungsten at high pressures has the rate law

$$v = k_r \quad (20A.9)$$

$\text{PH}_3$  decomposes at a constant rate until it has almost entirely disappeared. Zero-order reactions typically occur when there is a bottle-neck of some kind in the mechanism, as in heterogeneous reactions when the surface is saturated and the subsequent reaction slow and in a number of enzyme reactions when there is a large excess of substrate relative to the enzyme.

As we saw in *Brief illustration 20A.3*, when a rate law is not of the form in eqn 20A.7, the reaction does not have an overall order and may not even have definite orders with respect to each participant.

These remarks point to three important tasks:

- To identify the rate law and obtain the rate constant from the experimental data. We concentrate on this aspect in this Topic.
- To construct reaction mechanisms that are consistent with the rate law. We introduce the techniques for doing so in Topic 20E.
- To account for the values of the rate constants and explain their temperature dependence. This task is undertaken in Topic 20D.

### (d) The determination of the rate law

The determination of a rate law is simplified by the **isolation method** in which the concentrations of all the reactants except one are in large excess. If B is in large excess in a reaction between A and B, for example, then to a good approximation its concentration is constant throughout the reaction. Although the true rate law might be  $v = k_r[A][B]$ , we can approximate [B] by  $[B]_0$ , its initial value, and write

$$v = k'_r[A] \quad k'_r = k_r[B]_0 \quad (20A.10)$$

which has the form of a first-order rate law. Because the true rate law has been forced into first-order form by assuming that

the concentration of B is constant, eqn 20A.10 is called a **pseudo-first-order rate law**. The dependence of the rate on the concentration of each of the reactants may be found by isolating them in turn (by having all the other substances present in large excess), and so constructing a picture of the overall rate law.

In the **method of initial rates**, which is often used in conjunction with the isolation method, the rate is measured at the beginning of the reaction for several different initial concentrations of reactants. We shall suppose that the rate law for a reaction with A isolated is  $v = k_r' [A]^a$ , then its initial rate,  $v_0$ , is given by the initial values of the concentration of A, and we write  $v = k_r' [A]_0^a$ . Taking logarithms gives:

$$\log v_0 = \log k_r' + a \log [A]_0 \quad (20A.11)$$

A plot of the logarithms of the initial rates against the logarithms of a series of initial concentrations of A should be a straight line with slope  $a$ .

### Example 20A.2 Using the method of initial rates

The recombination of iodine atoms in the gas phase in the presence of argon was investigated and the order of the reaction was determined by the method of initial rates. The initial rates of reaction of  $2 \text{ I}(\text{g}) + \text{Ar}(\text{g}) \rightarrow \text{I}_2(\text{g}) + \text{Ar}(\text{g})$  were as follows:

$[\text{I}]_0 / (10^{-5} \text{ mol dm}^{-3})$	1.0	2.0	4.0	6.0
$v_0 / (\text{mol dm}^{-3} \text{ s}^{-1})$ (a)	$8.70 \times 10^{-4}$	$3.48 \times 10^{-3}$	$1.39 \times 10^{-2}$	$3.13 \times 10^{-2}$
(b)	$4.35 \times 10^{-3}$	$1.74 \times 10^{-2}$	$6.96 \times 10^{-2}$	$1.57 \times 10^{-1}$
(c)	$8.69 \times 10^{-3}$	$3.47 \times 10^{-2}$	$1.38 \times 10^{-1}$	$3.13 \times 10^{-1}$

The Ar concentrations are (a)  $1.0 \text{ mmol dm}^{-3}$ , (b)  $5.0 \text{ mmol dm}^{-3}$ , and (c)  $10.0 \text{ mmol dm}^{-3}$ . Determine the orders of reaction with respect to the I and Ar atom concentrations and the rate constant.

**Method** Plot the logarithm of the initial rate,  $\log v_0$ , against  $\log [\text{I}]_0$  for a given concentration of Ar and, separately, against  $\log [\text{Ar}]_0$  for a given concentration of I. The slopes of the two lines are the orders of reaction with respect to I and Ar, respectively. The intercepts with the vertical axis give  $\log k_r$ .

**Answer** The plots are shown in Fig. 20A.4. The slopes are 2 and 1, respectively, so the (initial) rate law is  $v_0 = k_r [\text{I}]_0^2 [\text{Ar}]_0$ . This rate law signifies that the reaction is second order in [I], first order in [Ar], and third order overall. The intercept corresponds to  $k_r = 9 \times 10^9 \text{ mol}^{-2} \text{ dm}^6 \text{ s}^{-1}$ .

**Figure 20A.4** The plot of  $\log v_0$  against (a)  $\log [\text{I}]_0$  for a given  $[\text{Ar}]_0$ , and (b)  $\log [\text{Ar}]_0$  for a given  $[\text{I}]_0$ .

*A note on good practice* The units of  $k_r$  come automatically from the calculation, and are always such as to convert the product of concentrations to a rate in concentration/time (for example,  $\text{mol dm}^{-3} \text{ s}^{-1}$ ).

**Self-test 20A.5** The initial rate of a reaction depended on concentration of a substance J as follows:

$[\text{J}]_0 / (\text{mmol dm}^{-3})$	5.0	8.2	17	30
$v_0 / (10^{-7} \text{ mol dm}^{-3} \text{ s}^{-1})$	3.6	9.6	41	130

Determine the order of the reaction with respect to J and calculate the rate constant.

Answer: 2,  $1.4 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

The method of initial rates might not reveal the full rate law, for once the products have been generated they might participate in the reaction and affect its rate. For example, products participate in the synthesis of HBr, because eqn 20A.6 shows that the full rate law depends on the concentration of HBr. To avoid this difficulty, the rate law should be fitted to the data throughout the reaction. The fitting may be done, in simple cases at least, by using a proposed rate law to predict the concentration of any component at any time, and comparing it with the data. A rate law should also be tested by observing whether the addition of products or, for gas phase reactions, a change in the surface-to-volume ratio in the reaction chamber affects the rate.

## Checklist of concepts

- 1. The rates of chemical reactions are measured by using techniques that monitor the concentrations of species present in the reaction mixture. Examples include **real-time** and **quenching** procedures, **flow** and **stopped-flow** techniques, and **flash photolysis**.
- 2. The **instantaneous rate** of a reaction is the slope of the tangent to the graph of concentration against time (expressed as a positive quantity).
- 3. A **rate law** is an expression for the reaction rate in terms of the concentrations of the species that occur in the overall chemical reaction.

## Checklist of equations

Property	Equation	Comment	Equation number
Extent of reaction	$\xi = (n_1 - n_{1,0})/\nu_1$	Definition	20A.1
Rate of a reaction	$\nu = (1/V)(d\xi/dt)$ , $\xi = (n_1 - n_{1,0})/\nu_1$	Definition	20A.2
Rate law (in some cases)	$\nu = k_r[A]^a[B]^b \dots$	$a, b, \dots$ : orders; $a + b + \dots$ : overall order	20A.7
Method of initial rates	$\log \nu_0 = \log k_r' + a \log[A]_0$		20A.11

### ► Why do you need to know this material?

You need the integrated rate law if you want to predict the composition of a reaction mixture as it approaches equilibrium. It is also used to determine the rate law and rate constants of a reaction, which is a necessary step in the formulation of the mechanism of the reaction.

### ► What is the key idea?

A comparison between experimental data and the integrated form of the rate law is used to verify a proposed rate law and determine the order and rate constant of a reaction.

### ► What do you need to know already?

You need to be familiar with the concepts of rate law, reaction order, and rate constant (Topic 20A). The manipulation of simple rate laws requires only elementary techniques of integration (see the *Resource section* for standard integrals).

Rate laws (Topic 20A) are differential equations. We must integrate them if we want to find the concentrations as a function of time. Even the most complex rate laws may be integrated numerically. However, in a number of simple cases analytical solutions, known as **integrated rate laws**, are easily obtained and prove to be very useful. We examine a few of these simple cases here.

## 20B.1 First-order reactions

As shown in the following *Justification*, the integrated form of the first-order rate law

$$\frac{d[A]}{dt} = -k_r[A] \quad (20B.1a)$$

is

$$\ln \frac{[A]}{[A]_0} = -k_r t \quad [A] = [A]_0 e^{-k_r t} \quad \text{Integrated first-order rate law} \quad (20B.1b)$$

where  $[A]_0$  is the initial concentration of A (at  $t=0$ ).

### Justification 20B.1 First-order integrated rate law

First, we rearrange eqn 20B.1a into

$$\frac{d[A]}{[A]^2} = -k_r dt$$

This expression can be integrated directly because  $k_r$  is a constant independent of  $t$ . Initially (at  $t=0$ ) the concentration of A is  $[A]_0$ , and at a later time  $t$  it is  $[A]$ , so we make these values the limits of the integrals and write

$$\int_{[A]_0}^{[A]} \frac{d[A]}{[A]} = -k_r \int_0^t dt$$

Because the integral of  $1/x$  is  $\ln x + \text{constant}$ , eqn 20B.1b is obtained immediately.

Equation 20B.1b shows that if  $\ln([A]/[A]_0)$  is plotted against  $t$ , then a first-order reaction will give a straight line of slope  $-k_r$ . Some rate constants determined in this way are given in Table 20B.1. The second expression in eqn 20B.1b shows that in a first-order reaction the reactant concentration decreases exponentially with time with a rate determined by  $k_r$  (Fig. 20B.1).

**Figure 20B.1** The exponential decay of the reactant in a first-order reaction. The larger the rate constant, the more rapid is the decay: here  $k_{r,\text{large}} = 3k_{r,\text{small}}$ .

Table 20B.1\* Kinetic data for first-order reactions

Reaction	Phase	$\theta/^\circ\text{C}$	$k_r/\text{s}^{-1}$	$t_{1/2}$
$2\text{N}_2\text{O}_5 \rightarrow 4\text{NO}_2 + \text{O}_2$	g	25	$3.38 \times 10^{-5}$	5.70 h
	$\text{Br}_2(\text{l})$	25	$4.27 \times 10^{-5}$	4.51 h
$\text{C}_2\text{H}_6 \rightarrow 2\text{CH}_3$	g	700	$5.36 \times 10^{-4}$	21.6 min

\* More values are given in the Resource section.

A useful indication of the rate of a first-order chemical reaction is the **half-life**,  $t_{1/2}$ , of a substance, the time taken for the concentration of a reactant to fall to half its initial value. This quantity is readily obtained from the integrated rate law. Thus, the time for  $[\text{A}]$  to decrease from  $[\text{A}]_0$  to  $\frac{1}{2}[\text{A}]_0$  in a first-order reaction is given by eqn 20B.1b as

$$k_r t_{1/2} = -\ln \frac{\frac{1}{2}[\text{A}]_0}{[\text{A}]_0} = -\ln \frac{1}{2} = \ln 2$$

Hence

$$t_{1/2} = \frac{\ln 2}{k_r} \quad \text{First-order reaction} \quad \text{Half-life} \quad (20\text{B.2})$$

(Note that  $\ln 2 = 0.693$ .) The main point to note about this result is that for a first-order reaction, the half-life of a reactant is independent of its initial concentration. Therefore, if the concentration of A at some *arbitrary* stage of the reaction is  $[\text{A}]$ , then it will have fallen to  $\frac{1}{2}[\text{A}]$  after a further interval of  $(\ln 2)/k_r$ . Some half-lives are given in Table 20B.1.

Another indication of the rate of a first-order reaction is the **time constant**,  $\tau$  (tau), the time required for the concentration of a reactant to fall to  $1/e$  of its initial value. From eqn 20B.1b it follows that

$$k_r \tau = -\ln \frac{\frac{1}{e}[\text{A}]_0}{[\text{A}]_0} = -\ln \frac{1}{e} = 1$$

That is, the time constant of a first-order reaction is the reciprocal of the rate constant:

$$\tau = \frac{1}{k_r} \quad \text{First-order reaction} \quad \text{Time constant} \quad (20\text{B.3})$$

### Example 20B.1 Analysing a first-order reaction

The variation in the partial pressure of azomethane with time was followed at 600 K, with the results given below. Confirm that the decomposition  $\text{CH}_3\text{N}_2\text{CH}_3(\text{g}) \rightarrow \text{CH}_3\text{CH}_3(\text{g}) + \text{N}_2(\text{g})$  is first order in azomethane, and find the rate constant, half-life, and time constant at 600 K.

$t/\text{s}$	0	1000	2000	3000	4000
$p/\text{Pa}$	10.9	7.63	5.32	3.71	2.59

**Method** As indicated in the text, to confirm that a reaction is first order, plot  $\ln([\text{A}]/[\text{A}]_0)$  against time and expect a straight line. Because the partial pressure of a gas is proportional to its concentration, an equivalent procedure is to plot  $\ln(p/p_0)$  against  $t$ . If a straight line is obtained, its slope can be identified with  $-k_r$ . The half-life and time constant are then calculated from  $k_r$  by using eqns 20B.2 and 20B.3, respectively.

**Answer** We draw up the following table:

$t/\text{s}$	0	1000	2000	3000	4000
$\ln(p/p_0)$	1	-0.357	-0.717	-1.078	-1.437

Figure 20B.2 shows the plot of  $\ln(p/p_0)$  against  $t$ . The plot is straight, confirming a first-order reaction, and its slope is  $-3.6 \times 10^{-4}$ . Therefore,  $k_r = 3.6 \times 10^{-4} \text{ s}^{-1}$ .

Figure 20B.2 The determination of the rate constant of a first-order reaction: a straight line is obtained when  $\ln [\text{A}]$  (or, as here,  $\ln p/p_0$ ) is plotted against  $t$ ; the slope gives  $k_r$ .

**A note on good practice** Because the horizontal and vertical axes of graphs are labelled with pure numbers, the slope of a graph is always dimensionless. For a graph of the form  $y = b + mx$  we can write  $y = b + (m \text{ units})(x/\text{units})$ , where 'units' are the units of  $x$ , and identify the (dimensionless) slope with ' $m$  units'. Then  $m = \text{slope}/\text{units}$ . In the present case, because the graph shown here is a plot of  $\ln(p/p_0)$  against  $t/\text{s}$  (with 'units' = s) and  $k_r$  is the negative value of the slope of  $\ln(p/p_0)$  against  $t$  itself,  $k_r = -\text{slope}/\text{s}$ .

It follows from eqns 5.2 and 5.3 that the half-life and time constant are, respectively,

$$t_{1/2} = \frac{\ln 2}{3.6 \times 10^{-4} \text{ s}^{-1}} = 1.9 \times 10^{-5} \text{ s} \quad \tau = \frac{1}{3.6 \times 10^{-4} \text{ s}^{-1}} = 2.8 \times 10^{-5} \text{ s}$$

**Self-test 20B.1** In a particular experiment, it was found that the concentration of  $\text{N}_2\text{O}_5$  in liquid bromine varied with time as follows:

$t/\text{s}$	0	200	400	600	1000
$[\text{N}_2\text{O}_5]/(\text{mol dm}^{-3})$	0.110	0.073	0.048	0.032	0.014

Confirm that the reaction is first order in  $\text{N}_2\text{O}_5$  and determine the rate constant.

Answer:  $k_r = 2.1 \times 10^{-3} \text{ s}^{-1}$

## 20B.2 Second-order reactions

We show in the following *Justification* that the integrated form of the second-order rate law

$$\frac{d[\text{A}]}{dt} = -k_r[\text{A}]^2 \quad (20\text{B.4a})$$

is either of the following two forms:

$$\frac{1}{[\text{A}]} - \frac{1}{[\text{A}]_0} = k_r t \quad \begin{array}{l} \text{Second-order} \\ \text{reaction} \end{array} \quad \begin{array}{l} \text{Integrated} \\ \text{rate law} \end{array} \quad (20\text{B.4b})$$

$$[\text{A}] = \frac{[\text{A}]_0}{1 + k_r t [\text{A}]_0} \quad \begin{array}{l} \text{Second-order} \\ \text{reaction;} \\ \text{alternative form} \end{array} \quad \begin{array}{l} \text{Integrated} \\ \text{rate law} \end{array} \quad (20\text{B.4c})$$

where  $[\text{A}]_0$  is the initial concentration of A (at  $t=0$ ).

### Justification 20B.2 Second-order integrated rate law

To integrate eqn 20B.4a we rearrange it into

$$\frac{d[\text{A}]}{[\text{A}]^2} = -k_r dt$$

The concentration is  $[\text{A}]_0$  at  $t=0$  and  $[\text{A}]$  at a general time  $t$  later. Therefore,

$$-\int_{[\text{A}]_0}^{[\text{A}]} \frac{d[\text{A}]}{[\text{A}]^2} = k_r \int_0^t dt$$

Because the integral of  $1/x^2$  is  $-1/x + \text{constant}$ , we obtain eqn 20B.4b by substitution of the limits

$$\frac{1}{[\text{A}]} + \text{constant} \Big|_{[\text{A}]_0}^{[\text{A}]} = \frac{1}{[\text{A}]} - \frac{1}{[\text{A}]_0} = k_r t$$

We can then rearrange this expression into eqn 20B.4c.

Equation 20B.4b shows that to test for a second-order reaction we should plot  $1/[\text{A}]$  against  $t$  and expect a straight line.

Table 20B.2\* Kinetic data for second-order reactions

Reaction	Phase	$\theta/^\circ\text{C}$	$k_r/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$
$2 \text{NOBr} \rightarrow 2 \text{NO} + \text{Br}_2$	g	10	0.80
$2 \text{I} \rightarrow \text{I}_2$	g	23	$7 \times 10^9$
$\text{CH}_3\text{Cl} + \text{CH}_3\text{O}^-$	$\text{CH}_3\text{OH}(\text{l})$	20	$2.29 \times 10^{-6}$

\* More values are given in the *Resource section*.

The slope of the graph is  $k_r$ . Some rate constants determined in this way are given in Table 20B.2. The rearranged form, eqn 20B.4c, lets us predict the concentration of A at any time after the start of the reaction. It shows that the concentration of A approaches zero more slowly than in a first-order reaction with the same initial rate (Fig. 20B.3).

It follows from eqn 20B.4b by substituting  $t=t_{1/2}$  and  $[\text{A}] = \frac{1}{2}[\text{A}]_0$  that the half-life of a species A that is consumed in a second-order reaction is

$$t_{1/2} = \frac{1}{k_r [\text{A}]_0} \quad \begin{array}{l} \text{Second-order reaction} \\ \text{Half-life} \end{array} \quad (20\text{B.5})$$

Therefore, unlike a first-order reaction, the half-life of a substance in a second-order reaction varies with the initial concentration. A practical consequence of this dependence is that species that decay by second-order reactions (which includes some environmentally harmful substances) may persist in low concentrations for long periods because their half-lives are long when their concentrations are low. In general, for an  $n$ th-order reaction (with  $n$  neither 0 nor 1) of the form  $\text{A} \rightarrow \text{products}$ , the half-life is related to the rate constant and the initial concentration of A by (see Problem 20B.16)

$$t_{1/2} = \frac{2^{n-1} - 1}{(n-1)k_r [\text{A}]_0^{n-1}} \quad \begin{array}{l} \text{nth-order reaction} \\ \text{Half-life} \end{array} \quad (20\text{B.6})$$

Figure 20B.3 The variation with time of the concentration of a reactant in a second-order reaction. The dotted lines are the corresponding decays in a first-order reaction with the same initial rate. For this illustration,  $k_{r,\text{large}} = 3k_{r,\text{small}}$ .

Another type of second-order reaction is one that is first order in each of two reactants A and B:

$$\frac{d[A]}{dt} = -k_r[A][B] \quad (20B.7)$$

To integrate this rate law we need to know how the concentration of B is related to that of A. For example, if the reaction is  $A+B \rightarrow P$ , where P denotes products, and the initial concentrations are  $[A]_0$  and  $[B]_0$ , then it is shown in the following *Justification* that at a time  $t$  after the start of the reaction, the concentrations satisfy the relation

$$\ln \frac{[B]/[B]_0}{[A]/[A]_0} = ([B]_0 - [A]_0)k_r t \quad (20B.8)$$

*Second-order reaction of the type  $A+B \rightarrow P$* 
Integrated rate law

Therefore, a plot of the expression on the left against  $t$  should be a straight line from which  $k_r$  can be obtained. As shown in the following *Brief illustration*, the rate constant may be estimated quickly by using data from only two measurements.

#### Brief illustration 20B.1 Second-order reactions

Consider a second-order reaction of the type  $A+B \rightarrow P$  carried out in a solution. Initially, the concentrations of reactants were  $[A]_0 = 0.075 \text{ mol dm}^{-3}$  and  $[B]_0 = 0.050 \text{ mol dm}^{-3}$ . After 1.0 h the concentration of B fell to  $[B] = 0.020 \text{ mol dm}^{-3}$ . Because  $\Delta[B] = \Delta[A]$ , it follows that during this time interval

$$\begin{aligned} \Delta[B] &= (0.020 - 0.050) \text{ mol dm}^{-3} = -0.030 \text{ mol dm}^{-3} \\ \Delta[A] &= -0.030 \text{ mol dm}^{-3} \end{aligned}$$

Therefore, the concentrations of A and B after 1.0 h are

$$\begin{aligned} [A] &= \Delta[A] + [A]_0 = (-0.030 + 0.075) \text{ mol dm}^{-3} = 0.045 \text{ mol dm}^{-3} \\ [B] &= 0.020 \text{ mol dm}^{-3} \end{aligned}$$

It follows from rearrangement of eqn 20B.8 that

$$k_r(3600 \text{ s}) = \frac{1}{(0.050 - 0.075) \text{ mol dm}^{-3}} \ln \frac{0.020/0.050}{0.045/0.075}$$

where we have used 1 hr = 3600 s. Solving this expression for the rate constant gives

$$k_r = 4.5 \times 10^{-3} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

**Self-test 20B.2** Calculate the half-life of the reactants for the reaction.

Answer:  $t_{1/2}(A) = 5.1 \times 10^3 \text{ s}$ ,  $t_{1/2}(B) = 2.1 \times 10^3 \text{ s}$

#### Justification 20B.3 Overall second-order rate law

It follows from the reaction stoichiometry that when the concentration of A has fallen to  $[A]_0 - x$ , the concentration of B will have fallen to  $[B]_0 - x$  (because each A that disappears entails the disappearance of one B). It follows that

$$\frac{d[A]}{dt} = -k_r([A]_0 - x)([B]_0 - x)$$

Because  $[A] = [A]_0 - x$ , it follows that  $d[A]/dt = -dx/dt$  and the rate law may be written as

$$\frac{dx}{dt} = k_r([A]_0 - x)([B]_0 - x)$$

The initial condition is that  $x=0$  when  $t=0$ ; so the integration required is

$$\int_0^x \frac{dx}{([A]_0 - x)([B]_0 - x)} = k_r \int_0^t dt$$

The integral on the right is simply  $k_r t$ . The integral on the left is evaluated by using the method of partial fractions (see *The chemist's toolkit* 20B.1):

$$\int_0^x \frac{dx}{([A]_0 - x)([B]_0 - x)} = \frac{1}{[B]_0 - [A]_0} \left\{ \ln \frac{[A]_0}{[A]_0 - x} - \ln \frac{[B]_0}{[B]_0 - x} \right\}$$

The two logarithms can be combined as follows:

$$\begin{aligned} \ln \frac{[A]_0}{[A]_0 - x} - \ln \frac{[B]_0}{[B]_0 - x} &= \ln \frac{[A]_0}{[A]} - \ln \frac{[B]_0}{[B]} \\ &= \ln \frac{1}{[A]/[A]_0} - \ln \frac{1}{[B]/[B]_0} \\ &= \ln \frac{[B]/[B]_0}{[A]/[A]_0} \end{aligned}$$

Combining all the results so far gives eqn 20B.8. Similar calculations may be carried out to find the integrated rate laws for other orders, and some are listed in Table 20B.3.

#### The chemist's toolkit 20B.1 Integration by the method of partial fractions

To solve an integral of the form

$$I = \int \frac{1}{(a-x)(b-x)} dx$$

where  $a$  and  $b$  are constants, we use the method of partial fractions in which a fraction that is the product of terms (as in the

denominator of this integrand) is written as a sum of fractions. To implement this procedure we write the integrand as

$$\frac{1}{(a-x)(b-x)} = \frac{1}{b-a} \left( \frac{1}{a-x} - \frac{1}{b-x} \right)$$

Then we integrate each term on the right. It follows that

$$I = \frac{1}{b-a} \left( \int \frac{dx}{a-x} - \int \frac{dx}{b-x} \right) \stackrel{\text{Integral A.2}}{=} \frac{1}{b-a} \left( \ln \frac{1}{a-x} - \ln \frac{1}{b-x} \right) a + \text{constant}$$

Table 20B.3 Integrated rate laws

Order	Reaction	Rate law*	$t_{1/2}$
0	A → P	$v = k_r$ $k_r t = x$ for $0 \leq x \leq [A]_0$	$[A]_0 / 2k_r$
1	A → P	$v = k_r[A]$ $k_r t = \ln \frac{[A]_0}{[A]_0 - x}$	$(\ln 2) / k_r$
2	A → P	$v = k_r[A]^2$ $k_r t = \frac{x}{[A]_0([A]_0 - x)}$	$1 / k_r[A]_0$
	A + B → P	$v = k_r[A][B]$ $k_r t = \frac{1}{[B]_0 - [A]_0} \ln \frac{[A]_0([B]_0 - x)}{([A]_0 - x)[B]_0}$	
	A + 2 B → P	$v = k_r[A][B]$ $k_r t = \frac{1}{[B]_0 - 2[A]_0} \ln \frac{[A]_0([B]_0 - 2x)}{([A]_0 - x)[B]_0}$	
	A → P with autocatalysis	$v = k_r[A][P]$ $k_r t = \frac{1}{[A]_0 + [P]_0} \ln \frac{[A]_0([P]_0 + x)}{([A]_0 - x)[P]_0}$	
3	A + 2 B → P	$v = k_r[A][B]^2$ $k_r t = \frac{2x}{(2[A]_0 - [B]_0)([B]_0 - 2x)[B]_0} + \frac{1}{(2[A]_0 - [B]_0)^2} \ln \frac{[A]_0([B]_0 - 2x)}{([A]_0 - x)[B]_0}$	
$n \geq 2$	A → P	$v = k_r[A]^n$ $k_r t = \frac{1}{n-1} \left\{ \frac{1}{([A]_0 - x)^{n-1}} - \frac{1}{[A]_0^{n-1}} \right\}$	$\frac{2^{n-1} - 1}{(n-1)k_r[A]_0^{n-1}}$

\*  $x = [P]$  and  $v = dx/dt$

## Checklist of concepts

- 1. An **integrated rate law** is an expression for the concentration of a reactant or product as a function of time (Table 20B.3).
- 2. The **half-life** of a reactant is the time it takes for its concentration to fall to half its initial value.
- 3. Analysis of experimental data using integrated rate laws allow for the prediction of the composition of a reaction system at any stage, the verification of the rate law, and the determination of the rate constant.

## Checklist of equations

Property	Equation	Comment	Equation number
Integrated rate law	$\ln([A]/[A]_0) = -k_r t$ or $[A] = [A]_0 e^{-k_r t}$	First order, $A \rightarrow P$	20B.1b
Half-life	$t_{1/2} = (\ln 2)/k_r$	First order, $A \rightarrow P$	20B.2
Time constant	$\tau = 1/k_r$	First order	20B.3
Integrated rate law	$1/[A] - 1/[A]_0 = k_r t$ or $[A] = [A]_0 / (1 + k_r t [A]_0)$	Second order, $A \rightarrow P$	20B.4b,c
Half-life	$t_{1/2} = 1/k_r [A]_0$	Second order, $A \rightarrow P$	20B.5
	$t_{1/2} = (2^{n-1} - 1)/(n-1)k_r [A]_0^{n-1}$	$n$ th order, $n \neq 0, 1$	20B.6
Integrated rate law	$\ln\{([B]/[B]_0)/([A]/[A]_0)\} = ([B]_0 - [A]_0)k_r t$	Second order, $A + B \rightarrow P$	20B.8

### ► Why do you need to know this material?

All reactions approach equilibrium, so it is important to be able to describe the changing composition as they approach this composition. Analysis of the time dependence shows that there is an important relation between the rate constants and the equilibrium constant.

### ► What is the key idea?

Both forward and reverse reactions must be incorporated into a reaction scheme to account for the approach to equilibrium.

### ► What do you need to know already?

You need to be familiar with the concepts of rate law, reaction order, and rate constant (Topic 20A), integrated rate laws (Topic 20B), and equilibrium constants (Topic 6A). As in Topic 20B, the manipulation of simple rate laws requires only elementary techniques of integration.

In practice, most kinetic studies are made on reactions that are far from equilibrium and if products are in low concentration the reverse reactions are unimportant. Close to equilibrium the products may be so abundant that the reverse reaction must be taken into account.

## 20C.1 First-order reactions approaching equilibrium

We can explore the variation of the composition with time as a reaction approaches equilibrium by considering a reaction in

which A forms B and both forward and reverse reactions are first order (as in some isomerizations):

The concentration of A is reduced by the forward reaction (at a rate  $k_f[A]$ ) but it is increased by the reverse reaction (at a rate  $k_r[B]$ ). The net rate of change at any stage is therefore

$$\frac{d[A]}{dt} = -k_f[A] + k_r[B] \quad (20C.2)$$

If the initial concentration of A is  $[A]_0$ , and no B is present initially, then at all times  $[A] + [B] = [A]_0$ . Therefore,

$$\begin{aligned} \frac{d[A]}{dt} &= -k_f[A] + k_r([A]_0 - [A]) \\ &= -(k_f + k_r)[A] + k_r[A]_0 \end{aligned} \quad (20C.3)$$

The solution of this first-order differential equation (as may be checked by differentiation, Problem 20C.1) is

$$[A] = \frac{k_r + k_f e^{-(k_f + k_r)t}}{k_f + k_r} [A]_0 \quad (20C.4)$$

Figure 20C.1 shows the time dependence predicted by this equation, with  $[B] = [A]_0 - [A]$ .

As  $t \rightarrow \infty$ , the concentrations reach their equilibrium values, which are given by eqn 20C.4 as:

Figure 20C.1 The approach of concentrations to their equilibrium values as predicted by eqn 20C.4 for a reaction  $A \rightleftharpoons B$  that is first order in each direction, and for which  $k_f = 2k_r'$ .

$$[A]_{\text{eq}} = \frac{k'_r[A]_0}{k_r + k'_r} \quad [B]_{\text{eq}} = [A]_0 - [A]_{\text{eq}} = \frac{k_r[A]_0}{k_r + k'_r} \quad (20C.5)$$

It follows that the equilibrium constant of the reaction is

$$K = \frac{[B]_{\text{eq}}}{[A]_{\text{eq}}} = \frac{k_r}{k'_r} \quad (20C.6)$$

(As explained in Topic 5E, we are justified in replacing activities with the numerical values of molar concentrations if the system is treated as ideal.) Exactly the same conclusion can be reached—more simply, in fact—by noting that, at equilibrium, the forward and reverse rates must be the same, so

$$k_r[A] = k'_r[B] \quad (20C.7)$$

This relation rearranges into eqn 20C.6. The theoretical importance of eqn 20C.6 is that it relates a thermodynamic quantity, the equilibrium constant, to quantities relating to rates. Its practical importance is that if one of the rate constants can be measured, then the other may be obtained if the equilibrium constant is known.

Equation 20C.6 is valid even if the forward and reverse reactions have different orders, but in that case we need to be careful with units. For instance, if the reaction  $A + B \rightarrow C$  is second order forward and first order in reverse, then the condition for equilibrium is  $k_r[A]_{\text{eq}}[B]_{\text{eq}} = k'_r[C]_{\text{eq}}$  and the dimensionless equilibrium constant in full dress is

$$K = \frac{[C]_{\text{eq}}/c^\ominus}{([A]_{\text{eq}}/c^\ominus)([B]_{\text{eq}}/c^\ominus)} = \left( \frac{[C]}{[A][B]} \right)_{\text{eq}} c^\ominus = \frac{k_r}{k'_r} \times c^\ominus$$

The presence of  $c^\ominus = 1 \text{ mol dm}^{-3}$  in the last term ensures that the ratio of second-order to first-order rate constants, with their different units, is turned into a dimensionless quantity.

#### Brief illustration 20C.1 The equilibrium constant from rate constants

The rates of the forward and reverse reactions for a dimerization reaction were found to be  $8.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  (second-order) and  $2.0 \times 10^6 \text{ s}^{-1}$  (first-order). The equilibrium constant for the dimerization is therefore

$$K = \frac{8.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}}{2.0 \times 10^6 \text{ s}^{-1}} \times 1 \text{ mol dm}^{-3} = 4.0 \times 10^2$$

**Self-test 20C.1** The equilibrium constant for the attachment of a drug molecule to a protein was measured as  $2.0 \times 10^2$ . In a separate experiment, the rate constant for the second-order attachment was found to be  $1.5 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . What is the rate constant for the loss of the drug molecule from the protein?

Answer:  $7.5 \times 10^5 \text{ s}^{-1}$

For a more general reaction, the overall equilibrium constant can be expressed in terms of the rate constants for all the intermediate stages of the reaction mechanism (see Problem 20C.4):

$$K = \frac{k_a}{k'_a} \times \frac{k_b}{k'_b} \times \dots \quad \text{Equilibrium constant in terms of the rate constants} \quad (20C.8)$$

where the  $k_r$  are the rate constants for the individual steps and the  $k'_r$  are those for the corresponding reverse steps.

## 20C.2 Relaxation methods

The term **relaxation** denotes the return of a system to equilibrium. It is used in chemical kinetics to indicate that an externally applied influence has shifted the equilibrium position of a reaction, normally suddenly, and that the reaction is adjusting to the equilibrium composition characteristic of the new conditions (Fig. 20C.2). We shall consider the response of reaction rates to a **temperature jump**, a sudden change in temperature. We know from Topic 6B that the equilibrium composition of a reaction depends on the temperature (provided  $\Delta_r H^\ominus$  is nonzero), so a shift in temperature acts as a perturbation on the system. One way of achieving a temperature jump is to discharge a capacitor through a sample that has been made conducting by the addition of ions, but laser or microwave discharges can also be used. Temperature jumps of between 5 and 10 K can be achieved in about 1  $\mu\text{s}$  with electrical discharges. The high energy output of pulsed lasers is sufficient to generate temperature jumps of between 10 and 30 K within nanoseconds in aqueous samples. Some equilibria are also sensitive to pressure, and **pressure-jump techniques** may then also be used.

We show in the following *Justification* that when a sudden temperature increase is applied to a simple  $A \rightleftharpoons B$  equilibrium that is first order in each direction, the composition relaxes exponentially to the new equilibrium composition:

**Figure 20C.2** The relaxation to the new equilibrium composition when a reaction initially at equilibrium at a temperature  $T_1$  is subjected to a sudden change of temperature, which takes it to  $T_2$ .

$$x = x_0 e^{-t/\tau} \quad \tau = \frac{1}{k_r + k'_r} \quad \begin{array}{l} \text{First-order} \\ \text{reaction} \end{array} \quad \begin{array}{l} \text{Relaxation after a} \\ \text{temperature jump} \end{array} \quad (20C.9)$$

where  $x_0$  is the departure from equilibrium immediately after the temperature jump,  $x$  is the departure from equilibrium at the new temperature after a time  $t$ , and  $k_r$  and  $k'_r$  are the forward and reverse rate constants, respectively, at the new temperature.

### Justification 20C.1 Relaxation to equilibrium

When the temperature of a system at equilibrium is increased suddenly, the rate constants change from their earlier values to the new values  $k_r$  and  $k'_r$  characteristic of that temperature, but the concentrations of A and B remain for an instant at their old equilibrium values. As the system is no longer at equilibrium, it readjusts to the new equilibrium concentrations, which are now given by

$$k_r[A]_{\text{eq}} = k'_r[B]_{\text{eq}}$$

and it does so at a rate that depends on the new rate constants. We write the deviation of [A] from its new equilibrium value as  $x$ , so  $[A] = [A]_{\text{eq}} + x$  and  $[B] = [B]_{\text{eq}} - x$ . The concentration of A then changes as follows:

$$\begin{aligned} \frac{d[A]}{dt} &= -k_r[A] + k'_r[B] \\ &= -k_r([A]_{\text{eq}} + x) + k'_r([B]_{\text{eq}} - x) \\ &= -(k_r + k'_r)x \end{aligned}$$

because the two terms involving the equilibrium concentrations cancel. Because  $d[A]/dt = dx/dt$ , this equation is a first-order differential equation with the solution that resembles eqn 20A.1b and is given in eqn 20C.9.

Equation 20C.9 shows that the concentrations of A and B relax into the new equilibrium at a rate determined by the sum of the two new rate constants. Because the equilibrium constant under the new conditions is  $K \approx k_r/k'_r$ , its value may be combined with the relaxation time measurement to find the individual  $k_r$  and  $k'_r$ .

### Example 20C.1 Analysing a temperature-jump experiment

The equilibrium constant for the autoprotolysis of water,  $\text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{H}^+(\text{aq}) + \text{OH}^-(\text{aq})$ , is  $K_w = a(\text{H}^+)a(\text{OH}^-) = 1.008 \times 10^{-14}$  at 298 K, where we have used the exact expression in terms of activities. After a temperature-jump, the reaction returns to equilibrium with a relaxation time of 37  $\mu\text{s}$  at 298 K and  $\text{pH} \approx 7$ . Given that the forward reaction is first order and the reverse is second order overall, calculate the rate constants for the forward and reverse reactions.

**Method** We need to derive an expression for the relaxation time,  $\tau$  (the time constant for return to equilibrium), in terms of  $k_r$  (forward, first-order reaction) and  $k'_r$  (reverse, second-order reaction). We can proceed as above, but it will be necessary to make the assumption that the deviation from equilibrium ( $x$ ) is so small that terms in  $x^2$  can be neglected. Relate  $k_r$  and  $k'_r$  through the equilibrium constant, but be careful with units because  $K_w$  is dimensionless.

**Answer** The forward rate at the final temperature is  $k_r[\text{H}_2\text{O}]$  and the reverse rate is  $k'_r[\text{H}^+][\text{OH}^-]$ . The net rate of deprotonation of  $\text{H}_2\text{O}$  is

$$\frac{d[\text{H}_2\text{O}]}{dt} = -k_r[\text{H}_2\text{O}] + k'_r[\text{H}^+][\text{OH}^-]$$

We write  $[\text{H}_2\text{O}] = [\text{H}_2\text{O}]_{\text{eq}} + x$ ,  $[\text{H}^+] = [\text{H}^+]_{\text{eq}} - x$ , and  $[\text{OH}^-] = [\text{OH}^-]_{\text{eq}} - x$ , and obtain

$$\begin{aligned} \frac{dx}{dt} &= -\{k_r + k'_r([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})\}x \\ &\quad -k_r[\text{H}_2\text{O}]_{\text{eq}} + k'_r[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}} + k'_r x^2 \\ &\approx -\{k_r + k'_r([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})\}x \end{aligned}$$

where we have neglected the term in  $x^2$  because it is so small and have used the equilibrium condition  $k_r[\text{H}_2\text{O}]_{\text{eq}} = k'_r[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}$  to eliminate the terms (in blue) that are independent of  $x$ . It follows that

$$\frac{1}{\tau} = k_r + k'_r([\text{H}^+]_{\text{eq}} + [\text{OH}^-]_{\text{eq}})$$

At this point we note that

$$\begin{aligned} K_w &= a(\text{H}^+)a(\text{OH}^-) \approx ([\text{H}^+]_{\text{eq}}/c^\ominus)([\text{OH}^-]_{\text{eq}}/c^\ominus) \\ &= [\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}/c^{\ominus 2} \end{aligned}$$

with  $c^\ominus = 1 \text{ mol dm}^{-3}$ . For this electrically neutral system,  $[\text{H}^+] = [\text{OH}^-]$ , so the concentration of each type of ion is  $K_w^{1/2}c^\ominus$ , and hence

$$\frac{1}{\tau} = k_r + k'_r(K_w^{1/2}c^\ominus + K_w^{1/2}c^\ominus) = k'_r \left\{ \frac{k_r}{k'_r} + 2K_w^{1/2}c^\ominus \right\}$$

At this point we note that

$$\frac{k_r}{k'_r} = \frac{[\text{H}^+]_{\text{eq}}[\text{OH}^-]_{\text{eq}}}{[\text{H}_2\text{O}]_{\text{eq}}} = \frac{K_w c^{\ominus 2}}{[\text{H}_2\text{O}]_{\text{eq}}}$$

and therefore

$$\frac{1}{\tau} = 2k'_r \left( 1 + \frac{K_w^{1/2}c^\ominus}{2[\text{H}_2\text{O}]_{\text{eq}}} \right) K_w^{1/2}c^\ominus = 2k'_r(1+K)K_w^{1/2}c^\ominus$$

The molar concentration of pure water is  $55.6 \text{ mol dm}^{-3}$ , so  $[\text{H}_2\text{O}]_{\text{eq}}/c^\ominus = 55.6$  and

$$K = \frac{(1.008 \times 10^{-14})^{1/2}}{2 \times 55.6} = 9.03 \times 10^{-10}$$

which implies that  $1 + K$  may be replaced by 1 and therefore that

$$k'_r \approx \frac{1}{2\tau K_w^{1/2} c^\ominus}$$

$$= \frac{1}{2(3.7 \times 10^{-5} \text{ s}) \times (1.008 \times 10^{-14})^{1/2} \times (1 \text{ mol dm}^{-3})}$$

$$= 1.4 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

It follows from the expression for  $k_r/k'_r$  that

$$k_r = \frac{K_w c^{\ominus 2} k'_r}{[\text{H}_2\text{O}]_{\text{eq}}}$$

$$= \frac{(1.008 \times 10^{-14}) \times (1 \text{ mol dm}^{-3})^2 \times (1.4 \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1})}{55.6 \text{ mol dm}^{-3}}$$

$$= 2.5 \times 10^{-5} \text{ s}^{-1}$$

The reaction is faster in ice, where  $k'_r = 8.6 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ .

*A note on good practice* Notice how we keep track of units through the use of  $c^\ominus$ :  $K$  and  $K_w$  are dimensionless;  $k'_r$  is expressed in  $\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and  $k_r$  is expressed in  $\text{s}^{-1}$ .

**Self-test 20C.2** Derive an expression for the relaxation time of a concentration when the reaction  $A + B \rightleftharpoons C + D$  is second order in both directions.

$$\text{Answer: } 1/\tau = k_r([A] + [B])_{\text{eq}} + k'_r([C] + [D])_{\text{eq}}$$

## Checklist of concepts

- 1. There is a relation between the equilibrium constant, a thermodynamic quantity, and the rate constants of the forward and reverse reactions (see Checklist of equations).
- 2. In **relaxation methods** of kinetic analysis, the equilibrium position of a reaction is first shifted suddenly and then allowed to readjust to the equilibrium composition characteristic of the new conditions.

## Checklist of equations

Property	Equation	Comment	Equation number
Equilibrium constant in terms of rate constants	$K = k_a/k'_a \times k_b/k'_b \times \dots$	include $c^\ominus$ as appropriate	20C.8
Relaxation of an equilibrium $A \rightleftharpoons B$ after a temperature jump	$x = x_0 e^{-t/\tau}$ $\tau = 1/(k_r + k'_r)$	First order in each direction	20C.9

### ► Why do you need to know this material?

The rates of reactions depend on the temperature. Exploration of this dependence leads to the formulation of theories that can help you understand the details of the processes that occur when reactant molecules meet and why a collection of reactants under specific conditions leads to certain products but not others.

### ► What is the key idea?

The temperature dependence of the rate of a reaction is summarized by the activation energy, the minimum energy needed for reaction to occur in an encounter between reactants.

### ► What do you need to know already?

You need to know that the rate of a chemical reaction is expressed by a rate constant (Topic 20A).

In this Topic we interpret the common experimental observation that chemical reactions usually go faster as the temperature is raised. We also begin to see how exploration of the temperature dependence of reaction rates can reveal some details of the energy requirements for molecular encounters that lead to the formation of products.

## 20D.1 The temperature dependence of reaction rates

It is found experimentally for many reactions that a plot of  $\ln k_r$  against  $1/T$  gives a straight line with a negative slope, indicating that an increase in  $\ln k_r$  (and therefore an increase in  $k_r$ ) results from a decrease in  $1/T$  (that is, an increase in  $T$ ). This behaviour is normally expressed mathematically by introducing two parameters, one representing the intercept and the other the slope of the straight line, and writing the **Arrhenius equation**

$$\ln k_r = \ln A - \frac{E_a}{RT} \quad \text{Arrhenius equation} \quad (20D.1)$$

The parameter  $A$ , which corresponds to the intercept of the line at  $1/T=0$  (at infinite temperature, Fig. 20D.1), is called the **pre-exponential factor** or the ‘frequency factor’. The parameter  $E_a$ , which is obtained from the slope of the line ( $-E_a/R$ ), is called the **activation energy**. Collectively the two quantities are called the **Arrhenius parameters** (Table 20D.1).

**Figure 20D.1** A plot of  $\ln k_r$  against  $1/T$  is a straight line when the reaction follows the behaviour described by the Arrhenius equation (eqn 20D.1). The slope gives  $-E_a/R$  and the intercept at  $1/T=0$  gives  $\ln A$ .

### Example 20D.1 Determining the Arrhenius parameters

The rate of the second-order decomposition of acetaldehyde (ethanal,  $\text{CH}_3\text{CHO}$ ) was measured over the temperature range 700–1000 K, and the rate constants are reported below. Find  $E_a$  and  $A$ .

T/K	700	730	760	790	810	840	910	1000
$k_r/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	0.011	0.035	0.105	0.343	0.789	2.17	20.0	145

**Method** According to eqn 20D.1, the data can be analysed by plotting  $\ln(k_r/\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$  against  $1/(T/\text{K})$ , or more conveniently  $(10^3 \text{ K})/T$ , and getting a straight line. Obtain the activation energy from the dimensionless slope by writing  $-E_a/R = \text{slope}/\text{units}$ , where in this case 'units' =  $1/(10^3 \text{ K})$ , so  $E_a = -\text{slope} \times R \times 10^3 \text{ K}$ . The intercept at  $1/T=0$  is  $\ln(A/\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$ . Use a least-squares procedure to determine the plot parameters.

**Answer** We draw up the following table:

$(10^3 \text{ K})/T$	1.43	1.37	1.32	1.27	1.23	1.19	1.10	1.00
$\ln(k_r/\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	-4.51	-3.35	-2.25	-1.07	-0.24	0.77	3.00	4.98

Now plot  $\ln k_r$  against  $1/T$  (Fig. 20D.2). The least-squares fit results in a line with slope  $-22.7$  and intercept  $27.7$ . Therefore,

$$E_a = 22.7 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (10^3 \text{ K}) = 189 \text{ kJ mol}^{-1}$$

$$A = e^{27.7} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} = 1.1 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

Note that  $A$  has the same units as  $k_r$ .

Figure 20D.2 The Arrhenius plot using the data in Example 20D.1.

**Self-test 20D.1** Determine  $A$  and  $E_a$  from the following data:

T/K	300	350	400	450	500
$k_r/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$7.9 \times 10^6$	$3.0 \times 10^7$	$7.9 \times 10^7$	$1.7 \times 10^8$	$3.2 \times 10^8$

Answer:  $8 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ,  $23 \text{ kJ mol}^{-1}$

Once the activation energy of a reaction is known, it is a simple matter to predict the value of a rate constant  $k_{r,2}$  at a temperature  $T_2$  from its value  $k_{r,1}$  at another temperature  $T_1$ . To do so, we write

Table 20D.1\* Arrhenius parameters

(1) First-order reactions	$A/\text{s}^{-1}$	$E_a/(\text{kJ mol}^{-1})$
$\text{CH}_3\text{NC} \rightarrow \text{CH}_3\text{CN}$	$3.98 \times 10^{13}$	160
$2 \text{ N}_2\text{O}_5 \rightarrow 4 \text{ NO}_2 + \text{O}_2$	$4.94 \times 10^{13}$	103.4
(2) Second-order reactions	$A/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E_a/(\text{kJ mol}^{-1})$
$\text{OH} + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{H}$	$8.0 \times 10^{10}$	42
$\text{NaC}_2\text{H}_3\text{O} + \text{CH}_3\text{I}$ in ethanol	$2.42 \times 10^{11}$	81.6

\* More values are given in the Resource section.

$$\ln k_{r,2} = \ln A - \frac{E_a}{RT_2}$$

and then subtract eqn 20D.1 (with  $T$  identified as  $T_1$  and  $k_r$  as  $k_{r,1}$ ), so obtaining

$$\ln k_{r,2} - \ln k_{r,1} = -\frac{E_a}{RT_2} + \frac{E_a}{RT_1}$$

We can rearrange this expression to

$$\ln \frac{k_{r,2}}{k_{r,1}} = \frac{E_a}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right) \quad \text{Temperature dependence of the rate constant} \quad (20D.2)$$

### Brief illustration 20D.1 The Arrhenius equation

For a reaction with an activation energy of  $50 \text{ kJ mol}^{-1}$ , an increase in the temperature from  $25^\circ\text{C}$  to  $37^\circ\text{C}$  (body temperature) corresponds to

$$\begin{aligned} \ln \frac{k_{r,2}}{k_{r,1}} &= \frac{50 \times 10^3 \text{ J mol}^{-1}}{8.3145 \text{ J K}^{-1} \text{ mol}^{-1}} \left( \frac{1}{298 \text{ K}} - \frac{1}{310 \text{ K}} \right) \\ &= \frac{50 \times 10^3}{8.3145} \left( \frac{1}{298} - \frac{1}{310} \right) = 0.781 \dots \end{aligned}$$

By taking natural antilogarithms (that is, by forming  $e^x$ ),  $k_{r,2} = 2.18 k_{r,1}$ . This result corresponds to slightly more than a doubling of the rate constant as the temperature is increased from  $298 \text{ K}$  to  $310 \text{ K}$ .

**Self-test 20D.2** The activation energy of one of the reactions in a biochemical process is  $87 \text{ kJ mol}^{-1}$ . What is the change in rate constant when the temperature falls from  $37^\circ\text{C}$  to  $15^\circ\text{C}$ ?

Answer:  $k_r(15^\circ\text{C}) = 0.076 k_r(37^\circ\text{C})$

The fact that  $E_a$  is given by the slope of the plot of  $\ln k_r$  against  $1/T$  leads to the following conclusions:

- The stronger the temperature dependence of the rate constant (that is, the steeper the slope), the higher the activation energy.

- A high activation energy signifies that the rate constant depends strongly on temperature.
- If a reaction has zero activation energy, its rate is independent of temperature.
- A negative activation energy indicates that the rate decreases as the temperature is raised.

Physical interpretation

The temperature dependence of some reactions is ‘non-Arrhenius’ in the sense that a straight line is not obtained when  $\ln k_r$  is plotted against  $1/T$ . However, it is still possible to define an activation energy at any temperature as

$$E_a = RT^2 \left( \frac{d \ln k_r}{dT} \right) \quad \text{Definition} \quad \text{Activation energy} \quad (20D.3)$$

This definition reduces to the earlier one (as the slope of a straight line) for a temperature-independent activation energy (see Problem 20D.1). However, the definition in eqn 20D.3 is more general than that in eqn 20D.1, because it allows  $E_a$  to be obtained from the slope (at the temperature of interest) of a plot of  $\ln k_r$  against  $1/T$  even if the Arrhenius plot is not a straight line. Non-Arrhenius behaviour is sometimes a sign that quantum mechanical tunnelling (Topic 8A) is playing a significant role in the reaction. In biological reactions it might signal that an enzyme has undergone a structural change and has become less efficient.

## 20D.2 The interpretation of the Arrhenius parameters

For the present Topic we shall regard the Arrhenius parameters as purely empirical quantities that enable us to summarize the variation of rate constants with temperature. However, it is useful to have an interpretation in mind. Topics 21A–21F provide a more elaborate interpretation.

### (a) A first look at the energy requirements of reactions

To interpret  $E_a$  we consider how the molecular potential energy changes in the course of a chemical reaction that begins with a collision between molecules of A and molecules of B (Fig. 20D.3). In the gas phase that is an actual collision; in solution it is best regarded as a close encounter, possibly with excess energy, and might involve the solvent too. As the reaction event proceeds, A and B come into contact, distort, and begin to exchange or discard atoms. The **reaction coordinate** summarizes the collection of motions, such as changes in interatomic distances and bond angles, that are directly involved in the formation of products from reactants. (The reaction coordinate is

**Figure 20D.3** A potential energy profile for an exothermic reaction. The height of the barrier between the reactants and products is the activation energy of the reaction.

essentially a geometrical concept and quite distinct from the extent of reaction.) The potential energy rises to a maximum and the cluster of atoms that corresponds to the region close to the maximum is called the **activated complex**.

After the maximum, the potential energy falls as the atoms rearrange in the cluster and reaches a value characteristic of the products. The climax of the reaction is at the peak of the potential energy, which corresponds to the activation energy  $E_a$ . Here two reactant molecules have come to such a degree of closeness and distortion that a small further distortion will send them in the direction of products. This crucial configuration is called the **transition state** of the reaction. Although some molecules entering the transition state might revert to reactants, if they pass through this configuration then it is inevitable that products will emerge from the encounter. (The terms ‘activated complex’ and ‘transition state’ are often used as synonyms; however, we shall preserve a distinction.)

We conclude from the preceding discussion that *the activation energy is the minimum energy reactants must have in order to form products*. For example, in a reaction mixture there are numerous molecular encounters each second, but only very few are sufficiently energetic to lead to reaction. The fraction of close encounters between reactants with energy in excess of  $E_a$  is given by the Boltzmann distribution (Foundations B and Topic 15A) as  $e^{-E_a/RT}$ . This interpretation is confirmed by comparing this expression with the Arrhenius equation written in the form

$$k_r = Ae^{-E_a/RT} \quad \text{Alternative form} \quad \text{Arrhenius equation} \quad (20D.4)$$

which is obtained by taking antilogarithms of both sides of eqn 20D.1. We show in the following *Justification* that the exponential factor in eqn 20D.4 can be interpreted as the fraction of encounters that have enough energy to lead to reaction. This point is explored further for gas-phase reactions in Topic 21A and for reactions in solution in Topic 21C.

**Justification 20D.1** Interpreting the activation energy

Suppose the energy levels available to the system form a uniform array of separation  $\epsilon$  (Fig. 20D.4). The Boltzmann distribution is

$$\frac{N_i}{N} = \frac{e^{-i\epsilon\beta}}{q} = (1 - e^{-\epsilon\beta})e^{-i\epsilon\beta}$$

where  $\beta = 1/kT$  and we have used the result in eqn 15B.2a for the partition function  $q$ . The total number of molecules in states with energy of at least  $i_{\min}\epsilon$  is

$$\sum_{i=i_{\min}}^{\infty} N_i = \sum_{i=0}^{\infty} N_i - \sum_{i=0}^{i_{\min}-1} N_i = N - \frac{N}{q} \sum_{i=0}^{i_{\min}-1} e^{-i\epsilon\beta}$$

The sum of the (blue) finite geometrical series is

$$\sum_{i=0}^{i_{\min}-1} e^{-i\epsilon\beta} = \frac{1 - e^{-i_{\min}\epsilon\beta}}{1 - e^{-\epsilon\beta}} = q(1 - e^{-i_{\min}\epsilon\beta})$$

**Figure 20D.4** Equally spaced energy levels of an idealized system. As shown in *Justification 20D.1*, the fraction of molecules with energy of at least  $e^{-\epsilon_{\min}/kT}$ .

Therefore, the fraction of molecules in states with energy of at least  $\epsilon_{\min} = i_{\min}\epsilon$  is

$$\frac{1}{N} \sum_{i=i_{\min}}^{\infty} N_i = 1 - (1 - e^{-i_{\min}\epsilon\beta}) = e^{-i_{\min}\epsilon\beta} = e^{-\epsilon_{\min}/kT}$$

which has the form of eqn 20D.4.

**Brief illustration 20D.2** The fraction of reactive collisions

From *Justification 20D.1* the fraction of molecules with energy at least  $\epsilon_{\min}$  is  $e^{-\epsilon_{\min}/kT}$ . By multiplying  $\epsilon_{\min}$  and  $k$  by  $N_A$ , Avogadro's constant, and identifying  $N_A\epsilon_{\min}$  with  $E_a$ , then the fraction  $f$  of molecular collisions that occur with a kinetic energy  $E_a$  becomes  $f = e^{-E_a/RT}$ . With  $E_a = 50 \text{ kJ mol}^{-1} = 5.0 \times 10^4 \text{ J mol}^{-1}$  and  $T = 298 \text{ K}$ , we calculate

$$f = e^{-(5.0 \times 10^4 \text{ J mol}^{-1}) / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1} \times 298 \text{ K})} = 1.7 \times 10^{-9}$$

or about 1 in a billion.

**Self-test 20D.3** At what temperature would  $f = 0.10$  if  $E_a = 50 \text{ kJ mol}^{-1}$ ?

Answer:  $T = 2612 \text{ K}$

The pre-exponential factor is a measure of the rate at which collisions occur irrespective of their energy. Hence, the product of  $A$  and the exponential factor,  $e^{-E_a/RT}$  gives the rate of *successful* collisions. We develop these remarks in Topics 21A and 21C, and see that they have their analogues for reactions that take place in liquids.

**(b) The effect of a catalyst on the activation energy**

The Arrhenius equation tells us that the rate constant of a reaction can be increased by increasing the temperature or by decreasing the energy of activation. Changing the temperature of a reaction mixture is an easy strategy. Reducing the energy of activation is more challenging, but is possible if a reaction takes place in the presence of a suitable **catalyst**, a substance that accelerates a reaction but undergoes no net chemical change. The catalyst lowers the activation energy of the reaction by providing an alternative path that avoids the slow, rate-determining step of the uncatalysed reaction (Fig 20D.5).

**Heterogeneous catalysts**, which are discussed in Topic 22C, function in a different phase from the reaction mixture. For example, some gas-phase reactions are accelerated in the presence of a solid catalyst. **Homogeneous catalysts** function in the same phase as the reaction mixture. For example, the  $\text{OH}^-$  ion is a catalyst for a number of organic and inorganic transformations in solution.

**Figure 20D.5** A catalyst provides a different path with a lower activation energy. The result is an increase in the rate of formation of products.

### Brief illustration 20D.3 The effect of a catalyst on the rate constant

The enzyme catalase reduces the activation energy for the decomposition of hydrogen peroxide from  $76 \text{ kJ mol}^{-1}$  to  $8 \text{ kJ mol}^{-1}$ . From eqn 20D.4 and assuming that the exponential factor is the same in both cases, it follows that the ratio of rate constants is:

$$\frac{k_{r,\text{catalysed}}}{k_{r,\text{uncatalysed}}} = \frac{Ae^{-E_{a,\text{catalysed}}/RT}}{Ae^{-E_{a,\text{uncatalysed}}/RT}} = e^{-(E_{a,\text{catalysed}} - E_{a,\text{uncatalysed}})/RT}$$

$$= e^{(68 \times 10^3 \text{ J mol}^{-1}) / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})} = 8.3 \times 10^{11}$$

**Self-test 20D.4** Consider the decomposition of hydrogen peroxide, which can be catalysed in solution by iodide ion. By how much is the activation energy of the reaction reduced if the rate constant of reaction increases by a factor of 2000 at 298 K upon addition of the catalyst?

Answer: 25 per cent

## Checklist of concepts

- 1. The **activation energy**, the parameter  $E_a$  in the **Arrhenius equation**, is the minimum energy of close molecular encounters able to result in reaction.
- 2. The larger the activation energy, the more sensitive the rate constant is to the temperature.
- 3. The **pre-exponential factor** is a measure of the rate at which encounters occur irrespective of their energy.
- 4. A **catalyst** lowers the activation energy of a reaction.

### ► Why do you need to know this material?

You need to know how to construct the rate law for a reaction that takes place by a sequence of steps partly because that gives insight into the atomic processes going on when reactions take place, but also because it indicates how the yield of desired products can be optimized.

### ► What is the key idea?

Many chemical reactions occur as a sequence of simpler steps, with corresponding rate laws that can be combined together by applying one or more approximations.

### ► What do you need to know already?

You need to be familiar with the concept of rate laws (Topic 20A) and how to integrate them (Topics 20B and 20C). You also need to be familiar with the Arrhenius equation for the effect of temperature on reaction rate (Topic 20D).

The study of reaction rates leads to an understanding of the **mechanisms** of reactions, their analysis into a sequence of elementary steps. Simple elementary steps have simple rate laws, which can be combined together by invoking one or more approximations. These approximations include the concept of the rate-determining step of a reaction, the steady-state concentration of a reaction intermediate, and the existence of a pre-equilibrium.

## 20E.1 Elementary reactions

Most reactions occur in a sequence of steps called **elementary reactions**, each of which involves only a small number of molecules or ions. A typical elementary reaction is

Note that the phase of the species is not specified in the chemical equation for an elementary reaction and the equation represents the specific process occurring to individual molecules. This equation, for instance, signifies that an H atom attacks a Br<sub>2</sub> molecule to produce an HBr molecule and a Br atom. The **molecularity** of an elementary reaction is the number of molecules coming together to react in an elementary reaction. In a **unimolecular reaction**, a single molecule shakes itself apart or its atoms into a new arrangement, as in the isomerization of cyclopropane to propene. In a **bimolecular reaction**, a pair of molecules collide and exchange energy, atoms, or groups of atoms, or undergo some other kind of change. It is most important to distinguish molecularity from order:

- *reaction order* is an empirical quantity, and obtained from the experimentally determined rate law;
- *molecularity* refers to an elementary reaction proposed as an individual step in a mechanism.

The rate law of a unimolecular elementary reaction is first-order in the reactant:

where P denotes products (several different species may be formed). A unimolecular reaction is first order because the

number of A molecules that decay in a short interval is proportional to the number available to decay. For instance, ten times as many decay in the same interval when there are initially 1000 A molecules as when there are only 100 present. Therefore, the rate of decomposition of A is proportional to its molar concentration at any moment during the reaction.

An elementary bimolecular reaction has a second-order rate law:

A bimolecular reaction is second-order because its rate is proportional to the rate at which the reactant species meet, which in turn is proportional to both their concentrations. Therefore, if we have evidence that a reaction is a single-step, bimolecular process, we can write down the rate law (and then go on to test it).

#### Brief illustration 20E.1 The rate laws of elementary steps

Bimolecular elementary reactions are believed to account for many homogeneous reactions, such as the dimerizations of alkenes and dienes and reactions such as

(where 'alc' signifies alcohol solution). There is evidence that the mechanism of this reaction is a single elementary step:

This mechanism is consistent with the observed rate law

$$v = k_r[\text{CH}_3\text{I}][\text{CH}_3\text{CH}_2\text{O}^-]$$

**Self-test 20E.1** The following are elementary processes: (a) the dimerization of NO(g) to form N<sub>2</sub>O<sub>2</sub>(g), and (b) the decomposition of the N<sub>2</sub>O<sub>2</sub>(g) dimer into NO(g) molecules. Write the rate laws for these processes.

Answer: (a) bimolecular process:  $k_r[\text{NO}]^2$ , (b) unimolecular process:  $k_r[\text{N}_2\text{O}_2]$

We shall see in the following sections how to combine a series of simple steps together into a mechanism and how to arrive at the corresponding overall rate law. For the present we emphasize that, *if the reaction is an elementary bimolecular process, then it has second-order kinetics, but if the kinetics is second order, then the reaction might be complex.* The postulated mechanism can be explored only by detailed detective work on the system and by investigating whether side products or intermediates appear during the course of the reaction. Detailed analysis of this kind was one of the ways, for example, in which the reaction  $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI}(\text{g})$  was shown to proceed by a complex mechanism. For many years the reaction had been accepted on good but insufficiently meticulous evidence as a fine example of

a simple bimolecular reaction,  $\text{H}_2 + \text{I}_2 \rightarrow \text{HI} + \text{HI}$ , in which atoms exchanged partners during a collision.

## 20E.2 Consecutive elementary reactions

Some reactions proceed through the formation of an intermediate (I), as in the consecutive unimolecular reactions

Note that the intermediate occurs in the reaction steps but does not appear in the overall reaction, which in this case is  $A \rightarrow P$ . We are ignoring any reverse reactions, so the reaction proceeds from all A to all P, not to an equilibrium mixture of the two. An example of this type of mechanism is the decay of a radioactive family, such as

(The times are half-lives.) The characteristics of this type of reaction are discovered by setting up the rate laws for the net rate of change of the concentration of each substance and then combining them in the appropriate manner.

The rate of unimolecular decomposition of A is

$$\frac{d[A]}{dt} = -k_a[A] \quad (20E.3a)$$

and A is not replenished. The intermediate I is formed from A (at a rate  $k_a[A]$ ) but decays to P (at a rate  $k_b[I]$ ). The net rate of formation of I is therefore

$$\frac{d[I]}{dt} = k_a[A] - k_b[I] \quad (20E.3b)$$

The product P is formed by the unimolecular decay of I:

$$\frac{d[P]}{dt} = k_b[I] \quad (20E.3c)$$

We suppose that initially only A is present and that its concentration is then  $[A]_0$ .

The first of the rate laws, eqn 20E.3a, is an ordinary first-order decay, so we can write

$$[A] = [A]_0 e^{-k_a t} \quad (20E.4a)$$

When this equation is substituted into eqn 20E.3b, we obtain after rearrangement

$$\frac{d[I]}{dt} + k_b[I] = k_a[A]_0 e^{-k_a t}$$

**Figure 20E.1** The concentrations of A, I, and P in the consecutive reaction scheme  $A \rightarrow I \rightarrow P$ . The curves are plots of eqns 20E.4a–c with  $k_a = 10k_b$ . If the intermediate I is in fact the desired product, it is important to be able to predict when its concentration is greatest; see *Example 20E.1*.

This differential equation has a standard form (see *Mathematical background 4*) and, after setting  $[I]_0 = 0$  (no intermediate present initially), the solution is

$$[I] = \frac{k_a}{k_b - k_a} (e^{-k_a t} - e^{-k_b t}) [A]_0 \quad (20E.4b)$$

At all times  $[A] + [I] + [P] = [A]_0$ , so it follows that

$$[P] = \left\{ 1 + \frac{k_a e^{-k_b t} - k_b e^{-k_a t}}{k_b - k_a} \right\} [A]_0 \quad (20E.4c)$$

The concentration of the intermediate I rises to a maximum and then falls to zero (Fig. 20E.1). The concentration of the product P rises from zero towards  $[A]_0$ , when all A has been converted to P.

### Example 20E.1 Analysing consecutive reactions

Suppose that in an industrial batch process a substance A produces the desired compound I which goes on to decay to a worthless product C, each step of the reaction being first order. At what time will I be present in greatest concentration?

**Method** The time dependence of the concentration of I is given by eqn 20E.4b. We can find the time at which [I] passes through a maximum,  $t_{\max}$ , by calculating  $d[I]/dt$  and setting the resulting rate equal to zero.

**Answer** It follows from eqn 20E.4b that

$$\frac{d[I]}{dt} = -\frac{k_a (k_a e^{-k_a t} - k_b e^{-k_b t}) [A]_0}{k_b - k_a}$$

This rate is equal to zero when  $k_a e^{-k_a t} = k_b e^{-k_b t}$ . Therefore,

$$t_{\max} = \frac{1}{k_a - k_b} \ln \frac{k_a}{k_b}$$

For a given value of  $k_a$ , as  $k_b$  increases both the time at which [I] is a maximum and the yield of I decrease.

**Self-test 20E.2** Calculate the maximum concentration of I and justify the last remark.

Answer:  $[I]_{\max}/[A]_0 = (k_a/k_b)^c$ ,  $c = k_b/(k_b - k_a)$

## 20E.3 The steady-state approximation

One feature of the calculation so far has probably not gone unnoticed: there is a considerable increase in mathematical complexity as soon as the reaction mechanism has more than a couple of steps and reverse reactions are taken into account. A reaction scheme involving many steps is nearly always unsolvable analytically, and alternative methods of solution are necessary. One approach is to integrate the rate laws numerically. An alternative approach, which continues to be widely used because it leads to convenient expressions and more readily digestible results, is to make an approximation.

The **steady-state approximation** (which is also widely called the **quasi-steady-state approximation**, QSSA, to distinguish it from a true steady state) assumes that the intermediate, I, is in a low, constant concentration. More specifically, after an initial **induction period**, an interval during which the concentrations of intermediates rise from zero, and during the major part of the reaction, the rates of change of concentrations of all reaction intermediates are negligibly small (Fig. 20E.2):

$$\frac{d[I]}{dt} \approx 0 \quad \text{Steady-state approximation} \quad (20E.5)$$

**Figure 20E.2** The basis of the steady-state approximation. It is supposed that the concentrations of intermediates remain small and hardly change during most of the course of the reaction.

**Figure 20E.3** A comparison of the exact result for the concentrations of a consecutive reaction and the concentrations obtained by using the steady-state approximation (dotted lines) for  $k_b = 20k_a$ . (The curve for [A] is unchanged.)

This approximation greatly simplifies the discussion of reaction schemes. For example, when we apply the approximation to the consecutive first-order mechanism, we set  $d[I]/dt = 0$  in eqn 20E.3b, which then becomes  $k_a[A] - k_b[I] = 0$ . Then

$$[I] = (k_a/k_b)[A] \quad (20E.6)$$

For this expression to be consistent with eqn 20E.5, we require  $k_a/k_b \ll 1$  (so that, even though [A] does depend on the time, the dependence of [I] on the time is negligible). On substituting this value of [I] into eqn 20E.3c, that equation becomes

$$\frac{d[P]}{dt} = k_b[I] \approx k_a[A] \quad (20E.7)$$

and we see that P is formed by a first-order decay of A, with a rate constant  $k_a$ , the rate-constant of the slower, rate-determining, step. We can write down the solution of this equation at once by substituting the solution for [A], eqn 20E.4a, and integrating:

$$[P] = k_a[A]_0 \int_0^t e^{-k_a t'} dt' = (1 - e^{-k_a t})[A]_0 \quad (20E.8)$$

This is the same (approximate) result as before, eqn 20E.4c (when  $k_b \gg k_a$ ), but much more quickly obtained. Figure 20E.3 compares the approximate solutions found here with the exact solutions found earlier:  $k_b$  does not have to be very much bigger than  $k_a$  for the approach to be reasonably accurate.

### Example 20E.2 Using the steady-state approximation

Devise the rate law for the decomposition of  $N_2O_5$ ,  $2 N_2O_5(g) \rightarrow 4 NO_2(g) + O_2(g)$  on the basis of the following mechanism:

*A note on good practice* Note that when writing the equation for an elementary reaction all the species are displayed individually; so we write  $A \rightarrow B + B$ , for instance, not  $A \rightarrow 2 B$ .

**Method** First identify the intermediates and write expressions for their net rates of formation. Then, all net rates of change of the concentrations of intermediates are set equal to zero and the resulting equations are solved algebraically.

**Answer** The intermediates are NO and  $NO_3$ ; the net rates of change of their concentrations are

$$\begin{aligned} \frac{d[NO]}{dt} &= k_b[NO_2][NO_3] - k_c[NO][N_2O_5] \approx 0 \\ \frac{d[NO_3]}{dt} &= k_a[N_2O_5] - k'_a[NO_2][NO_3] - k_b[NO_2][NO_3] \approx 0 \end{aligned}$$

The solutions of these two simultaneous equations (in blue) are

$$[NO_3] = \frac{k_a[N_2O_5]}{(k'_a + k_b)[NO_2]} \quad [NO] = \frac{k_b[NO_2][NO_3]}{k_c[N_2O_5]} = \frac{k_a k_b}{(k'_a + k_b)k_c}$$

The net rate of change of concentration of  $N_2O_5$  is then

$$\begin{aligned} \frac{d[N_2O_5]}{dt} &= -k_a[N_2O_5] + k'_a[NO_2][NO_3] - k_c[NO][N_2O_5] \\ &= -k_a[N_2O_5] + \frac{k_a k'_a [N_2O_5]}{k'_a + k_b} - \frac{k_a k_b}{k'_a + k_b} [N_2O_5] \\ &= -\frac{2k_a k_b [N_2O_5]}{k'_a + k_b} \end{aligned}$$

That is,  $N_2O_5$  decays with a first-order rate law with a rate constant that depends on  $k_a$ ,  $k'_a$  and  $k_b$  but not on  $k_c$ .

**Self-test 20E.3** Derive the rate law for the decomposition of ozone in the reaction  $2 O_3(g) \rightarrow 3 O_2(g)$  on the basis of the (incomplete) mechanism

$$\text{Answer: } d[O_3]/dt = -2k_a k_b [O_3]^2 / (k'_a [O_2] + k_b [O_3])$$

## 20E.4 The rate-determining step

Equation 20E.8 shows that when  $k_b \gg k_a$  the formation of the final product P depends on only the *smaller* of the two rate constants. That is, the rate of formation of P depends on the rate at

**Figure 20E.4** In these diagrams of reaction schemes, heavy arrows represent fast steps and light arrows represent slow steps. (a) The first step is rate-determining; (b) the second step is rate-determining; (c) although one step is slow, it is not rate-determining because there is a fast route that circumvents it.

which I is formed, not on the rate at which I changes into P. For this reason, the step  $A \rightarrow I$  is called the ‘rate-determining step’ of the reaction. Its existence has been likened to building a six-lane highway up to a single-lane bridge: the traffic flow is governed by the rate of crossing the bridge. Similar remarks apply to more complicated reaction mechanisms. In general, the **rate-determining step** (RDS) is the slowest step in a mechanism and controls the overall rate of the reaction. The rate-determining step is not just the slowest step: it must be slow *and* be a crucial gateway for the formation of products. If a faster reaction can also lead to products, then the slowest step is irrelevant because the slow reaction can then be sidestepped (Fig. 20E.4).

The rate law of a reaction that has a rate-determining step can often—but certainly not always—be written down almost by inspection. If the first step in a mechanism is rate-determining, then the rate of the overall reaction is equal to the rate of the first step because all subsequent steps are so fast that once the first intermediate is formed it results immediately in the formation of products. Figure 20E.5 shows the reaction profile for a mechanism of this kind in which the slowest step is the one with the highest activation energy. Once over the initial

**Figure 20E.5** The reaction profile for a mechanism in which the first step (RDS) is rate-determining.

barrier, the intermediates cascade into products. However, a rate-determining step may also stem from the low concentration of a crucial reactant and need not correspond to the step with highest activation barrier.

#### Brief illustration 20E.2 The rate law of a mechanism with a rate-determining step

The oxidation of NO to NO<sub>2</sub>,  $2 \text{NO}(\text{g}) + \text{O}_2(\text{g}) \rightarrow 2 \text{NO}_2(\text{g})$ , proceeds by the following mechanism:

with rate law (see the *Self-test*)

$$\frac{d[\text{NO}_2]}{dt} = \frac{2k_a k_b [\text{NO}]^2 [\text{O}_2]}{k'_a + k_b [\text{O}_2]}$$

When the concentration of O<sub>2</sub> in the reaction mixture is so large that the third step is very fast in the sense that  $[\text{O}_2]k_b \gg k'_a$ , then the rate law simplifies to

$$\frac{d[\text{NO}_2]}{dt} = 2k_a [\text{NO}]^2$$

and the formation of N<sub>2</sub>O<sub>2</sub> in the first step is rate-determining. We could have written the rate law by inspection of the mechanism, because the rate law for the overall reaction is simply the rate law of that rate-determining step.

**Self-test 20E.4** Verify that application of the steady-state approximation to the intermediate N<sub>2</sub>O<sub>2</sub> results in the rate law.

## 20E.5 Pre-equilibria

From a simple sequence of consecutive reactions we now turn to a slightly more complicated mechanism in which an intermediate I reaches an equilibrium with the reactants A and B:

The rate constants are  $k_a$  and  $k'_a$  for the forward and reverse reactions of the equilibrium and  $k_b$  for the final step. This scheme involves a **pre-equilibrium**, in which an intermediate is in equilibrium with the reactants. A pre-equilibrium can arise when the rate of decay of the intermediate back into reactants is much faster than the rate at which it forms products; thus, the condition is possible when  $k'_a \gg k_b$  but not when  $k_b \gg k'_a$ . Because we assume that A, B, and I are in equilibrium, we can write

$$K = \frac{[\text{I}]}{[\text{A}][\text{B}]} \quad \text{with} \quad K = \frac{k_a}{k'_a} \quad (20\text{E.10})$$

In writing these equations, we are presuming that the rate of reaction of I to form P is too slow to affect the maintenance of the pre-equilibrium (see the following *Example*). We are also ignoring the fact, as is commonly done, that the standard concentration  $c^\ominus$  should appear in the expression for  $K$  to ensure that it is dimensionless. The rate of formation of P may now be written:

$$\frac{d[P]}{dt} = k_b[I] = k_b K[A][B] \quad (20E.11)$$

This rate law has the form of a second-order rate law with a composite rate constant:

$$\frac{d[P]}{dt} = k_r[A][B] \quad \text{with} \quad k_r = k_b K = \frac{k_a k_b}{k'_a} \quad (20E.12)$$

### Example 20E.3 Analysing a pre-equilibrium

Repeat the pre-equilibrium calculation but without ignoring the fact that I is slowly leaking away as it forms P.

**Method** Begin by writing the net rates of change of the concentrations of the substances and then invoke the steady-state approximation for the intermediate I. Use the resulting expression to obtain the rate of change of the concentration of P.

**Answer** The net rates of change of P and I are

$$\begin{aligned} \frac{d[P]}{dt} &= k_b[I] \\ \frac{d[I]}{dt} &= k_a[A][B] - k'_a[I] - k_b[I] \approx 0 \end{aligned}$$

The second equation solves to

$$[I] \approx \frac{k_a[A][B]}{k'_a + k_b}$$

When we substitute this result into the expression for the rate of formation of P, we obtain

$$\frac{d[P]}{dt} \approx k_r[A][B] \quad \text{with} \quad k_r = \frac{k_a k_b}{k'_a + k_b}$$

This expression reduces to that in eqn 20E.12 when the rate constant for the decay of I into products is much smaller than that for its decay into reactants,  $k_b \ll k'_a$ .

**Self-test 20E.5** Show that the pre-equilibrium mechanism in which  $2A \rightleftharpoons I(K)$  followed by  $I+B \rightarrow P(k_b)$  results in an overall third-order reaction.

Answer:  $d[P]/dt = k_b K[A]^2[B]$

One feature to note is that although each of the rate constants in eqn 20E.12 increases with temperature, that might not

**Figure 20E.6** For a reaction with a pre-equilibrium, there are three activation energies to take into account: two referring to the reversible steps of the pre-equilibrium and one for the final step. The relative magnitudes of the activation energies determine whether the overall activation energy is (a) positive or (b) negative.

be true of  $k_r$  itself. Thus, if the rate constant  $k'_a$  increases more rapidly than the product  $k_a k_b$  increases, then  $k_r = k_a k_b / k'_a$  will decrease with increasing temperature and the reaction will go more slowly as the temperature is raised. Mathematically, we would say that the composite reaction had a 'negative activation energy'. For example, suppose that each rate constant in eqn 20E.12 exhibits an Arrhenius temperature dependence (Topic 20D). It follows from the Arrhenius equation (eqn 20D.4,  $k_r = A e^{-E_a/RT}$ ) that

$$k_r = \frac{(A_a e^{-E_{a,a}/RT})(A_b e^{-E_{a,b}/RT})}{A'_a e^{-E_{a,a'}/RT}} \stackrel{e^{x+y} = e^x e^y}{\cong} \frac{A_a A_b}{A'_a} e^{-(E_{a,a} + E_{a,b} - E_{a,a'})/RT}$$

The effective activation energy of the reaction is therefore

$$E_a = E_{a,a} + E_{a,b} - E_{a,a'} \quad (20E.13)$$

This activation energy is positive if  $E_{a,a} + E_{a,b} > E_{a,a'}$  (Fig. 20E.6a) but negative if  $E_{a,a'} > E_{a,a} + E_{a,b}$  (Fig. 20E.6b). An important consequence of this discussion is that we have to be very cautious about making predictions about the effect of temperature on reactions that are the outcome of several steps.

## 20E.6 Kinetic and thermodynamic control of reactions

In some cases reactants can give rise to a variety of products, as in nitrations of mono-substituted benzene, when various proportions of the *ortho*-, *meta*-, and *para*-substituted products are obtained, depending on the directing power of the original

substituent. Suppose two products,  $P_1$  and  $P_2$ , are produced by the following competing reactions:

The relative proportion in which the two products have been produced at a given stage of the reaction (before it has reached equilibrium) is given by the ratio of the two rates, and therefore of the two rate constants:

$$\frac{[P_2]}{[P_1]} = \frac{k_{r,2}}{k_{r,1}} \quad \text{Kinetic control} \quad (20E.14)$$

This ratio represents the **kinetic control** over the proportions of products, and is a common feature of the reactions encountered in organic chemistry where reactants are chosen that facilitate pathways favouring the formation of a desired product. If a reaction is allowed to reach equilibrium, then the proportion of products is determined by thermodynamic rather than kinetic considerations, and the ratio of concentrations is controlled by considerations of the standard Gibbs energies of all the reactants and products.

### Brief illustration 20E.3 The outcome of kinetic control

Consider two products formed from reactant R in reactions for which: (a) product  $P_1$  is thermodynamically more stable than product  $P_2$ ; and (b) the activation energy  $E_a$  for the reaction leading to  $P_2$  is greater than that leading to  $P_1$ . It follows from eqn 20E.14 and the Arrhenius equation ( $k_r = Ae^{-E_a/RT}$ , eqn 20D.4) that the ratio of products is

$$\frac{[P_2]}{[P_1]} = \frac{k_2}{k_1} = \frac{A_2 e^{-E_{a,2}/RT}}{A_1 e^{-E_{a,1}/RT}} = \frac{A_2}{A_1} e^{-(E_{a,2}-E_{a,1})/RT} = \frac{A_2}{A_1} e^{-\Delta E_a/RT}$$

Because  $\Delta E_a = E_{a,2} - E_{a,1} > 0$ , as  $T$  increases,

- the term  $\Delta E_a/RT$  decreases, and
- the term  $e^{-\Delta E_a/RT}$  increases.

Consequently, the ratio  $[P_2]/[P_1]$  increases with increasing temperature before equilibrium is reached.

**Self-test 20E.6** Consider the reactions from *Brief illustration 20E.3*. Derive an expression for the ratio  $[P_2]/[P_1]$  when the reaction is under thermodynamic control. State your assumptions.

Answer:  $[P_2]/[P_1] = e^{-(\Delta_r G_2^\ominus - \Delta_r G_1^\ominus)/RT}$ , assuming that activities can be replaced by concentrations

## Checklist of concepts

1. The **mechanism** of reaction is the sequence of elementary steps that leads from reactants to products.
2. The **molecularity** of an elementary reaction is the number of molecules coming together to react.
3. An elementary unimolecular reaction has first-order kinetics; an elementary bimolecular reaction has second-order kinetics.
4. The **rate-determining step** is the slowest step in a reaction mechanism that controls the rate of the overall reaction.
5. In the **steady-state approximation**, it is assumed that the concentrations of all reaction intermediates remain constant and small throughout the reaction.
6. **Pre-equilibrium** is a state in which an intermediate is in equilibrium with the reactants and which arises when the rates of formation of the intermediate and its decay back into reactants are much faster than its rate of formation of products.
7. Provided a reaction has not reached equilibrium, the products of competing reactions are controlled by kinetics.

## Checklist of equations

Property	Equation	Comment	Equation number
Unimolecular reaction	$d[A]/dt = -k_r[A]$	$A \rightarrow P$	20E.1
Bimolecular reaction	$d[A]/dt = -k_r[A][B]$	$A + B \rightarrow P$	20E.2
Consecutive reactions	$[A] = [A]_0 e^{-k_a t}$ $[I] = (k_a / (k_b - k_a))(e^{-k_a t} - e^{-k_b t})[A]_0$ $[P] = \{1 + (k_a e^{-k_b t} - k_b e^{-k_a t}) / (k_b - k_a)\}[A]_0$	$A \xrightarrow{k_a} I \xrightarrow{k_b} P$	20E.4
Steady-state approximation	$d[I]/dt \approx 0$	I is an intermediate	20E.5

### ► Why do you need to know this material?

Some important reactions have complex mechanisms and need special treatment, so you need to see how to make and implement assumptions about the relative rates of the steps in a mechanism.

### ► What is the key idea?

The steady-state approximation can often be used to derive rate laws for proposed mechanisms.

### ► What do you need to know already?

You need to be familiar with the concept of rate laws (Topic 20A) and the steady-state approximation (Topic 20E).

Many reactions take place by mechanisms that involve several elementary steps. We focus here on the kinetic analysis of a special class of reactions in the gas phase and polymerization kinetics. Photochemical processes are treated in Topic 20G and the role of catalysis in Topics 20H and 22C.

## 20F.1 Unimolecular reactions

A number of gas-phase reactions follow first-order kinetics, as in the isomerization of cyclopropane:

The problem with the interpretation of first-order rate laws is that presumably a molecule acquires enough energy to react as a result of its collisions with other molecules. However, collisions are simple bimolecular events, so how can they result in a first-order rate law? First-order gas-phase reactions are widely called ‘unimolecular reactions’ because they also involve an elementary unimolecular step in which the reactant molecule changes into the product. This term must be used with caution, however, because the overall mechanism has bimolecular as well as unimolecular steps.

The first successful explanation of unimolecular reactions was provided by Frederick Lindemann in 1921 and then elaborated by Cyril Hinshelwood. In the **Lindemann–Hinshelwood mechanism** it is supposed that a reactant molecule A becomes energetically excited by collision with another A molecule in a bimolecular step (Fig. 20F.1):

The energized molecule ( $\text{A}^*$ ) might lose its excess energy by collision with another molecule:

Alternatively, the excited molecule might shake itself apart and form products P. That is, it might undergo the unimolecular decay

**Figure 20F.1** A representation of the Lindemann–Hinshelwood mechanism of unimolecular reactions. The species A is excited by collision with A, and the excited A molecule ( $\text{A}^*$ ) may either be deactivated by a collision with A or go on to decay by a unimolecular process to form products.

If the unimolecular step is slow enough to be the rate-determining step, the overall reaction will have first-order kinetics, as observed. This conclusion can be demonstrated explicitly by applying the steady-state approximation to the net rate of formation of  $A^*$ :

$$\frac{d[A^*]}{dt} = k_a[A]^2 - k'_a[A][A^*] - k_b[A^*] \approx 0 \quad (20F.2)$$

This equation solves to

$$[A^*] = \frac{k_a[A]^2}{k_b + k'_a[A]} \quad (20F.3)$$

so the rate law for the formation of P is

$$\frac{d[P]}{dt} = k_b[A^*] = \frac{k_a k_b [A]^2}{k_b + k'_a [A]} \quad (20F.4)$$

At this stage the rate law is not first-order. However, if the rate of deactivation by ( $A^*, A$ ) collisions is much greater than the rate of unimolecular decay, in the sense that  $k'_a[A][A^*] \gg k_b[A^*]$ , or (after cancelling the  $[A^*]$ ),  $k'_a[A] \gg k_b$ , then we can neglect  $k_b$  in the denominator and obtain

$$\frac{d[P]}{dt} = k_r[A] \quad \text{with} \quad k_r = \frac{k_a k_b}{k'_a} \quad \text{Lindemann-Hinshelwood rate law} \quad (20F.5)$$

Equation 20F.5 is a first-order rate law, as we set out to show.

The Lindemann-Hinshelwood mechanism can be tested because it predicts that, as the concentration (and therefore the partial pressure) of A is reduced, the reaction should switch to overall second-order kinetics. Thus, when  $k'_a[A] \ll k_b$ , the rate law in eqn 20F.4 becomes

$$\frac{d[P]}{dt} = k_a[A]^2 \quad (20F.6)$$

The physical reason for the change of order is that at low pressures the rate-determining step is the bimolecular formation of  $A^*$ . If we write the full rate law in eqn 20F.4 as

$$\frac{d[P]}{dt} = k_r[A] \quad \text{with} \quad k_r = \frac{k_a k_b [A]}{k_b + k'_a [A]} \quad (20F.7)$$

then the expression for the effective rate constant,  $k_r$ , can be rearranged (by inverting each side) to

$$\frac{1}{k_r} = \frac{k'_a}{k_a k_b} + \frac{1}{k_a [A]} \quad \text{Lindemann-Hinshelwood mechanism} \quad \text{Effective rate constant} \quad (20F.8)$$

Hence, a test of the theory is to plot  $1/k_r$  against  $1/[A]$ , and to expect a straight line. This behaviour is observed often at low concentrations but deviations are common at high concentrations. In Topic 21A we develop the description of the mechanism to take into account experimental results over a range of concentrations and pressures.

### Example 20F.1 Analysing the Lindemann-Hinshelwood mechanism

At 300 K the effective rate constant for a gaseous reaction  $A \rightarrow P$ , which has a Lindemann-Hinshelwood mechanism, is  $k_{r,1} = 2.50 \times 10^{-4} \text{ s}^{-1}$  at  $[A]_1 = 5.21 \times 10^{-4} \text{ mol dm}^{-3}$  and  $k_{r,2} = 2.10 \times 10^{-5} \text{ s}^{-1}$  at  $[A]_2 = 4.81 \times 10^{-6} \text{ mol dm}^{-3}$ . Calculate the rate constant for the activation step in the mechanism.

**Method** Use eqn 20F.8 to write an expression for the difference  $1/k_{r,2} - 1/k_{r,1}$  and then use the data to solve for  $k_a$ , the rate constant for the activation step.

**Answer** It follows from eqn 20F.8 that

$$\frac{1}{k_{r,2}} - \frac{1}{k_{r,1}} = \frac{1}{k_a} \left( \frac{1}{[A]_2} - \frac{1}{[A]_1} \right)$$

and so

$$\begin{aligned} k_a &= \frac{1/[A]_2 - 1/[A]_1}{1/k_{r,2} - 1/k_{r,1}} \\ &= \frac{1/(4.81 \times 10^{-6} \text{ mol dm}^{-3}) - 1/(5.21 \times 10^{-4} \text{ mol dm}^{-3})}{1/(2.10 \times 10^{-5} \text{ s}^{-1}) - 1/(2.50 \times 10^{-4} \text{ s}^{-1})} \\ &= 4.72 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} \end{aligned}$$

**Self-test 20F.1** The effective rate constants for a gaseous reaction  $A \rightarrow P$ , which has a Lindemann-Hinshelwood mechanism, are  $1.70 \times 10^{-3} \text{ s}^{-1}$  and  $2.20 \times 10^{-4} \text{ s}^{-1}$  at  $[A] = 4.37 \times 10^{-4} \text{ mol dm}^{-3}$  and  $1.00 \times 10^{-5} \text{ mol dm}^{-3}$ , respectively. Calculate the rate constant for the activation step in the mechanism.

Answer:  $24.6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

## 20F.2 Polymerization kinetics

There are two major classes of polymerization processes and the average molar mass of the product varies with time in distinctive ways. In **stepwise polymerization** any two monomers present in the reaction mixture can link together at any time and growth of the polymer is not confined to chains that are already forming (Fig. 20F.2). As a result, monomers are consumed early in the reaction and, as we shall see, the average molar mass of the product grows linearly with time. In **chain polymerization** an activated monomer, M, attacks another monomer, links to it, then that unit attacks another monomer, and so on. The monomer is used up as it becomes linked to

Figure 20F.2 In stepwise polymerization, growth can start at any pair of monomers (in green), and so new chains (in purple) begin to form throughout the reaction.

the growing chains (Fig. 20F.3). High polymers are formed rapidly and only the yield, not the average molar mass, of the polymer is increased by allowing long reaction times.

### (a) Stepwise polymerization

Stepwise polymerization commonly proceeds by a **condensation reaction**, in which a small molecule (typically  $\text{H}_2\text{O}$ ) is eliminated in each step. Stepwise polymerization is the mechanism of production of polyamides, as in the formation of nylon-66:

Figure 20F.3 The process of chain polymerization. Chains (in purple) grow as each chain acquires additional monomers (in green).

Polyesters and polyurethanes are formed similarly (the latter without elimination). A polyester, for example, can be regarded as the outcome of the stepwise condensation of a hydroxyacid  $\text{HO}-\text{R}-\text{COOH}$ . We shall consider the formation of a polyester from such a monomer, and measure its progress in terms of the concentration of the  $-\text{COOH}$  groups in the sample (which we denote  $A$ ), for these groups gradually disappear as the condensation proceeds. Because the condensation reaction can occur between molecules containing any number of monomer units, chains of many different lengths can grow in the reaction mixture.

In the absence of a catalyst, we can expect the condensation to be overall second-order in the concentration of the  $-\text{OH}$  and  $-\text{COOH}$  (or  $A$ ) groups, and write

$$\frac{d[A]}{dt} = -k_r[\text{OH}][A] \quad (20F.9a)$$

However, because there is one  $-\text{OH}$  group for each  $-\text{COOH}$  group, this equation is the same as

$$\frac{d[A]}{dt} = -k_r[A]^2 \quad (20F.9b)$$

If we assume that the rate constant for the condensation is independent of the chain length, then  $k_r$  remains constant throughout the reaction. The solution of this rate law is given by eqn 20B.4, and is

$$[A] = \frac{[A]_0}{1 + k_r t [A]_0} \quad (20F.10)$$

The fraction,  $p$ , of  $-\text{COOH}$  groups that have condensed at time  $t$  is, after application of eqn 20F.10:

$$p = \frac{[A]_0 - [A]}{[A]_0} = \frac{k_r t [A]_0}{1 + k_r t [A]_0} \quad \begin{array}{l} \text{Stepwise} \\ \text{polymerization} \end{array} \quad \begin{array}{l} \text{Fraction of} \\ \text{condensed} \\ \text{groups} \end{array} \quad (20F.11)$$

Next, we calculate the **degree of polymerization**, which is defined as the average number of monomer residues per polymer molecule. This quantity is the ratio of the initial concentration of  $A$ ,  $[A]_0$ , to the concentration of end groups,  $[A]$ , at the time of interest, because there is one  $A$  group per polymer molecule. For example, if there were initially 1000  $A$  groups and there are now only 10, each polymer must be 100 units long on average. Because we can express  $[A]$  in terms of  $p$  (the first part of eqn 20F.11), the average number of monomers per polymer molecule,  $\langle N \rangle$ , is

**Figure 20F.4** The average chain length of a polymer as a function of the fraction of reacted monomers,  $p$ . Note that  $p$  must be very close to 1 for the chains to be long.

$$\langle N \rangle = \frac{[A]_0}{[A]} = \frac{1}{1-p} \quad \begin{array}{l} \text{Stepwise} \\ \text{polymerization} \end{array} \quad \begin{array}{l} \text{Degree of} \\ \text{polymerization} \end{array} \quad (20F.12a)$$

This result is illustrated in Fig. 20F.4. When we express  $p$  in terms of the rate constant  $k_r$  (the second part of eqn 20F.11), we find

$$\langle N \rangle = 1 + k_r t [A]_0 \quad \begin{array}{l} \text{Stepwise} \\ \text{polymerization} \end{array} \quad \begin{array}{l} \text{Degree of polymerization} \\ \text{in terms of the rate} \\ \text{constant} \end{array} \quad (20F.12b)$$

The average length grows linearly with time. Therefore, the longer a stepwise polymerization proceeds, the higher the average molar mass of the product.

#### Brief illustration 20F.1 The degree of polymerization

Consider a polymer formed by a stepwise process with  $k_r = 1.00 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and an initial monomer concentration of  $[A]_0 = 4.00 \times 10^{-3} \text{ mol dm}^{-3}$ . From eqn 20F.12b, the degree of polymerization at  $t = 1.5 \times 10^4 \text{ s}$  is

$$\begin{aligned} \langle N \rangle &= 1 + (1.00 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}) \times (1.5 \times 10^4 \text{ s}) \\ &\quad \times (4.00 \times 10^{-3} \text{ mol dm}^{-3}) = 61 \end{aligned}$$

From eqn 20F.12a, the fraction condensed,  $p$ , is

$$p = \frac{\langle N \rangle - 1}{\langle N \rangle} = \frac{61 - 1}{61} = 0.98$$

**Self-test 20F.2** Calculate the fraction condensed and the degree of polymerization at  $t = 1.0 \text{ h}$  of a polymer formed by a stepwise process with  $k_r = 1.80 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and an initial monomer concentration of  $3.00 \times 10^{-2} \text{ mol dm}^{-3}$ .

Answer:  $\langle N \rangle = 2.9$ ;  $p = 0.66$

## (b) Chain polymerization

Many gas-phase reactions and liquid-phase polymerization reactions are **chain reactions**. In a chain reaction, a reaction intermediate produced in one step generates an intermediate in a subsequent step, then that intermediate generates another intermediate, and so on. The intermediates in a chain reaction are called **chain carriers**. In a **radical chain reaction** the chain carriers are radicals (species with unpaired electrons).

Chain polymerization occurs by addition of monomers to a growing polymer, often by a radical chain process. It results in the rapid growth of an individual polymer chain for each activated monomer. Examples include the addition polymerizations of ethene, methyl methacrylate, and styrene, as in

and subsequent reactions. The central feature of the kinetic analysis (which is summarized in the following *Justification*) is that the rate of polymerization is proportional to the square root of the initiator,  $\text{In}$ , concentration:

$$v = k_r [\text{In}]^{1/2} [\text{M}] \quad \begin{array}{l} \text{Chain} \\ \text{polymerization} \end{array} \quad \begin{array}{l} \text{Rate of} \\ \text{polymerization} \end{array} \quad (20F.13)$$

#### Justification 20F.1 The rate of chain polymerization

There are three basic types of reaction step in a chain polymerization process:

(a) Initiation:

where  $\text{In}$  is the initiator,  $\text{R}\cdot$  the radical that  $\text{In}$  forms, and  $\cdot\text{M}_1$  is a monomer radical. We have shown a reaction in which a radical is produced, but in some polymerizations the initiation step leads to the formation of an ionic chain carrier. The rate-determining step is the formation of the radicals  $\text{R}\cdot$  by homolysis of the initiator, so the rate of initiation is equal to the  $v_i$  given above.

(b) Propagation:

If we assume that the rate of propagation is independent of chain size for sufficiently large chains, then we can use only

the equation given above to describe the propagation process. Consequently, for sufficiently large chains, the rate of propagation is equal to the overall rate of polymerization.

Because this chain of reactions propagates quickly, the rate at which the total concentration of radicals grows is equal to the rate of the rate-determining initiation step. It follows that

$$\left(\frac{d[\cdot M]}{dt}\right)_{\text{production}} = 2f k_i [\text{In}]$$

where  $f$  is the fraction of radicals  $R\cdot$  that successfully initiate a chain.

(c) Termination:

In **mutual termination** two growing radical chains combine. In termination by **disproportionation** a hydrogen atom transfers from one chain to another, corresponding to the oxidation of the donor and the reduction of the acceptor. In **chain transfer**, a new chain initiates at the expense of the one currently growing.

Here we suppose that only mutual termination occurs. If we assume that the rate of termination is independent of the length of the chain, the rate law for termination is

$$v_t = k_t [\cdot M]^2$$

and the rate of change of radical concentration by this process is

$$\left(\frac{d[\cdot M]}{dt}\right)_{\text{depletion}} = -2k_t [\cdot M]^2$$

The steady-state approximation gives:

$$\frac{d[\cdot M]}{dt} = 2f k_i [\text{In}] - 2k_t [\cdot M]^2 \approx 0$$

The steady-state concentration of radical chains is therefore

$$[\cdot M] = \left(\frac{f k_i}{k_t}\right)^{1/2} [\text{In}]^{1/2}$$

Because the rate of propagation of the chains is the negative of the rate at which the monomer is consumed, we can write  $v_p = -d[M]/dt$  and

$$v_p = k_p [\cdot M][M] = k_p \left(\frac{f k_i}{k_t}\right)^{1/2} [\text{In}]^{1/2} [M]$$

This rate is also the rate of polymerization, which has the form of eqn 20F.13.

The **kinetic chain length**,  $\lambda$ , is the ratio of the number of monomer units consumed per activated centre produced in the initiation step:

$$\lambda = \frac{\text{number of monomer units consumed}}{\text{number of activated centres produced}} \quad \text{Definition Kinetic chain length (20F.14a)}$$

The kinetic chain length can be expressed in terms of the rate expressions in *Justification* 20F.1. To do so, we recognize that monomers are consumed at the rate that chains propagate. Then,

$$\lambda = \frac{\text{rate of propagation of chains}}{\text{rate of production of radicals}} \quad \text{Kinetic chain length in terms of reaction rates (20F.14b)}$$

By making the steady-state approximation, we set the rate of production of radicals equal to the termination rate. Therefore, we can write the expression for the kinetic chain length as

$$\lambda = \frac{k_p [\cdot M][M]}{2k_t [\cdot M]^2} = \frac{k_p [M]}{2k_t [\cdot M]}$$

When we substitute the steady-state expression,  $[\cdot M] = (fk_i/k_t)^{1/2} [\text{In}]^{1/2}$ , for the radical concentration, we obtain

$$\lambda = k_t [M] [\text{In}]^{-1/2} \quad \text{Chain polymerization Kinetic chain length (20F.15)}$$

with  $k_t = k_p (fk_i k_t)^{-1/2}$

Consider a polymer produced by a chain mechanism with mutual termination. In this case, the average number of monomers in a polymer molecule,  $\langle N \rangle$ , produced by the reaction is the sum of the numbers in the two combining polymer chains. The average number of units in each chain is  $\lambda$ . Therefore,

$$\langle N \rangle = 2\lambda = 2k_t [M] [\text{In}]^{-1/2} \quad \text{Chain polymerization Degree of polymerization (20F.16)}$$

with  $k_t$  given in eqn 20F.15. We see that, the slower the initiation of the chain (the smaller the initiator concentration and the smaller the initiation rate constant), the greater is the kinetic chain length, and therefore the higher is the average molar mass of the polymer. Some of the consequences of molar mass for polymers are explored in Topic 17D: here we have seen how we can exercise kinetic control over them.

## Checklist of concepts

- 1. The **Lindemann–Hinshelwood mechanism** of ‘unimolecular’ reactions account for the first-order kinetics of some gas-phase reactions.
- 2. In **stepwise polymerization** any two monomers in the reaction mixture can link together at any time.
- 3. The longer a stepwise polymerization proceeds, the higher the average molar mass of the product.
- 4. In **chain polymerization** an activated monomer attacks another monomer and links to it.
- 5. The slower the initiation of the chain, the higher the average molar mass of the polymer.
- 6. The **kinetic chain length** is the ratio of the number of monomer units consumed per activated centre produced in the initiation step.

## Checklist of equations

Property	Equation	Comment	Equation number
Lindemann–Hinshelwood rate law	$d[P]/dt = k_r[A]$ with $k_r = k_a k_b / k'_a$	$k'_a[A] \gg k_b$	20F.5
Effective rate constant	$1/k_r = k'_a/k_a k_b + 1/k_a[A]$	Lindemann–Hinshelwood mechanism	20F.8
Fraction of condensed groups	$p = k_r t[A]_0 / (1 + k_r t[A]_0)$	Stepwise polymerization	20F.11
Degree of polymerization	$\langle N \rangle = 1/(1-p) = 1 + k_r t[A]_0$	Stepwise polymerization	20F.12
Rate of polymerization	$v = k_r [\text{In}]^{1/2} [M]$	Chain polymerization	20F.13
Kinetic chain length	$\lambda = k_r [M] [\text{In}]^{-1/2}$ , $k_r = k_p (fk_i k_t)^{-1/2}$	Chain polymerization	20F.15
Degree of polymerization	$\langle N \rangle = 2k_r [M] [\text{In}]^{-1/2}$	Chain polymerization	20F.16

### ► Why do you need to know this material?

Many chemical and biological processes, including photosynthesis and vision, can be initiated by the absorption of electromagnetic radiation, so you need to know how to include its effect in rate laws. You also need to see how to obtain insight into these processes by the quantitative analysis of their mechanisms.

### ► What is the key idea?

The mechanisms of many photochemical reactions lead to relatively simple rate laws that yield rate constants and quantitative measures of the efficiency with which radiant energy induces reactions.

### ► What do you need to know already?

You need to be familiar with the concepts of singlet and triplet states (Topics 9B and 13B), modes of radiative decay (fluorescence and phosphorescence, Topic 13B), concepts of electronic spectroscopy (Topic 13A), and the formulation of a rate law from a proposed mechanism (Topic 20E).

**Photochemical processes** are initiated by the absorption of electromagnetic radiation. Among the most important of these processes are those that capture the radiant energy of the Sun. Some of these reactions lead to the heating of the atmosphere during the daytime by absorption of ultraviolet radiation. Others include the absorption of visible radiation during photosynthesis. Without photochemical processes, the Earth would be simply a warm, sterile, rock.

## 20G.1 Photochemical processes

Table 20G.1 summarizes common photochemical reactions. Photochemical processes are initiated by the absorption of radiation by at least one component of a reaction mixture. In a **primary process**, products are formed directly from the excited state of a reactant. Examples include fluorescence (Topic 13B) and the *cis-trans* photoisomerization of retinal. Products of a **secondary process** originate from intermediates that are

Table 20G.1 Examples of photochemical processes

Process	General form	Example
Ionization	$A^* \rightarrow A^+ + e^-$	$\text{NO}^* \xrightarrow{134\text{ nm}} \text{NO}^+ + e^-$
Electron transfer	$A^* + B \rightarrow A^+ + B^-$ or $A^- + B^+$	$[\text{Ru}(\text{bpy})_3]^{2+*} + \text{Fe}^{3+} \xrightarrow{452\text{ nm}} [\text{Ru}(\text{bpy})_3]^{3+} + \text{Fe}^{2+}$
Dissociation	$A^* \rightarrow B + C$	$\text{O}_3^* \xrightarrow{1180\text{ nm}} \text{O}^2 + \text{O}$
	$A^* + B - C \rightarrow A + B + C$	$\text{Hg}^* + \text{CH}_4 \xrightarrow{254\text{ nm}} \text{Hg} + \text{CH}_3 + \text{H}$
Addition	$2 A^* \rightarrow B$	$2 \left( \text{retinal} \right)^* \xrightarrow{230\text{ nm}} \text{cis-retinal} + \text{trans-retinal}$
	$A^* + B \rightarrow AB$	
Abstraction	$A^* + B - C \rightarrow A - B + C$	$\text{Hg}^* + \text{H}_2 \xrightarrow{254\text{ nm}} \text{HgH} + \text{H}$
Isomerization or rearrangement	$A^* \rightarrow A'$	$\text{retinal} \xrightarrow{380\text{ nm}} \text{isomerized retinal}$

\* Excited state.

Triplet-triplet	$T^* + T^* \rightarrow S^{**} + S$

\* Denotes an excited state, S a singlet state, T a triplet state, and M is a third-body.

formed directly from the excited state of a reactant, such as oxidative processes initiated by the oxygen atom formed by ozone photodissociation.

Competing with the formation of photochemical products are numerous primary photophysical processes that can deactivate the excited state (Table 20G.2). Therefore, it is important to consider the timescales of the formation and decay of excited states before describing the mechanisms of photochemical reactions.

Electronic transitions caused by absorption of ultraviolet and visible radiation occur within  $10^{-16}$ – $10^{-15}$  s. We expect, then, the upper limit for the rate constant of a first-order photochemical reaction to be about  $10^{16} \text{ s}^{-1}$ . Fluorescence is slower than absorption, with typical lifetimes of  $10^{-12}$ – $10^{-6}$  s. Therefore, the excited singlet state can initiate very fast photochemical reactions in the femtosecond ( $10^{-15}$  s) to picosecond ( $10^{-12}$  s) range. Examples of such ultrafast reactions are the initial events of vision and of photosynthesis. Typical intersystem crossing (ISC, Topic 13B) and phosphorescence times for large organic molecules are  $10^{-12}$ – $10^{-4}$  s and  $10^{-6}$ – $10^{-1}$  s, respectively. As a consequence of their long lifetimes, excited triplet states are photochemically important. Indeed, because phosphorescence decay is several orders of magnitude slower than most typical reactions, species in excited triplet states can undergo a very large number of collisions with other reactants before they lose their energy radiatively.

### Brief illustration 20G.1 The nature of the excited state

To judge whether the excited singlet or triplet state of the reactant is a suitable product precursor, we compare the emission lifetimes with the time constant for chemical reaction of the reactant,  $\tau$  (Topic 20B). Consider a unimolecular photochemical reaction with rate constant  $k_r = 1.7 \times 10^4 \text{ s}^{-1}$  and therefore time constant  $\tau = 1/(1.7 \times 10^4 \text{ s}^{-1}) = 59 \mu\text{s}$  that involves a reactant with an observed fluorescence lifetime of 1.0 ns and an observed phosphorescence lifetime of 1.0 ms. The excited singlet state is too short-lived to be a major source of product in this reaction. On the other hand, the relatively long-lived excited triplet state is a good candidate for a precursor.

**Self-test 20G.1** Consider a molecule with a fluorescence lifetime of 10.0 ns that undergoes unimolecular photoisomerization. What approximate value of the half-life would be consistent with the excited singlet state being the product precursor?

Answer: The value of  $t_{1/2}$  should be less than about 7 ns

## 20G.2 The primary quantum yield

The rates of deactivation of the excited state by radiative, non-radiative, and chemical processes determine the yield of product in a photochemical reaction. The **primary quantum yield**,  $\phi$ , is defined as the number of photophysical or photochemical events that lead to primary products divided by the number of photons absorbed by the molecule in the same interval:

$$\phi = \frac{\text{number of events}}{\text{number of photons absorbed}} \quad \text{Definition} \quad \text{Primary quantum yield} \quad (20G.1a)$$

When both the numerator and denominator of this expression are divided by the time interval over which the events occur, we see that the primary quantum yield is also the rate of radiation-induced primary events divided by the rate of photon absorption,  $I_{\text{abs}}$ :

$$\phi = \frac{\text{rate of process}}{\text{rate of photon absorption}} = \frac{\nu}{I_{\text{abs}}} \quad \text{Primary quantum yield in terms of rates of processes} \quad (20G.1b)$$

### Example 20G.1 Calculating a primary quantum yield

In an experiment to determine the quantum yield of a photochemical reaction, the absorbing substance was exposed to 490 nm light from a 100 W source for 2700 s, with 60 per cent of the incident light being absorbed. As a result of irradiation,

0.344 mol of the absorbing substance decomposed. Determine the primary quantum yield.

**Method** We need to calculate the terms used in eqn 20G.1a. To calculate the number of absorbed photons  $N_{\text{abs}}$ , which is the denominator of the expression on the right-hand side of eqn 20G.1a, we note that:

- The energy absorbed by the substance is  $E_{\text{abs}} = fPt$ , where  $P$  is the incident power,  $t$  is the time of exposure, and the factor  $f$  (in this case  $f = 0.60$ ) is the proportion of incident light that is absorbed.
- $E_{\text{abs}}$  is also related to the number  $N_{\text{abs}}$  of absorbed photons through  $E_{\text{abs}} = N_{\text{abs}}hc/\lambda$ , where  $hc/\lambda$  is the energy of a single photon of wavelength  $\lambda$  (eqn 7A.5).

By combining both expressions for the absorbed energy, the value of  $N_{\text{abs}}$  follows readily. The number of photochemical events, and hence the numerator of the expression on the right-hand side of eqn 20G.1a, is simply the number of decomposed molecules  $N_{\text{decomposed}}$ . The primary quantum yield follows from  $\phi = N_{\text{decomposed}}/N_{\text{abs}}$ .

**Answer** From the expressions for the absorbed energy, it follows that

$$E_{\text{abs}} = fPt = N_{\text{abs}} \left( \frac{hc}{\lambda} \right)$$

and therefore that  $N_{\text{abs}} = fPt\lambda/hc$ . Now we use eqn 20G.1a to write

$$\phi = \frac{N_{\text{decomposed}}}{N_{\text{abs}}} = \frac{N_{\text{decomposed}}hc}{fPt\lambda}$$

With  $N_{\text{decomposed}} = (0.344 \text{ mol}) \times (6.022 \times 10^{23} \text{ mol}^{-1})$ ,  $P = 100 \text{ W} = 100 \text{ J s}^{-1}$ ,  $t = 2700 \text{ s}$ ,  $\lambda = 490 \text{ nm} = 4.90 \times 10^{-7} \text{ m}$ , and  $f = 0.60$  it follows that

$$\phi = \frac{(0.344 \text{ mol}) \times (6.022 \times 10^{23} \text{ mol}^{-1}) \times (6.626 \times 10^{-34} \text{ J s}) \times (2.998 \times 10^8 \text{ m s}^{-1})}{0.60 \times (100 \text{ J s}^{-1}) \times (2700 \text{ s}) \times (4.90 \times 10^{-7} \text{ m})} = 0.52$$

**Self-test 20G.2** In an experiment to measure the quantum yield of a photochemical reaction, the absorbing substance was exposed to 320 nm radiation from a 87.5 W source for 38 min. The intensity of the transmitted light was 0.35 that of the incident light. As a result of irradiation, 0.324 mol of the absorbing substance decomposed. Determine the primary quantum yield.

Answer:  $\phi = 0.93$

A molecule in an excited state must either decay to the ground state or form a photochemical product. Therefore, the total number of molecules deactivated by radiative processes,

non-radiative processes, and photochemical reactions must be equal to the number of excited species produced by absorption of the incident radiation. We conclude that the sum of primary quantum yields  $\phi_i$  for *all* photophysical and photochemical events  $i$  must be equal to 1, regardless of the number of reactions involving the excited state:

$$\sum_i \phi_i = \sum_i \frac{\nu_i}{I_{\text{abs}}} = 1 \quad (20G.2)$$

It follows that for an excited singlet state that decays to the ground state only by the photophysical processes described in Section 20G.1 (and without reacting), we write

$$\phi_{\text{F}} + \phi_{\text{IC}} + \phi_{\text{P}} = 1$$

where  $\phi_{\text{F}}$ ,  $\phi_{\text{IC}}$ , and  $\phi_{\text{P}}$  are the quantum yields of fluorescence, internal conversion, and phosphorescence, respectively (intersystem crossing from the singlet to the triplet state is taken into account by the presence of  $\phi_{\text{P}}$ ). The quantum yield of photon emission by fluorescence and phosphorescence is  $\phi_{\text{emission}} = \phi_{\text{F}} + \phi_{\text{P}}$ , which is less than 1. If the excited singlet state also participates in a primary photochemical reaction with quantum yield  $\phi_{\text{P}}$ , we write

$$\phi_{\text{F}} + \phi_{\text{IC}} + \phi_{\text{P}} + \phi_{\text{r}} = 1$$

We can now strengthen the link between reaction rates and primary quantum yield already established by eqns 20G.1 and 20G.2. By taking the constant  $I_{\text{abs}}$  out of the sum in eqn 20G.2 and rearranging, we obtain  $I_{\text{abs}} = \sum_i \nu_i$ . Substituting this result into eqn 20G.2 gives the general result

$$\phi_i = \frac{\nu_i}{\sum_i \nu_i} \quad (20G.3)$$

Therefore, the primary quantum yield may be determined directly from the experimental rates of *all* photophysical and photochemical processes that deactivate the excited state.

## 20G.3 Mechanism of decay of excited singlet states

Consider the formation and decay of an excited singlet state in the absence of a chemical reaction:

Absorption:	$S + h\nu_1 \rightarrow S^*$	$\nu_{\text{abs}} = I_{\text{abs}}$
Fluorescence:	$S^* \rightarrow S + h\nu_{\text{f}}$	$\nu_{\text{F}} = k_{\text{F}}[S^*]$
Internal conversion:	$S^* \rightarrow S$	$\nu_{\text{IC}} = k_{\text{IC}}[S^*]$
Intersystem crossing:	$S^* \rightarrow T^*$	$\nu_{\text{ISC}} = k_{\text{ISC}}[S^*]$

in which S is an absorbing singlet-state species, S\* an excited singlet state, T\* an excited triplet state, and  $h\nu_i$  and  $h\nu_f$  are the energies of the incident and fluorescent photons, respectively. From the methods presented in Topic 20E and the rates of the steps that form and destroy the excited singlet state S\*, we write the rate of formation and decay of S\* as:

$$\text{Rate of formation of } S^* = I_{\text{abs}}$$

$$\begin{aligned} \text{Rate of disappearance of } S^* &= k_F[S^*] + k_{\text{ISC}}[S^*] + k_{\text{IC}}[S^*] \\ &= (k_F + k_{\text{ISC}} + k_{\text{IC}})[S^*] \end{aligned}$$

It follows that the excited state decays by a first-order process so, when the light is turned off, the concentration of S\* varies with time  $t$  as:

$$[S^*](t) = [S^*]_0 e^{-t/\tau_0} \quad (20G.4)$$

where the **observed lifetime**,  $\tau_0$ , of the first excited singlet state is defined as:

$$\tau_0 = \frac{1}{k_F + k_{\text{ISC}} + k_{\text{IC}}} \quad \text{Definition} \quad \begin{array}{l} \text{Observed} \\ \text{lifetime of} \\ \text{the excited} \\ \text{singlet state} \end{array} \quad (20G.5)$$

We show in the following *Justification* that the quantum yield of fluorescence is

$$\phi_{F,0} = \frac{k_F}{k_F + k_{\text{ISC}} + k_{\text{IC}}} \quad \text{Quantum yield of fluorescence} \quad (20G.6)$$

### Justification 20G.1 The quantum yield of fluorescence

Most fluorescence measurements are conducted by illuminating a relatively dilute sample with a continuous and intense beam of light or ultraviolet radiation. It follows that  $[S^*]$  is small and constant, so we may invoke the steady-state approximation (Topic 20E) and write:

$$\begin{aligned} \frac{d[S^*]}{dt} &= I_{\text{abs}} - k_F[S^*] - k_{\text{ISC}}[S^*] - k_{\text{IC}}[S^*] \\ &= I_{\text{abs}} - (k_F + k_{\text{ISC}} + k_{\text{IC}})[S^*] \approx 0 \end{aligned}$$

Consequently,

$$I_{\text{abs}} = (k_F + k_{\text{ISC}} + k_{\text{IC}})[S^*]$$

By using this expression and eqn 20G.1b, we write the quantum yield of fluorescence as:

$$\phi_{F,0} = \frac{\nu_F}{I_{\text{abs}}} = \frac{k_F[S^*]}{(k_F + k_{\text{ISC}} + k_{\text{IC}})[S^*]}$$

which, by cancelling the  $[S^*]$ , simplifies to eqn 20G.6.

The observed fluorescence lifetime can be measured by using a pulsed laser technique. First, the sample is excited with a short

light pulse from a laser using a wavelength at which S absorbs strongly. Then, the exponential decay of the fluorescence intensity after the pulse is monitored. From eqns 20G.5 and 20G.6, it follows that

$$\tau_0 = \frac{1}{k_F + k_{\text{ISC}} + k_{\text{IC}}} = \frac{k_F}{k_F + k_{\text{ISC}} + k_{\text{IC}}} \times \frac{1}{k_F} = \frac{\phi_{F,0}}{k_F} \quad (20G.7)$$

### Brief illustration 20G.2 The fluorescence rate constant

The fluorescence quantum yield and observed fluorescence lifetime of tryptophan in water are  $\phi_{F,0} = 0.20$  and  $\tau_0 = 2.6$  ns, respectively. It follows from eqn 20G.7 that the fluorescence rate constant  $k_F$  is

$$k_F = \frac{\phi_{F,0}}{\tau_0} = \frac{0.20}{2.6 \times 10^{-9} \text{ s}} = 7.7 \times 10^7 \text{ s}^{-1}$$

**Self-test 20G.3** A substance has a fluorescence quantum yield of  $\phi_{F,0} = 0.35$ . In an experiment to measure the fluorescence lifetime of this substance, it was observed that the fluorescence emission decayed with a half-life of 5.6 ns. Determine the fluorescence rate constant of this substance.

Answer:  $k_F = 4.3 \times 10^7 \text{ s}^{-1}$

## 20G.4 Quenching

The shortening of the lifetime of the excited state by the presence of another species is called **quenching**. Quenching may be either a desired process, such as in energy or electron transfer, or an undesired side reaction that can decrease the quantum yield of a desired photochemical process. Quenching effects may be studied by monitoring the emission from the excited state that is involved in the photochemical reaction.

The addition of a quencher, Q, opens an additional channel for deactivation of S\*:

The **Stern–Volmer equation**, which is derived in the following *Justification*, relates the fluorescence quantum yields  $\phi_{F,0}$  and  $\phi_F$  measured in the absence and presence, respectively, of a quencher Q at a molar concentration  $[Q]$ :

$$\frac{\phi_{F,0}}{\phi_F} = 1 + \tau_0 k_Q [Q] \quad \text{Stern–Volmer equation} \quad (20G.8)$$

This equation tells us that a plot of  $\phi_{F,0}/\phi_F$  against  $[Q]$  should be a straight line with slope  $\tau_0 k_Q$ . Such a plot is called a **Stern–Volmer plot** (Fig. 20G.1). The method may also be applied to the quenching of phosphorescence.

**Figure 20G.1** The format of a Stern–Volmer plot and the interpretation of the slope in terms of the rate constant for quenching and the observed fluorescence lifetime in the absence of quencher.

### Justification 20G.2 The Stern–Volmer equation

With the addition of quenching, the steady-state approximation for  $[S^*]$  now gives:

$$\frac{d[S^*]}{dt} = I_{\text{abs}} - (k_F + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q])[S^*] \approx 0$$

and the fluorescence quantum yield in the presence of the quencher is:

$$\phi_F = \frac{k_F}{k_F + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}$$

It follows that

$$\begin{aligned} \frac{\phi_{F,0}}{\phi_F} &= \frac{k_F}{k_F + k_{\text{ISC}} + k_{\text{IC}}} \times \frac{k_F + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}{k_F} \\ &= \frac{k_F + k_{\text{ISC}} + k_{\text{IC}} + k_Q[Q]}{k_F + k_{\text{ISC}} + k_{\text{IC}}} \\ &= 1 + \frac{k_Q}{k_F + k_{\text{ISC}} + k_{\text{IC}}}[Q] \end{aligned}$$

By using eqn 20G.7, this expression simplifies to eqn 20G.8.

Because the fluorescence intensity and lifetime are both proportional to the fluorescence quantum yield (specifically, from eqn 20G.7,  $\tau = \phi_F/k_F$ ), plots of  $I_{F,0}/I_F$  and  $\tau_0/\tau$  (where the subscript 0 indicates a measurement in the absence of quencher) against  $[Q]$  should also be linear with the same slope and intercept as those shown for eqn 20G.8.

### Example 20G.2 Determining the quenching rate constant

The molecule 2,2'-bipyridine (1, bpy) forms a complex with the  $\text{Ru}^{2+}$  ion. Tris-(2,2'-bipyridyl)ruthenium(II),  $\text{Ru}(\text{bpy})_3^{2+}$

(2), has a strong metal-to-ligand charge transfer (MLCT) transition (Topic 13A) at 450 nm.

The quenching of the  $^* \text{Ru}(\text{bpy})_3^{2+}$  excited state by  $\text{Fe}^{3+}$  (present as the complex ion  $\text{Fe}(\text{OH})_6^{3+}$ ) in acidic solution was monitored by measuring emission lifetimes at 600 nm. Determine the quenching rate constant for this reaction from the following data:

$[\text{Fe}(\text{OH})_6^{3+}]/(10^{-4} \text{ mol dm}^{-3})$	0	1.6	4.7	7	9.4
$\tau/(10^{-7} \text{ s})$	6	4.05	3.37	2.96	2.17

**Method** Rewrite the Stern–Volmer equation (eqn 20G.8) for use with lifetime data; then fit the data to a straight-line.

**Answer** Upon substitution of  $\tau_0/\tau$  for  $\phi_{F,0}/\phi_F$  in eqn 20G.8 and after rearrangement, we obtain:

$$\frac{1}{\tau} = \frac{1}{\tau_0} + k_Q[Q]$$

Figure 20G.2 shows a plot of  $1/\tau$  against  $[\text{Fe}^{3+}]$  and the results of a fit to this expression. The slope of the line is  $2.8 \times 10^9$ , so  $k_Q = 2.8 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . This example shows that measurements of emission lifetimes are preferred because they yield the value of  $k_Q$  directly. To determine the value of  $k_Q$  from intensity or quantum yield measurements, it is necessary to make an independent measurement of  $\tau_0$ .

**Self-test 20G.4** The quenching of tryptophan fluorescence by dissolved  $\text{O}_2$  gas was monitored by measuring

**Figure 20G.2** The Stern–Volmer plot of the data for Example 20G.2.

emission lifetimes at 348 nm in aqueous solutions. Determine the quenching rate constant for this process from the following data:

$[\text{O}_2]/(10^{-2} \text{ mol dm}^{-3})$	0	2.3	5.5	8	10.8
$\tau/(10^{-9} \text{ s})$	2.6	1.5	0.92	0.71	0.57

Answer:  $1.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

Three common mechanisms for bimolecular quenching of an excited singlet (or triplet) state are:

Collisional deactivation:	$\text{S}^* + \text{Q} \rightarrow \text{S} + \text{Q}$
Resonance energy transfer:	$\text{S}^* + \text{Q} \rightarrow \text{S} + \text{Q}^*$
Electron transfer:	$\text{S}^* + \text{Q} \rightarrow \text{S}^{\pm} + \text{Q}^{\mp}$

The quenching rate constant itself does not give much insight into the mechanism of quenching. For the system of *Example 20G.2*, it is known that the quenching of the excited state of  $\text{Ru}(\text{bpy})_3^{2+}$  is a result of electron transfer to  $\text{Fe}^{3+}$ , but the quenching data do not allow us to prove the mechanism.

There are, however, some criteria that govern the relative efficiencies of collisional quenching, resonance energy transfer, and electron transfer. Collisional quenching is particularly efficient when Q is a species, such as iodide ion, which receives energy from  $\text{S}^*$  and then decays to the ground state primarily by releasing energy as heat. As we show in detail in Topic 21E, according to the **Marcus theory** of electron transfer, which was proposed by R.A. Marcus in 1965, the rates of electron transfer (from ground or excited states) depend on:

- The distance between the donor and acceptor, with electron transfer becoming more efficient as the distance between donor and acceptor decreases.
- The reaction Gibbs energy,  $\Delta_r G$ , with electron transfer becoming more efficient as the reaction becomes more exergonic. For example, it follows from the thermodynamic principles that lead to the electrochemical series (Topic 6D) that efficient photo-oxidation of S requires that the reduction potential of  $\text{S}^*$  be lower than the reduction potential of Q.
- The reorganization energy, the energy cost incurred by molecular rearrangements of donor, acceptor, and solvent medium during electron transfer. The electron transfer rate is predicted to increase as this reorganization energy is matched closely by the reaction Gibbs energy.

Electron transfer can also be studied by time-resolved spectroscopy (Topic 13C). The oxidized and reduced products often have electronic absorption spectra distinct from those of their neutral parent compounds. Therefore, the rapid appearance of

such known features in the absorption spectrum after excitation by a laser pulse may be taken as indication of quenching by electron transfer. In the following section we explore resonance energy transfer in detail.

## 20G.5 Resonance energy transfer

We visualize the process  $\text{S}^* + \text{Q} \rightarrow \text{S} + \text{Q}^*$  as follows. The oscillating electric field of the incoming electromagnetic radiation induces an oscillating electric dipole moment in S. Energy is absorbed by S if the frequency of the incident radiation,  $\nu$ , is such that  $\nu = \Delta E_S/h$ , where  $\Delta E_S$  is the energy separation between the ground and excited electronic states of S and  $h$  is Planck's constant. This is the 'resonance condition' for absorption of radiation (essentially the Bohr frequency condition, eqn 7A.12). The oscillating dipole on S can now affect electrons bound to a nearby Q molecule by inducing an oscillating dipole moment in them. If the frequency of oscillation of the electric dipole moment in S is such that  $\nu = \Delta E_Q/h$  then Q will absorb energy from S.

The efficiency,  $\eta_T$ , of resonance energy transfer is defined as

$$\eta_T = 1 - \frac{\phi_F}{\phi_{F,0}} \quad \text{Definition} \quad \text{Efficiency of resonance energy transfer} \quad (20G.9)$$

According to the **Förster theory** of resonance energy transfer, energy transfer is efficient when:

- The energy donor and acceptor are separated by a short distance (of the order of nanometres).
- Photons emitted by the excited state of the donor can be absorbed directly by the acceptor.

For donor–acceptor systems held rigidly either by covalent bonds or by a protein 'scaffold',  $\eta_T$  increases with decreasing distance,  $R$ , according to

$$\eta_T = \frac{R_0^6}{R_0^6 + R^6} \quad \text{Efficiency of energy transfer in terms of the donor–acceptor distance} \quad (20G.10)$$

where  $R_0$  is a parameter (with dimensions of distance) that is characteristic of each donor–acceptor pair. It can be regarded as the distance at which energy transfer is 50 per cent efficient for a given donor–acceptor pair. (You can verify this assertion by using  $R = R_0$  in eqn 20G.10.) Equation 20G.10 has been verified experimentally and values of  $R_0$  are available for a number of donor–acceptor pairs (Table 20G.3).

The emission and absorption spectra of molecules span a range of wavelengths, so the second requirement of the Förster theory is met when the emission spectrum of the donor molecule overlaps significantly with the absorption spectrum of the

**Table 20G.3** Values of  $R_0$  for some donor–acceptor pairs\*

Donor <sup>‡</sup>	Acceptor <sup>‡</sup>	$R_0$ /nm
Naphthalene	Dansyl	2.2
Dansyl	ODR	4.3
Pyrene	Coumarin	3.9
1,5-I AEDANS	FITC	4.9
Tryptophan	1,5-I AEDANS	2.2
Tryptophan	Haem (heme)	2.9

\*Additional values may be found in J.R. Lacowicz *Principles of fluorescence spectroscopy*, Kluwer Academic/Plenum, New York (1999).

<sup>‡</sup>Abbreviations:

Dansyl: 5-dimethylamino-1-naphthalenesulfonic acid

FITC: fluorescein 5-isothiocyanate

1,5-I AEDANS: 5-(((2-iodoacetyl)amino)ethyl)aminonaphthalene-1-sulfonic acid

ODR: octadecyl-rhodamine

**Figure 20G.3** According to the Förster theory, the rate of energy transfer from a molecule  $S^*$  in an excited state to a quencher molecule  $Q$  is optimized at radiation frequencies in which the emission spectrum of  $S^*$  overlaps with the absorption spectrum of  $Q$ , as shown in the (dark green) shaded region.

acceptor. In the overlap region, photons emitted by the donor have the appropriate energy to be absorbed by the acceptor (Fig. 20G.3).

Equation 20G.10 forms the basis of **fluorescence resonance energy transfer** (FRET), in which the dependence of the energy transfer efficiency,  $\eta_T$ , on the distance,  $R$ , between energy donor and acceptor is used to measure distances in biological systems. In a typical FRET experiment, a site on a

biopolymer or membrane is labelled covalently with an energy donor and another site is labelled covalently with an energy acceptor. In certain cases, the donor or acceptor may be natural constituents of the system, such as amino acid groups, cofactors, or enzyme substrates. The distance between the labels is then calculated from the known value of  $R_0$  and eqn 20G.10. Several tests have shown that the FRET technique is useful for measuring distances ranging from 1 to 9 nm.

### Brief illustration 20G.3 The FRET technique

As an illustration of the FRET technique, consider a study of the protein rhodopsin. When an amino acid on the surface of rhodopsin was labelled covalently with the energy donor 1,5-I AEDANS (3), the fluorescence quantum yield of the label decreased from 0.75 to 0.68 due to quenching by the visual pigment 11-*cis*-retinal (4). From eqn 20G.10, we calculate  $\eta_T = 1 - 0.68/0.75 = 0.093$  and from eqn 20G.10 and the known value of  $R_0 = 5.4$  nm for the 1,5-I AEDANS/11-*cis*-retinal pair we calculate  $R = 7.9$  nm. Therefore, we take 7.9 nm to be the distance between the surface of the protein and 11-*cis*-retinal.

**Self-test 20G.5** An amino acid on the surface of a protein was labelled covalently with 1,5-I AEDANS and another was labelled covalently with FITC. The fluorescence quantum yield of 1,5-I AEDANS decreased by 10 per cent due to quenching by FITC. What is the distance between the amino acids?

Answer: 7.1 nm

If donor and acceptor molecules diffuse in solution or in the gas phase, Förster theory predicts that the efficiency of quenching by energy transfer increases as the average distance travelled between collisions of donor and acceptor decreases. That is, the quenching efficiency increases with concentration of quencher, as predicted by the Stern–Volmer equation.

## Checklist of concepts

1. The **primary quantum yield** of a photochemical reaction is the number of reactant molecules producing specified primary products for each photon absorbed.
2. The **observed lifetime** of an excited state is related to the quantum yield and rate constant of emission.
3. A **Stern–Volmer plot** is used to analyse the kinetics of fluorescence quenching in solution.
4. Collisional deactivation, electron transfer, and resonance energy transfer are common fluorescence quenching processes.

- 5. The efficiency of resonance energy transfer decreases with increasing separation between donor and acceptor molecules.

## Checklist of equations

Property	Equation	Comment	Equation number
Primary quantum yield	$\phi = \nu / I_{\text{abs}}$		20G.1b

### ► Why do you need to know this material?

The role of enzymes in controlling chemical reactions is central to biology and the maintenance of life. It is at the centre of attention of much of the application of physical chemistry to biology.

### ► What is the key idea?

Enzymes are homogeneous catalysts that can have a dramatic effect on the rates of the reactions they control but are subject to inhibition.

### ► What do you need to know already?

You need to be familiar with the analysis of reaction mechanisms in terms of the steady-state approximation (Topic 20E).

A catalyst is a substance that accelerates a reaction but undergoes no net chemical change (Topic 20D): the catalyst lowers the activation energy of the reaction by providing an alternative path that avoids the slow, rate-determining step of the uncatalysed reaction (Fig. 20H.1). **Enzymes**, which are homogeneous biological catalysts, are very specific and can have a dramatic effect on the reactions they control. The enzyme catalase reduces the activation energy from  $76\text{ kJ mol}^{-1}$  to  $8\text{ kJ mol}^{-1}$ , corresponding to an acceleration of the reaction by a factor of  $10^{15}$  at 298 K.

**Figure 20H.1** A catalyst provides a different path with a lower activation energy. The result is an increase in the rate of formation of product.

## 20H.1 Features of enzymes

Enzymes act in the aqueous environment of cells. These biologically ubiquitous compounds are special proteins or nucleic acids that contain an **active site**, which is responsible for binding the **substrates**, the reactants, and processing them into products. As is true of any catalyst, the active site returns to its original state after the products are released. Many enzymes consist primarily of proteins, some featuring organic or inorganic co-factors in their active sites. However, certain RNA molecules can also be biological catalysts, forming *ribozymes*. A very important example of a ribozyme is the *ribosome*, a large assembly of proteins and catalytically active RNA molecules responsible for the synthesis of proteins in the cell.

The structure of the active site is specific to the reaction that it catalyses, with groups in the substrate interacting with groups in the active site by intermolecular interactions, such as hydrogen bonding, electrostatic forces, and van der Waals interactions. Figure 20H.2 shows two models that explain the binding of a substrate to the active site of an enzyme. In the **lock-and-key model**, the active site and substrate have complementary three-dimensional structures and dock without the need for major atomic rearrangements. Experimental evidence favours the **induced fit model**, in which binding of the substrate induces a conformational change in the active site. Only after the change does the substrate fit snugly in the active site.

Enzyme-catalysed reactions are prone to inhibition by molecules that interfere with the formation of product. Many drugs for the treatment of disease function by inhibiting

**Figure 20H.2** Two models that explain the binding of a substrate to the active site of an enzyme. In the lock-and-key model, the active site and substrate have complementary three-dimensional structures and dock without the need for major atomic rearrangements. In the induced fit model, binding of the substrate induces a conformational change in the active site. The substrate fits well in the active site after the conformational change has taken place.

enzymes. For example, an important strategy in the treatment of acquired immune deficiency syndrome (AIDS) involves the steady administration of a specially designed protease inhibitor. The drug inhibits an enzyme that is key to the formation of the protein envelope surrounding the genetic material of the human immunodeficiency virus (HIV). Without a properly formed envelope, HIV cannot replicate in the host organism.

## 20H.2 The Michaelis–Menten mechanism

Experimental studies of enzyme kinetics are typically conducted by monitoring the initial rate of product formation in a solution in which the enzyme is present at very low concentration. Indeed, enzymes are such efficient catalysts that significant accelerations may be observed even when their concentration is more than three orders of magnitude smaller than that of the substrate.

The principal features of many enzyme-catalysed reactions are as follows:

- For a given initial concentration of substrate,  $[S]_0$ , the initial rate of product formation is proportional to the total concentration of enzyme,  $[E]_0$ .
- For a given  $[E]_0$  and low values of  $[S]_0$ , the rate of product formation is proportional to  $[S]_0$ .
- For a given  $[E]_0$  and high values of  $[S]_0$ , the rate of product formation becomes independent of  $[S]_0$ , reaching a maximum value known as the **maximum velocity**,  $v_{\max}$ .

The **Michaelis–Menten mechanism** accounts for these features. According to this mechanism, an enzyme–substrate

complex is formed in the first step and either the substrate is released unchanged or after modification to form products:

We show in the following *Justification* that this mechanism leads to the **Michaelis–Menten equation** for the rate of product formation

$$v = \frac{k_b [E]_0}{1 + K_M / [S]_0} \quad \text{Michaelis–Menten equation} \quad (20H.1)$$

where  $K_M = (k'_a + k_b) / k_a$  is the **Michaelis constant**, characteristic of a given enzyme acting on a given substrate and having the dimensions of a molar concentration.

### Justification 20H.1 The Michaelis–Menten equation

The rate of product formation according to the Michaelis–Menten mechanism is

$$v = k_b [ES]$$

We can obtain the concentration of the enzyme–substrate complex by invoking the steady-state approximation and writing

$$\frac{d[ES]}{dt} = k_a [E][S] - k'_a [ES] - k_b [ES] \approx 0$$

It follows that

$$[ES] = \frac{k_a [E][S]}{k'_a + k_b}$$

where  $[E]$  and  $[S]$  are the concentrations of *free* enzyme and substrate, respectively. Now we define the Michaelis constant as

$$K_M = \frac{k'_a + k_b}{k_a}$$

To express the rate law in terms of the concentrations of enzyme and substrate added, we note that  $[E]_0 = [E] + [ES]$  and

$$[E]_0 = \frac{K_M [ES]}{[S]} + [ES] = [ES] \{1 + K_M / [S]\}$$

Moreover, because the substrate is typically in large excess relative to the enzyme, the free substrate concentration is approximately equal to the initial substrate concentration and we can write  $[S] \approx [S]_0$ . It then follows that:

$$[ES] = \frac{[E]_0}{1 + K_M / [S]_0}$$

Equation 20H.1 is obtained when this expression for  $[ES]$  is substituted into that for the rate of product formation ( $v = k_b [ES]$ ).

Equation 20H.1 shows that, in accord with experimental observations (Fig. 20H.3):

- When  $[S]_0 \ll K_M$ , the rate is proportional to  $[S]_0$ :

$$v = \frac{k_b}{K_M} [S]_0 [E]_0 \quad (20H.2a)$$

- When,  $[S]_0 \gg K_M$ , the rate reaches its maximum value and is independent of  $[S]_0$ :

$$v = v_{\max} = k_b [E]_0 \quad (20H.2b)$$

Substitution of the definition of  $v_{\max}$  into eqn 20H.1 gives

$$v = \frac{v_{\max}}{1 + K_M/[S]_0} \quad (20H.3a)$$

which can be rearranged into a form suitable for data analysis by linear regression by taking reciprocals of both sides:

$$\frac{1}{v} = \frac{1}{v_{\max}} + \left( \frac{K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad \text{Lineweaver–Burk plot} \quad (20H.3b)$$

A **Lineweaver–Burk plot** is a plot of  $1/v$  against  $1/[S]_0$ , and according to eqn 20H.3b it should yield a straight line with slope of  $K_M/v_{\max}$ , a  $y$ -intercept at  $1/v_{\max}$ , and an  $x$ -intercept at  $-1/K_M$  (Fig. 20H.4). The value of  $k_b$  is then calculated from the  $y$ -intercept and eqn 20H.2b. However, the plot cannot give the individual rate constants  $k_a$  and  $k'_a$  that appear in the expression for  $K_M$ . The stopped-flow technique described in Topic 20A can give the additional data needed, because the rate of formation of the enzyme–substrate complex can be found by monitoring the concentration after mixing the enzyme and substrate. This procedure gives a value for  $k_a$ , and  $k'_a$  is then found by combining this result with the values of  $k_b$  and  $K_M$ .

**Figure 20H.3** The variation of the rate of an enzyme-catalysed reaction with substrate concentration. The approach to a maximum rate,  $v_{\max}$ , for large  $[S]$  is explained by the Michaelis–Menten mechanism.

**Figure 20H.4** A Lineweaver–Burk plot for the analysis of an enzyme-catalysed reaction that proceeds by a Michaelis–Menten mechanism and the significance of the intercepts and the slope.

### Example 20H.1 Analysing a Lineweaver–Burk plot

The enzyme carbonic anhydrase catalyses the hydration of  $\text{CO}_2$  in red blood cells to give bicarbonate (hydrogencarbonate) ion:  $\text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{l}) \rightarrow \text{HCO}_3^-(\text{aq}) + \text{H}^+(\text{aq})$ . The following data were obtained for the reaction at  $\text{pH}=7.1$ ,  $273.5\text{ K}$ , and an enzyme concentration of  $2.3\text{ nmol dm}^{-3}$ :

$[\text{CO}_2]/$ ( $\text{mmol dm}^{-3}$ )	1.25	2.5	5	20
$v/$ ( $\text{mmol dm}^{-3}\text{ s}^{-1}$ )	$2.78 \times 10^{-2}$	$5.00 \times 10^{-2}$	$8.33 \times 10^{-2}$	$1.67 \times 10^{-1}$

Determine the maximum velocity and the Michaelis constant for the reaction at  $273.5\text{ K}$ .

**Method** Prepare a Lineweaver–Burk plot and determine the values of  $K_M$  and  $v_{\max}$  by linear regression analysis.

**Answer** We draw up the following table:

$1/([\text{CO}_2]/(\text{mmol dm}^{-3}))$	0.800	0.400	0.200	0.0500
$1/(v/(\text{mmol dm}^{-3}\text{ s}^{-1}))$	36.0	20.0	12.0	6.0

Figure 20H.5 shows the Lineweaver–Burk plot for the data. The slope is 40.0 and the  $y$ -intercept is 4.00. Hence,

$$v_{\max}/(\text{mmol dm}^{-3}\text{ s}^{-1}) = \frac{1}{\text{intercept}} = \frac{1}{4.00} = 0.250$$

and

$$K_M/(\text{mmol dm}^{-3}) = \frac{\text{slope}}{\text{intercept}} = \frac{40.00}{4.00} = 10.0$$

*A note on good practice* The slope and the intercept are unit-less: all graphs should be plotted as pure numbers.

Figure 20H.5 The Lineweaver–Burk plot of the data for Example 20H.1.

**Self-test 20H.1** The enzyme  $\alpha$ -chymotrypsin is secreted in the pancreas of mammals and cleaves peptide bonds made between certain amino acids. Several solutions containing the small peptide *N*-glutaryl-L-phenylalanine-*p*-nitroanilide at different concentrations were prepared and the same small amount of  $\alpha$ -chymotrypsin was added to each one. The following data were obtained on the initial rates of the formation of product:

[S]/ (mmol dm <sup>-3</sup> )	0.334	0.450	0.667	1.00	1.33	1.67
$v$ / (mmol dm <sup>-3</sup> s <sup>-1</sup> )	0.152	0.201	0.269	0.417	0.505	0.667

Determine the maximum velocity and the Michaelis constant for the reaction.

Answer:  $v_{\max} = 2.80 \text{ mmol dm}^{-3} \text{ s}^{-1}$ ,  $K_M = 5.89 \text{ mmol dm}^{-3}$

## 20H.3 The catalytic efficiency of enzymes

The **turnover frequency**, or **catalytic constant**, of an enzyme,  $k_{\text{cat}}$ , is the number of catalytic cycles (turnovers) performed by the active site in a given interval divided by the duration of the interval. This quantity has units of a first-order rate constant and, in terms of the Michaelis–Menten mechanism, is numerically equivalent to  $k_b$ , the rate constant for release of product from the enzyme–substrate complex. It follows from the identification of  $k_{\text{cat}}$  with  $k_b$  and from eqn 20H.2b that

$$k_{\text{cat}} = k_b = \frac{v_{\max}}{[E]_0} \quad \text{Turnover frequency} \quad (20H.4)$$

The **catalytic efficiency**,  $\eta$  (eta), of an enzyme is the ratio  $k_{\text{cat}}/K_M$ . The higher the value of  $\eta$ , the more efficient is the

enzyme. We can think of the catalytic efficiency as the effective rate constant of the enzymatic reaction. From  $K_M = (k'_a + k_b)/k_a$  and eqn 20H.4, it follows that

$$\eta = \frac{k_{\text{cat}}}{K_M} = \frac{k_a k_b}{k'_a + k_b} \quad \text{Catalytic efficiency} \quad (20H.5)$$

The efficiency reaches its maximum value of  $k_a$  when  $k_b \gg k'_a$ . Because  $k_a$  is the rate constant for the formation of a complex from two species that are diffusing freely in solution, the maximum efficiency is related to the maximum rate of diffusion of E and S in solution. This limit (which is discussed further in Topic 21B) leads to rate constants of about  $10^8$ – $10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  for molecules as large as enzymes at room temperature. The enzyme catalase has  $\eta = 4.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and is said to have attained ‘catalytic perfection’, in the sense that the rate of the reaction it catalyses is controlled only by diffusion: it acts as soon as a substrate makes contact.

### Brief illustration 20H.1 The catalytic efficiency of an enzyme

To determine the catalytic efficiency of carbonic anhydrase at 273.5 K from the results from Example 20H.1, we begin by using eqn 20H.4 to calculate  $k_{\text{cat}}$ :

$$k_{\text{cat}} = \frac{v_{\max}}{[E]_0} = \frac{2.5 \times 10^{-4} \text{ mol dm}^{-3} \text{ s}^{-1}}{2.3 \times 10^{-9} \text{ mol dm}^{-3}} = 1.1 \times 10^5 \text{ s}^{-1}$$

The catalytic efficiency follows from eqn 20H.5:

$$\eta = \frac{k_{\text{cat}}}{K_M} = \frac{1.1 \times 10^5 \text{ s}^{-1}}{2.3 \times 10^{-9} \text{ mol dm}^{-3}} = 1.1 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

**Self-test 20H.2** The enzyme-catalysed conversion of a substrate at 298 K has  $K_M = 0.032 \text{ mol dm}^{-3}$  and  $v_{\max} = 4.25 \times 10^{-4} \text{ mol dm}^{-3} \text{ s}^{-1}$  when the enzyme concentration is  $3.60 \times 10^{-9} \text{ mol dm}^{-3}$ . Calculate  $k_{\text{cat}}$  and  $\eta$ . Is the enzyme ‘catalytically perfect’?

Answer:  $k_{\text{cat}} = 1.18 \times 10^5 \text{ s}^{-1}$ ,  $\eta = 7.9 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ; the enzyme is not ‘catalytically perfect’

## 20H.4 Mechanisms of enzyme inhibition

An inhibitor, In, decreases the rate of product formation from the substrate by binding to the enzyme, to the ES complex, or to the enzyme and ES complex simultaneously. The most general kinetic scheme for enzyme inhibition is then:

The lower the values of  $K_1$  and  $K'_1$  the more efficient are the inhibitors. The rate of product formation is always given by  $v = k_b[ES]$ , because only ES leads to product. As shown in the following *Justification*, the rate of reaction in the presence of an inhibitor is

$$v = \frac{v_{\max}}{\alpha' + \alpha K_M/[S]_0} \quad \text{Effect of inhibition on the rate} \quad (20H.7)$$

where  $\alpha = 1 + [In]/K_1$  and  $\alpha' = 1 + [In]/K'_1$ . This equation is very similar to the Michaelis–Menten equation for the uninhibited enzyme (eqn 20H.1) and is also amenable to analysis by a Lineweaver–Burk plot:

$$\frac{1}{v} = \frac{\alpha'}{v_{\max}} + \left( \frac{\alpha K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad (20H.8)$$

### Justification 20H.2 Enzyme inhibition

By mass balance, the total concentration of enzyme is:

$$[E]_0 = [E] + [EIn] + [ES] + [ESIn]$$

By using eqns 20H.6a and 20H.6b and the definitions

$$\alpha = 1 + \frac{[In]}{K_1} \quad \text{and} \quad \alpha' = 1 + \frac{[In]}{K'_1}$$

it follows that

$$[E]_0 = [E]\alpha + [ES]\alpha'$$

By using  $K_M = [E][S]/[ES]$  and replacing  $[S]$  with  $[S]_0$  we can write

$$[E]_0 = \frac{K_M[ES]}{[S]_0} \alpha + [ES]\alpha' = [ES] \left( \frac{\alpha K_M}{[S]_0} + \alpha' \right)$$

The expression for the rate of product formation is then:

$$v = k_b[ES] = \frac{k_b[E]_0}{\alpha K_M/[S]_0 + \alpha'}$$

which, upon replacement of  $k_b[E]_0$  with  $v_{\max}$ , gives eqn 20H.7.

There are three major modes of inhibition that give rise to distinctly different kinetic behaviour (Fig. 20H.6). In **competitive inhibition** the inhibitor binds only to the active site of the enzyme and thereby inhibits the attachment of the substrate.

**Figure 20H.6** Lineweaver–Burk plots characteristic of the three major modes of enzyme inhibition: (a) competitive inhibition, (b) uncompetitive inhibition, and (c) non-competitive inhibition, showing the special case  $\alpha = \alpha' > 1$ .

This condition corresponds to  $\alpha > 1$  and  $\alpha' = 1$  (because  $ESIn$  does not form). In this limit, eqn 20H.8 becomes

$$\frac{1}{v} = \frac{1}{v_{\max}} + \left( \frac{\alpha K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad \text{Competitive inhibition}$$

The y-intercept is unchanged but the slope of the Lineweaver–Burk plot increases by a factor of  $\alpha$  relative to the slope for data on the uninhibited enzyme (Fig. 20H.6a).

In **uncompetitive inhibition** the inhibitor binds to a site of the enzyme that is removed from the active site, but only if the substrate is already present. The inhibition occurs because  $ESI$  reduces the concentration of  $ES$ , the active type of complex. In this case  $\alpha = 1$  (because  $EI$  does not form) and  $\alpha' > 1$  and eqn 20H.8 becomes

$$\frac{1}{v} = \frac{\alpha'}{v_{\max}} + \left( \frac{K_M}{v_{\max}} \right) \frac{1}{[S]_0} \quad \text{Uncompetitive inhibition}$$

The y-intercept of the Lineweaver–Burk plot increases by a factor of  $\alpha'$  relative to the y-intercept for data on the uninhibited enzyme but the slope does not change (Fig. 20H.6b).

In **non-competitive inhibition** (also called **mixed inhibition**) the inhibitor binds to a site other than the active site, and its presence reduces the ability of the substrate to bind to the active site. Inhibition occurs at both the  $E$  and  $ES$  sites. This condition corresponds to  $\alpha > 1$  and  $\alpha' > 1$ . Both the slope and y-intercept of the Lineweaver–Burk plot increase upon addition of the inhibitor. Figure 20H.6c shows the special case of  $K_1 = K'_1$  and  $\alpha = \alpha'$ , which results in intersection of the lines at the x-axis.

In all cases, the efficiency of the inhibitor may be obtained by determining  $K_M$  and  $v_{\max}$  from a control experiment with uninhibited enzyme and then repeating the experiment with a known concentration of inhibitor. From the slope and  $y$ -intercept of the Lineweaver–Burk plot for the inhibited enzyme, the mode of inhibition, the values of  $\alpha$  or  $\alpha'$ , and the values of  $K_I$  and  $K_I'$  may be obtained.

### Example 20H.2 Distinguishing between types of inhibition

Five solutions of a substrate, S, were prepared with the concentrations given in the first column below and each one was divided into five equal volumes. The same concentration of enzyme was present in each one. An inhibitor, In, was then added in four different concentrations to the samples, and the initial rate of formation of product was determined with the results given below. Does the inhibitor act competitively or noncompetitively? Determine  $K_I$  and  $K_M$ .

$[S]_0/(\text{mmol dm}^{-3})$	$[\text{In}]/(\text{mmol dm}^{-3})$				
	0	0.20	0.40	0.60	0.80
0.050	0.033	0.026	0.021	0.018	0.016
0.10	0.055	0.045	0.038	0.033	0.029
0.20	0.083	0.071	0.062	0.055	0.050
0.40	0.111	0.100	0.091	0.084	0.077
0.60	0.116	0.116	0.108	0.101	0.094

 $v/(\mu\text{mol dm}^{-3} \text{ s}^{-1})$ 

**Method** Draw a series of Lineweaver–Burk plots for different inhibitor concentrations. If the plots resemble those in Fig. 20H.6a, then the inhibition is competitive. On the other hand, if the plots resemble those in Fig. 20H.6b, then the inhibition is non-competitive. To find  $K_I$ , we need to determine the slope at each value of  $[\text{In}]$ , which is equal to  $\alpha K_M/v_{\max}$  or  $K_M/v_{\max} + K_M[\text{In}]/K_I v_{\max}$ , then plot this slope against  $[\text{In}]$ ; the intercept at  $[\text{In}] = 0$  is the value of  $K_M/v_{\max}$  and the slope is  $K_M/K_I v_{\max}$ .

**Answer** First we draw up a table of  $1/[S]_0$  and  $1/v$  for each value of  $[\text{I}]$ :

$1/([S]_0/(\text{mmol dm}^{-3}))$	$[\text{In}]/(\text{mmol dm}^{-3})$				
	0	0.20	0.40	0.60	0.80
20	30	38	48	56	62
10	18	22	26	30	34
5.0	12	14	16	18	20
2.5	9.01	10.0	11.0	11.9	13.0
1.7	7.94	8.62	9.26	9.90	10.6

 $1/v/(\mu\text{mol dm}^{-3} \text{ s}^{-1})$ 

The five plots (one for each  $[\text{In}]$ ) are given in Fig. 20H.7. We see that they pass through the same intercept on the vertical axis, so the inhibition is competitive.

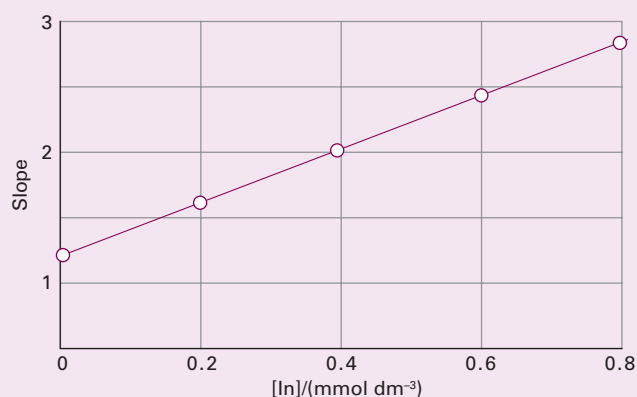

**Figure 20H.7** Lineweaver–Burk plots for the data in Example 20H.2. Each line corresponds to a different concentration of inhibitor.

The mean of the (least squares) intercepts is 5.83, so  $v_{\max} = 0.172 \mu\text{mol dm}^{-3} \text{ s}^{-1}$  (note how it picks up the units for  $v$  in the data). The (least squares) slopes of the lines are as follows:

$[\text{In}]/(\text{mmol dm}^{-3})$	0	0.20	0.40	0.60	0.80
Slope	1.219	1.627	2.090	2.489	2.832

These values are plotted in Fig. 20H.8. The intercept at  $[\text{In}] = 0$  is 1.234, so  $K_M = 0.212 \text{ mmol dm}^{-3}$ . The (least squares) slope of the line is 2.045, so

$$K_I/(\text{mmol dm}^{-3}) = \frac{K_M}{\text{slope} \times v_{\max}} = \frac{0.212}{2.045 \times 0.172}$$

**Figure 20H.8** Plot of the slopes of the plots in Fig. 20H.7 against  $[\text{In}]$  based on the data in Example 20H.2.

**Self-test 20H.3** Repeat the question using the following data:

[S] <sub>0</sub> /(mmol dm <sup>-3</sup> )	[In]/(mmol dm <sup>-3</sup> )					v/(μmol dm <sup>-3</sup> s <sup>-1</sup> )
	0	0.20	0.40	0.60	0.80	
0.050	0.020	0.015	0.012	0.0098	0.0084	
0.10	0.035	0.026	0.021	0.017	0.015	
0.20	0.056	0.042	0.033	0.028	0.024	
0.40	0.080	0.059	0.047	0.039	0.034	
0.60	0.093	0.069	0.055	0.046	0.039	

Answer: Non-competitive,  $K_M = 0.30 \text{ mmol dm}^{-3}$ ,  
 $K_I = 0.57 \text{ mmol dm}^{-3}$

## Checklist of concepts

- 1. Enzymes are homogeneous biological catalysts.
- 2. The Michaelis–Menten mechanism of enzyme kinetics accounts for the dependence of rate on the concentration of the substrate and the enzyme.
- 3. A Lineweaver–Burk plot is used to determine the parameters that occur in the Michaelis–Menten mechanism.
- 4. In **competitive inhibition** of an enzyme, the inhibitor binds only to the active site of the enzyme.
- 5. In **uncompetitive inhibition** the inhibitor binds to a site of the enzyme that is removed from the active site, but only if the substrate is already present.
- 6. In **non-competitive inhibition**, the inhibitor binds to a site other than the active site.

## Checklist of equations

Property	Equation	Comment	Equation number

# CHAPTER 20 Chemical kinetics

## TOPIC 20A The rates of chemical reactions

### Discussion question

**20A.1** Summarize the characteristic of zeroth-order, first-order, second-order, and pseudofirst-order reactions.

**20A.2** When can a reaction order not be ascribed?

**20A.3** What are the advantages of ascribing an order to a reaction?

**20A.4** Summarize the experimental procedures that can be used to monitor the composition of a reaction system.

### Exercises

**20A.1(a)** Predict how the total pressure varies during the gas-phase reaction  $2 \text{ICl}(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{I}_2(\text{g}) + 2 \text{HCl}(\text{g})$  in a constant-volume container.

**20A.1(b)** Predict how the total pressure varies during the gas-phase reaction  $\text{N}_2(\text{g}) + 3 \text{H}_2(\text{g}) \rightarrow 2 \text{NH}_3(\text{g})$  in a constant-volume container.

**20A.2(a)** The rate of the reaction  $\text{A} + 2 \text{B} \rightarrow 3 \text{C} + \text{D}$  was reported as  $2.7 \text{ mol dm}^{-3} \text{ s}^{-1}$ . State the rates of formation and consumption of the participants.

**20A.2(b)** The rate of the reaction  $\text{A} + 3 \text{B} \rightarrow \text{C} + 2 \text{D}$  was reported as  $2.7 \text{ mol dm}^{-3} \text{ s}^{-1}$ . State the rates of formation and consumption of the participants.

**20A.3(a)** The rate of formation of C in the reaction  $2 \text{A} + \text{B} \rightarrow 2 \text{C} + 3 \text{D}$  is  $2.7 \text{ mol dm}^{-3} \text{ s}^{-1}$ . State the reaction rate, and the rates of formation or consumption of A, B, and D.

**20A.3(b)** The rate of consumption of B in the reaction  $\text{A} + 3 \text{B} \rightarrow \text{C} + 2 \text{D}$  is  $2.7 \text{ mol dm}^{-3} \text{ s}^{-1}$ . State the reaction rate, and the rates of formation or consumption of A, C, and D.

**20A.4(a)** The rate law for the reaction in Exercise 20A.2(a) was found to be  $\nu = k_r[\text{A}][\text{B}]$ . What are the units of  $k_r$  when the concentrations are in moles per

cubic decimetre? Express the rate law in terms of the rates of formation and consumption of (i) A, (ii) C.

**20A.4(b)** The rate law for the reaction in Exercise 20A.2(b) was found to be  $\nu = k_r[\text{A}][\text{B}]^2$ . What are the units of  $k_r$  when the concentrations are in moles per cubic decimetre? Express the rate law in terms of the rates of formation and consumption of (i) A, (ii) C.

**20A.5(a)** The rate law for the reaction in Exercise 20A.3(a) was reported as  $d[\text{C}]/dt = k_r[\text{A}][\text{B}][\text{C}]$ . Express the rate law in terms of the reaction rate  $\nu$ ; what are the units for  $k_r$  in each case when the concentrations are in moles per cubic decimetre?

**20A.5(b)** The rate law for the reaction in Exercise 20A.3(b) was reported as  $d[\text{C}]/dt = k_r[\text{A}][\text{B}][\text{C}]^{-1}$ . Express the rate law in terms of the reaction rate  $\nu$ ; what are the units for  $k_r$  in each case when the concentrations are in moles per cubic decimetre?

**20A.6(a)** If the rate laws are expressed with (i) concentrations in moles per cubic decimetre, (ii) pressures in kilopascals, what are the units of the second-order and third-order rate constants?

**20A.6(b)** If the rate laws are expressed with (i) concentrations in molecules per cubic metre, (ii) pressures in pascals, what are the units of the second-order and third-order rate constants?

### Problems

**20A.1** At 400 K, the rate of decomposition of a gaseous compound initially at a pressure of 12.6 kPa, was  $9.71 \text{ Pa s}^{-1}$  when 10.0 per cent had reacted and  $7.67 \text{ Pa s}^{-1}$  when 20.0 per cent had reacted. Determine the order of the reaction.

**20A.2** The following initial-rate data were obtained on the rate of binding of glucose with the enzyme hexokinase present at a concentration of  $1.34 \text{ mmol dm}^{-3}$ . What is (a) the order of reaction with respect to glucose, (b) the rate constant?

$[\text{C}_6\text{H}_{12}\text{O}_6]/(\text{mmol dm}^{-3})$	1.00	1.54	3.12	4.02
$\nu_0/(\text{mol dm}^{-3} \text{ s}^{-1})$	5.0	7.6	15.5	20.0

**20A.3** The following data were obtained on the initial rates of a reaction of a d-metal complex with a reactant Y in aqueous solution. What is (a) the order of reaction with respect to the complex and Y, (b) the rate constant? For the experiments (i),  $[\text{Y}] = 2.7 \text{ mmol dm}^{-3}$  and for experiments (ii)  $[\text{Y}] = 6.1 \text{ mmol dm}^{-3}$ .

[complex]/(mmol dm <sup>-3</sup> )		8.01	9.22	12.11
$\nu_0/(\text{mol dm}^{-3} \text{ s}^{-1})$	(i)	125	144	190
	(ii)	640	730	960

**20A.4** The following kinetic data ( $\nu_0$  is the initial rate) were obtained for the reaction  $2 \text{ICl}(\text{g}) + \text{H}_2(\text{g}) \rightarrow \text{I}_2(\text{g}) + 2 \text{HCl}(\text{g})$ :

Experiment	$[\text{ICl}]_0/(\text{mmol dm}^{-3})$	$[\text{H}_2]_0/(\text{mmol dm}^{-3})$	$\nu_0/(\text{mol dm}^{-3} \text{ s}^{-1})$
1	1.5	1.5	$3.7 \times 10^{-7}$
2	3.0	1.5	$7.4 \times 10^{-7}$
3	3.0	4.5	$22 \times 10^{-7}$
4	4.7	2.7	?

(a) Write the rate law for the reaction. (b) From the data, determine the value of the rate constant. (c) Use the data to predict the reaction rate for experiment 4.

## TOPIC 20B Integrated rate laws

### Discussion questions

**20B.1** Describe the main features, including advantages and disadvantages, of the following experimental methods for determining the rate law of a reaction: the isolation method, the method of initial rates, and fitting data to integrated rate law expressions.

**20B.2** Write the rate law that corresponds to each of the following expressions: (a)  $[A] = [A]_0 - k_r t$ , (b)  $\ln([A]/[A]_0) = -k_r t$ , and (c)  $[A] = [A]_0 / (1 + k_r t [A]_0)$ .

### Exercises

**20B.1(a)** At 518 °C, the half-life for the decomposition of a sample of gaseous acetaldehyde (ethanal) initially at 363 Torr was 410 s. When the pressure was 169 Torr, the half-life was 880 s. Determine the order of the reaction.

**20B.1(b)** At 400 K, the half-life for the decomposition of a sample of a gaseous compound initially at 55.5 kPa was 340 s. When the pressure was 28.9 kPa, the half-life was 178 s. Determine the order of the reaction.

**20B.2(a)** The rate constant for the first-order decomposition of  $N_2O_5$  in the reaction  $2 N_2O_5(g) \rightarrow 4 NO_2(g) + O_2(g)$  is  $k_r = 3.38 \times 10^{-5} s^{-1}$  at 25 °C. What is the half-life of  $N_2O_5$ ? What will be the pressure, initially 500 Torr, after (i) 50 s, (ii) 20 min after initiation of the reaction?

**20B.2(b)** The rate constant for the first-order decomposition of a compound A in the reaction  $2 A \rightarrow P$  is  $k_r = 3.56 \times 10^{-7} s^{-1}$  at 25 °C. What is the half-life of A? What will be the pressure, initially 33.0 kPa after (i) 50 s, (ii) 20 min after initiation of the reaction?

**20B.3(a)** The second-order rate constant for the reaction  $CH_3COOC_2H_5(aq) + OH^-(aq) \rightarrow CH_3CO_2^-(aq) + CH_3CH_2OH(aq)$  is  $0.11 dm^3 mol^{-1} s^{-1}$ . What is the concentration of ester ( $CH_3COOC_2H_5$ ) after (i) 20 s, (ii) 15 min when ethyl acetate is added to sodium hydroxide so that the initial concentrations are  $[NaOH] = 0.060 mol dm^{-3}$  and  $[CH_3COOC_2H_5] = 0.110 mol dm^{-3}$ ?

**20B.3(b)** The second-order rate constant for the reaction  $A + 2 B \rightarrow C + D$  is  $0.34 dm^3 mol^{-1} s^{-1}$ . What is the concentration of C after (i) 20 s, (ii) 15 min when the reactants are mixed with initial concentrations of  $[A] = 0.027 mol dm^{-3}$  and  $[B] = 0.130 mol dm^{-3}$ ?

**20B.4(a)** A reaction  $2 A \rightarrow P$  has a second-order rate law with  $k_r = 4.30 \times 10^{-4} dm^3 mol^{-1} s^{-1}$ . Calculate the time required for the concentration of A to change from  $0.210 mol dm^{-3}$  to  $0.010 mol dm^{-3}$ .

**20B.4(b)** A reaction  $2 A \rightarrow P$  has a third-order rate law with  $k_r = 6.50 \times 10^{-4} dm^6 mol^{-2} s^{-1}$ . Calculate the time required for the concentration of A to change from  $0.067 mol dm^{-3}$  to  $0.015 mol dm^{-3}$ .

### Problems

**20B.1** For a first-order reaction of the form  $A \rightarrow n B$  (with  $n$  possibly fractional), the concentration of the product varies with time as  $[B] = n[B]_0(1 - e^{-k_r t})$ . Plot the time dependence of  $[A]$  and  $[B]$  for the cases  $n = \frac{1}{2}$ , 1, and 2.

**20B.2** For a second-order reaction of the form  $A \rightarrow n B$  (with  $n$  possibly fractional), the concentration of the product varies with time as  $[B] = nk_r t [A]_0^2 / (1 + k_r t [A]_0)$ . Plot the time dependence of  $[A]$  and  $[B]$  for the cases  $n = \frac{1}{2}$ , 1, and 2.

**20B.3** The data below apply to the formation of urea from ammonium cyanate,  $NH_4CNO \rightarrow NH_2CONH_2$ . Initially 22.9 g of ammonium cyanate was dissolved in enough water to prepare 1.00 dm<sup>3</sup> of solution. Determine the order of the reaction, the rate constant, and the mass of ammonium cyanate left after 300 min.

$t/\text{min}$	0	20.0	50.0	65.0	150
$m(\text{urea})/\text{g}$	0	7.0	12.1	13.8	17.7

**20B.4** The data below apply to the reaction,  $(CH_3)_3CBr + H_2O \rightarrow (CH_3)_3COH + HBr$ . Determine the order of the reaction, the rate constant, and the molar concentration of  $(CH_3)_3CBr$  after 43.8 h.

$t/\text{h}$	0	3.15	6.20	10.00	18.30	30.80
$[(CH_3)_3CBr]/(10^{-2} mol dm^{-3})$	10.39	8.96	7.76	6.39	5.53	2.07

**20B.5** The thermal decomposition of an organic nitrile produced the following data:

$t/(10^3 s)$	0	2.00	4.00	6.00	8.00	10.00	12.00	$\infty$
$[\text{nitrile}]/(mol dm^{-3})$	1.50	1.26	1.07	0.92	0.81	0.72	0.65	0.40

Determine the order of the reaction and the rate constant.

**20B.6** A second-order reaction of the type  $A + 2 B \rightarrow P$  was carried out in a solution that was initially  $0.050 mol dm^{-3}$  in A and  $0.030 mol dm^{-3}$  in B. After 1.0 h the concentration of A had fallen to  $0.010 mol dm^{-3}$ . (a) Calculate the rate constant. (b) What is the half-life of the reactants?

**20B.7\*** The oxidation of  $HSO_3^-$  by  $O_2$  in aqueous solution is a reaction of importance to the processes of acid rain formation and flue gas desulfurization. R.E. Connick et al. (*Inorg. Chem.* 34, 4543 (1995)) report that the reaction  $2 HSO_3^-(aq) + O_2(g) \rightarrow 2 SO_4^{2-}(aq) + 2 H^+(aq)$  follows the rate law  $v = k_r [HSO_3^-]^2 [H^+]^2$ . Given  $pH = 5.6$  and an oxygen molar concentration of  $0.24 mmol dm^{-3}$  (both presumed constant), an initial  $HSO_3^-$  molar concentration of  $50 \mu mol dm^{-3}$ , and a rate constant of  $3.6 \times 10^6 dm^9 mol^{-3} s^{-1}$ , what is the initial rate of reaction? How long would it take for  $HSO_3^-$  to reach half its initial concentration?

**20B.8** Pharmacokinetics is the study of the rates of absorption and elimination of drugs by organisms. In most cases, elimination is slower than absorption and is a more important determinant of availability of a drug for binding to its target. A drug can be eliminated by many mechanisms, such as metabolism in the liver, intestine, or kidney followed by excretion of breakdown products through urine or faeces. As an example of pharmacokinetic analysis, consider the elimination of beta adrenergic blocking agents (beta blockers), drugs used in the treatment of hypertension. After intravenous administration of a beta blocker, the blood plasma of a patient was analysed for remaining drug and the data are shown below, where  $c$  is the drug concentration measured at a time  $t$  after the injection.

$t/\text{min}$	30	60	120	150	240	360	480
$c/(\text{ng cm}^{-3})$	699	622	413	292	152	60	24

(a) Is removal of the drug a first- or second-order process? (b) Calculate the rate constant and half-life of the process. *Comment:* An essential

\* These problems were supplied by Charles Trapp and Carmen Giunta.

aspect of drug development is the optimization of the half-life of elimination, which needs to be long enough to allow the drug to find and act on its target organ but not so long that harmful side effects become important.

**20B.9** The following data have been obtained for the decomposition of  $\text{N}_2\text{O}_5(\text{g})$  at  $67^\circ\text{C}$  according to the reaction  $2 \text{N}_2\text{O}_5(\text{g}) \rightarrow 4 \text{NO}_2(\text{g}) + \text{O}_2(\text{g})$ . Determine the order of the reaction, the rate constant, and the half-life. It is not necessary to obtain the result graphically; you may do a calculation using estimates of the rates of change of concentration.

$t/\text{min}$	0	1	2	3	4	5
$[\text{N}_2\text{O}_5]/(\text{mol dm}^{-3})$	1.000	0.705	0.497	0.349	0.246	0.173

**20B.10** The gas phase decomposition of acetic acid at 1189 K proceeds by way of two parallel reactions:

What is the maximum percentage yield of the ketene  $\text{CH}_2\text{CO}$  obtainable at this temperature?

**20B.11** Sucrose is readily hydrolysed to glucose and fructose in acidic solution. The hydrolysis is often monitored by measuring the angle of rotation of plane-polarized light passing through the solution. From the angle of rotation the concentration of sucrose can be determined. An experiment on the hydrolysis of sucrose in 0.50 M  $\text{HCl}(\text{aq})$  produced the following data:

$t/\text{min}$	0	14	39	60	80	110	140	170	210
$[\text{sucrose}]/(\text{mol dm}^{-3})$	0.316	0.300	0.274	0.256	0.238	0.211	0.190	0.170	0.146

Determine the rate constant of the reaction and the half-life of a sucrose molecule.

**20B.12** The composition of a liquid phase reaction  $2 \text{A} \rightarrow \text{B}$  was followed by a spectrophotometric method with the following results:

$t/\text{min}$	0	10	20	30	40	$\infty$
$[\text{B}]/(\text{mol dm}^{-3})$	0	0.089	0.153	0.200	0.230	0.312

Determine the order of the reaction and its rate constant.

**20B.13** The ClO radical decays rapidly by way of the reaction,  $2 \text{ClO} \rightarrow \text{Cl}_2 + \text{O}_2$ . The following data have been obtained:

$t/\text{ms}$	0.12	0.62	0.96	1.60	3.20	4.00	5.75
$[\text{ClO}]/(\mu\text{mol dm}^{-3})$	8.49	8.09	7.10	5.79	5.20	4.77	3.95

Determine the rate constant of the reaction and the half-life of a ClO radical.

**20B.14** Cyclopropane isomerizes into propene when heated to  $500^\circ\text{C}$  in the gas phase. The extent of conversion for various initial pressures has been followed by gas chromatography by allowing the reaction to proceed for a time with various initial pressures:

$p_0/\text{Torr}$	200	200	400	400	600	600
$t/\text{s}$	100	200	100	200	100	200
$p/\text{Torr}$	186	173	373	347	559	520

where  $p_0$  is the initial pressure and  $p$  is the final pressure of cyclopropane. What is the order and rate constant for the reaction under these conditions?

**20B.15** The addition of hydrogen halides to alkenes has played a fundamental role in the investigation of organic reaction mechanisms. In one study (M.J. Haugh and D.R. Dalton, *J. Amer. Chem. Soc.* **97**, 5674 (1975)), high pressures of hydrogen chloride (up to 25 atm) and propene (up to 5 atm) were examined over a range of temperatures and the amount of 2-chloropropane formed was determined by NMR. Show that if the reaction  $\text{A} + \text{B} \rightarrow \text{P}$  proceeds for a short time  $\delta t$ , the concentration of product follows  $[\text{P}]/[\text{A}] = k_r[\text{A}]^{m-1}[\text{B}]^n \delta t$  if the reaction is  $m$ th-order in A and  $n$ th-order in B. In a series of runs the ratio of [chloropropane] to [propene] was independent of [propene] but the ratio of [chloropropane] to [HCl] for constant amounts of propene depended on [HCl]. For  $\delta t \approx 100 \text{ h}$  (which is short on the time scale of the reaction) the latter ratio rose from zero to 0.05, 0.03, 0.01 for  $p(\text{HCl}) = 10 \text{ atm}$ , 7.5 atm, 5.0 atm. What are the orders of the reaction with respect to each reactant?

**20B.16** Show that  $t_{1/2}$  is given by eqn 20B.6 for a reaction that is  $n$ th order in A. Then deduce an expression for the time it takes for the concentration of a substance to fall to one-third the initial value in an  $n$ th-order reaction.

**20B.17** Derive an integrated expression for a second-order rate law  $v = k_r[\text{A}]$  [B] for a reaction of stoichiometry  $2 \text{A} + 3 \text{B} \rightarrow \text{P}$ .

**20B.18** Derive the integrated form of a third-order rate law  $v = k_r[\text{A}]^2[\text{B}]$  in which the stoichiometry is  $2 \text{A} + \text{B} \rightarrow \text{P}$  and the reactants are initially present in (a) their stoichiometric proportions, (b) with B present initially in twice the amount.

**20B.19** Show that the ratio  $t_{1/2}/t_{3/4}$ , where  $t_{1/2}$  is the half-life and  $t_{3/4}$  is the time for the concentration of A to decrease to  $3/4$  of its initial value (implying that  $t_{3/4} < t_{1/2}$ ), can be written as a function of  $n$  alone, and can therefore be used as a rapid assessment of the order of a reaction.

## TOPIC 20C Reactions approaching equilibrium

### Discussion questions

**20C.1** Describe the strategy of a temperature-jump experiment. What parameters of a reaction are accessible from this technique?

**20C.2** What feature of a reaction would ensure that its rate would respond to a pressure jump?

### Exercises

**20C.1(a)** The equilibrium  $\text{NH}_3(\text{aq}) + \text{H}_2\text{O}(\text{l}) \rightleftharpoons \text{NH}_4^+(\text{aq}) + \text{OH}^-(\text{aq})$  at  $25^\circ\text{C}$  is subjected to a temperature jump which slightly increased the concentration of  $\text{NH}_4^+(\text{aq})$  and  $\text{OH}^-(\text{aq})$ . The measured relaxation time is 7.61 ns. The equilibrium constant for the system is  $1.78 \times 10^{-5}$  at  $25^\circ\text{C}$ , and the

equilibrium concentration of  $\text{NH}_3(\text{aq})$  is  $0.15 \text{ mol dm}^{-3}$ . Calculate the rate constants for the forward and reverse steps.

**20C.1(b)** The equilibrium  $\text{A} \rightleftharpoons \text{B} + \text{C}$  at  $25^\circ\text{C}$  is subjected to a temperature jump which slightly increases the concentrations of B and C. The measured

relaxation time is  $3.0\ \mu\text{s}$ . The equilibrium constant for the system is  $2.0 \times 10^{-16}$  at  $25\ ^\circ\text{C}$ , and the equilibrium concentrations of B and C at  $25\ ^\circ\text{C}$  are both

$0.20\ \text{mmol dm}^{-3}$ . Calculate the rate constants for the forward and reverse steps.

## Problems

**20C.1** Show by differentiation that eqn 20C.4 is a solution of eqn 20C.3.

**20C.2** Set up the rate equations and plot the corresponding graphs for the approach to an equilibrium of the form  $A \rightleftharpoons 2 B$ .

**20C.3** The reaction  $A \rightleftharpoons 2 B$  is first-order in both directions. Derive an expression for the concentration of A as a function of time when the initial molar concentrations of A and B are  $[A]_0$  and  $[B]_0$ . What is the final composition of the system?

**20C.4** Show that eqn 20C.8 is an expression for the overall equilibrium constant in terms of the rate constants for the intermediate steps of a reaction mechanism. To facilitate the task, begin with a mechanism containing three steps, and then argue that your expression may be generalized for any number of steps.

**20C.5** Consider the dimerization  $2 A \rightleftharpoons A_2$ , with forward rate constant  $k_a$  and backward rate constant  $k'_a$ . (a) Derive the following expression for the relaxation time in terms of the total concentration of protein,  $[A]_{\text{tot}} = [A] + 2[A_2]$ :

$$\frac{1}{\tau^2} = k'_a{}^2 + 8k_a k'_a [A]_{\text{tot}}$$

(b) Describe the computational procedures that lead to the determination of the rate constants  $k_a$  and  $k'_a$  from measurements of  $\tau$  for different values of  $[A]_{\text{tot}}$ . (c) Use the data provided below and the procedure you outlined in part (b) to calculate the rate constants  $k_a$  and  $k'_a$  and the equilibrium constant  $K$  for formation of hydrogen-bonded dimers of 2-pyridone:

$[P]/(\text{mol dm}^{-3})$	0.500	0.352	0.251	0.151	0.101
$\tau/\text{ns}$	2.3	2.7	3.3	4.0	5.3

**20C.6** Consider the dimerization  $2 A \rightleftharpoons A_2$  with forward rate constant  $k_f$  and backward rate constant  $k'_f$ . Show that the relaxation time is  $\tau = 1/(k'_f + 4k_f[A]_{\text{eq}})$ .

## TOPIC 20D The Arrhenius equation

### Discussion question

**20D.1** Define the terms in and discuss the validity of the expression  $\ln k_f = \ln A - E_a/RT$ .

**20D.2** What might account for the failure of the Arrhenius equation at low temperatures?

### Exercises

**20D.1(a)** The rate constant for the decomposition of a certain substance is  $3.80 \times 10^{-3}\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $35\ ^\circ\text{C}$  and  $2.67 \times 10^{-2}\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $50\ ^\circ\text{C}$ . Evaluate the Arrhenius parameters of the reaction.

**20D.1(b)** The rate constant for the decomposition of a certain substance is  $2.25 \times 10^{-2}\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $29\ ^\circ\text{C}$  and  $4.01 \times 10^{-2}\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $37\ ^\circ\text{C}$ . Evaluate the Arrhenius parameters of the reaction.

**20D.2(a)** The rate of a chemical reaction is found to triple when the temperature is raised from  $24\ ^\circ\text{C}$  to  $49\ ^\circ\text{C}$ . Determine the activation energy.

**20D.2(b)** The rate of a chemical reaction is found to double when the temperature is raised from  $25\ ^\circ\text{C}$  to  $35\ ^\circ\text{C}$ . Determine the activation energy.

## Problems

**20D.1** Show that the definition of  $E_a$  given in eqn 20D.3 reduces to eqn 20D.1 for a temperature-independent activation energy.

**20D.2** A first-order decomposition reaction is observed to have the following rate constants at the indicated temperatures. Estimate the activation energy.

$k_f/(10^{-3}\ \text{s}^{-1})$	2.46	45.1	576
$\theta/^\circ\text{C}$	0	20.0	40.0

**20D.3** The second-order rate constants for the reaction of oxygen atoms with aromatic hydrocarbons have been measured (R. Atkinson and J.N. Pitts, *J. Phys. Chem.* **79**, 295 (1975)). In the reaction with benzene the rate constants are  $1.44 \times 10^7\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $300.3\ \text{K}$ ,  $3.03 \times 10^7\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $341.2\ \text{K}$ , and  $6.9 \times 10^7\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$  at  $392.2\ \text{K}$ . Find the pre-exponential factor and activation energy of the reaction.

**20D.4\*** Methane is a by-product of a number of natural processes (such as digestion of cellulose in ruminant animals, anaerobic decomposition of

organic waste matter), and industrial processes (such as food production and fossil fuel use). Reaction with the hydroxyl radical OH is the main path by which  $\text{CH}_4$  is removed from the lower atmosphere. T. Gierczak et al. (*J. Phys. Chem. A* **101**, 3125 (1997)) measured the rate constants for the elementary bimolecular gas-phase reaction of methane with the hydroxyl radical over a range of temperatures of importance to atmospheric chemistry. Deduce the Arrhenius parameters  $A$  and  $E_a$  from the following measurements:

$T/\text{K}$	295	223	218	213	206	200	195
$k_f/(10^6\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1})$	3.55	0.494	0.452	0.379	0.295	0.241	0.217

**20D.5\*** As we saw in Problem 20D.4, reaction with the hydroxyl radical OH is the main path by which  $\text{CH}_4$ , a by-product of many natural and industrial processes, is removed from the lower atmosphere. T. Gierczak et al. (*J. Phys. Chem. A* **101**, 3125 (1997)) measured the rate constants for the bimolecular gas-phase reaction  $\text{CH}_4(\text{g}) + \text{OH}(\text{g}) \rightarrow \text{CH}_3(\text{g}) + \text{H}_2\text{O}(\text{g})$  and

found  $A = 1.13 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and  $E_a = 14.1 \text{ kJ mol}^{-1}$  for the Arrhenius parameters. (a) Estimate the rate of consumption of  $\text{CH}_4$ . Take the average OH concentration to be  $1.5 \times 10^{-21} \text{ mol dm}^{-3}$ , that of  $\text{CH}_4$  to be  $40 \text{ nmol dm}^{-3}$ , and the temperature to be  $-10^\circ\text{C}$ . (b) Estimate the global annual mass of  $\text{CH}_4$

consumed by this reaction (which is slightly less than the amount introduced to the atmosphere) given an effective volume for the Earth's lower atmosphere of  $4 \times 10^{21} \text{ dm}^3$ .

## TOPIC 20E Reaction mechanisms

### Discussion questions

- 20E.1** Distinguish between reaction order and molecularity.  
**20E.2** Assess the validity of the statement that the rate-determining step is the slowest step in a reaction mechanism.  
**20E.3** Distinguish between a pre-equilibrium approximation and a steady-state approximation. Why might they lead to different conclusions?

**20E.4** Explain and illustrate how reaction orders may change under different circumstances.

**20E.5** Distinguish between kinetic and thermodynamic control of a reaction. Suggest criteria for expecting one rather than the other.

**20E.6** Explain how it is possible for the activation energy of a reaction to be negative.

### Exercises

**20E.1(a)** The reaction mechanism for the decomposition of  $\text{A}_2$

involves an intermediate A. Deduce the rate law for the reaction in two ways by (i) assuming a pre-equilibrium and (ii) making a steady-state approximation.

**20E.1(b)** The reaction mechanism for renaturation of a double helix from its strands A and B:

involves an intermediate. Deduce the rate law for the reaction in two ways by (i) assuming a pre-equilibrium and (ii) making a steady-state approximation.

**20E.2(a)** The mechanism of a composite reaction consists of a fast pre-equilibrium step with forward and reverse activation energies of  $25 \text{ kJ mol}^{-1}$  and  $38 \text{ kJ mol}^{-1}$ , respectively, followed by an elementary step of activation energy  $10 \text{ kJ mol}^{-1}$ . What is the activation energy of the composite reaction?

**20E.2(b)** The mechanism of a composite reaction consists of a fast pre-equilibrium step with forward and reverse activation energies of  $27 \text{ kJ mol}^{-1}$  and  $35 \text{ kJ mol}^{-1}$ , respectively, followed by an elementary step of activation energy  $15 \text{ kJ mol}^{-1}$ . What is the activation energy of the composite reaction?

### Problems

**20E.1** Use mathematical software or a spreadsheet to examine the time dependence of  $[\text{I}]$  in the reaction mechanism  $\text{A} \xrightarrow{k_a} \text{I} \xrightarrow{k_b} \text{P}$ . In all of the following calculations, use  $[\text{A}]_0 = 1 \text{ mol dm}^{-3}$  and a time range of 0 to 5 s. (a) Plot  $[\text{In}]$  against  $t$  for  $k_a = 10 \text{ s}^{-1}$  and  $k_b = 1 \text{ s}^{-1}$ . (b) Increase the ratio  $k_b/k_a$  steadily by decreasing the value of  $k_a$  and examine the plot of  $[\text{I}]$  against  $t$  at each turn. What approximation about  $d[\text{I}]/dt$  becomes increasingly valid?

**20E.2** Use mathematical software or a spreadsheet to investigate the effects on  $[\text{A}]$ ,  $[\text{I}]$ ,  $[\text{P}]$ , and  $t_{\text{max}}$  of decreasing the ratio  $k_a/k_b$  from 10 (as in Fig. 20E.1) to 0.01. Compare your results with those shown in Fig. 20E.3.

**20E.3** Set up the rate equations for the reaction mechanism:

Show that, under specific circumstances, the mechanism is equivalent to

**20E.4** Derive an equation for the steady state rate of the sequence of reactions  $\text{A} \rightleftharpoons \text{B} \rightleftharpoons \text{C} \rightleftharpoons \text{D}$ , with  $[\text{A}]$  maintained at a fixed value and the product D removed as soon as it is formed.

**20E.5** Show that the following mechanism can account for the rate law of the reaction in Problem 20B.15:

What further tests could you apply to verify this mechanism?

**20E.6** Polypeptides are polymers of amino acids. Suppose that a long polypeptide chain can undergo a transition from a helical conformation to a random coil. Consider a mechanism for a helix-coil transition that begins in the middle of the chain:

in which  $h$  and  $c$  label, respectively, an amino acid in a helical or coil part of the chain. The first conversion from  $h$  to  $c$ , also called a nucleation step, is relatively slow, so neither step may be rate determining. (a) Set up the rate equations for this mechanism. (b) Apply the steady-state approximation and show that, under these circumstances, the mechanism is equivalent to  $hhhh\dots \rightleftharpoons cccc\dots$

## TOPIC 20F Examples of reaction mechanisms

### Discussion questions

**20F.1** Discuss the range of validity of the expression  $k_r = k_a k_b [A] / (k_b + k_a' [A])$  for the effective rate constant of a unimolecular reaction according to the Lindemann–Hinshelwood mechanism.

**20F.2** Bearing in mind distinctions between the mechanisms of stepwise and chain polymerization, describe ways in which it is possible to control the molar mass of a polymer by manipulating the kinetic parameters of polymerization.

### Exercises

**20F.1(a)** The effective rate constant for a gaseous reaction which has a Lindemann–Hinshelwood mechanism is  $2.50 \times 10^{-4} \text{ s}^{-1}$  at 1.30 kPa and  $2.10 \times 10^{-5} \text{ s}^{-1}$  at 12 Pa. Calculate the rate constant for the activation step in the mechanism.

**20F.1(b)** The effective rate constant for a gaseous reaction which has a Lindemann–Hinshelwood mechanism is  $1.7 \times 10^{-3} \text{ s}^{-1}$  at 1.09 kPa and  $2.2 \times 10^{-4} \text{ s}^{-1}$  at 25 Pa. Calculate the rate constant for the activation step in the mechanism.

**20F.2(a)** Calculate the fraction condensed and the degree of polymerization at  $t = 5.00 \text{ h}$  of a polymer formed by a stepwise process with  $k_r = 1.39 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and an initial monomer concentration of  $10.0 \text{ mmol dm}^{-3}$ .

**20F.2(b)** Calculate the fraction condensed and the degree of polymerization at  $t = 10.00 \text{ h}$  of a polymer formed by a stepwise process with  $k_r = 2.80 \times 10^{-2} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and an initial monomer concentration of  $50.0 \text{ mmol dm}^{-3}$ .

**20F.3(a)** Consider a polymer formed by a chain process. By how much does the kinetic chain length change if the concentration of initiator increases by a factor of 3.6 and the concentration of monomer decreases by a factor of 4.2?

**20F.3(b)** Consider a polymer formed by a chain process. By how much does the kinetic chain length change if the concentration of initiator decreases by a factor of 10.0 and the concentration of monomer increases by a factor of 5.0?

### Problems

**20F.1** The isomerization of cyclopropane over a limited pressure range was examined in Problem 20B.14. If the Lindemann mechanism of unimolecular reactions is to be tested we also need data at low pressures. These have been obtained (H.O. Pritchard et al., *Proc. R. Soc. A* 217, 563 (1953)):

$p/\text{Torr}$	84.1	11.0	2.89	0.569	0.120	0.067
$10^4 k_r/\text{s}^{-1}$	2.98	2.23	1.54	0.857	0.392	0.303

Test the Lindemann–Hinshelwood theory with these data.

**20F.2** Calculate the average polymer length in a polymer produced by a chain mechanism in which termination occurs by a disproportionation reaction of the form  $M \cdot + M \cdot \rightarrow M + M$ .

**20F.3** Derive an expression for the time dependence of the degree of polymerization for a stepwise polymerization in which the reaction is acid-catalysed by the  $-\text{COOH}$  acid functional group. The rate law is  $d[A]/dt = -k_r[A]^2[\text{OH}]$ .

## TOPIC 20G Photochemistry

### Discussion questions

**20G.1** Consult literature sources and list the observed ranges of timescales during which the following processes occur: radiative decay of excited electronic states, molecular rotational motion, molecular vibrational motion, proton transfer reactions, energy transfer between fluorescent

molecules used in FRET analysis, electron transfer events between complex ions in solution, and collisions in liquids.

**20G.2** Discuss experimental procedures that make it possible to differentiate between quenching by energy transfer, collisions, and electron transfer.

### Exercises

**20G.1(a)** In a photochemical reaction  $A \rightarrow 2B + C$ , the quantum yield with 500 nm light is  $210 \text{ mol einstein}^{-1}$  (1 einstein = 1 mol photons). After exposure of 300 mmol of A to the light, 2.28 mmol of B is formed. How many photons were absorbed by A?

**20G.1(b)** In a photochemical reaction  $A \rightarrow B + C$ , the quantum yield with 500 nm light is  $120 \text{ mol einstein}^{-1}$  (1 einstein = 1 mol photons). After exposure

of 200 mmol A to the light, 1.77 mmol B is formed. How many photons were absorbed by A?

**20G.2(a)** Consider the quenching of an organic fluorescent species with  $\tau_0 = 6.0 \text{ ns}$  by a d-metal ion with  $k_Q = 3.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Predict the concentration of quencher required to decrease the fluorescence intensity of the organic species to 50 per cent of the unquenched value.

**20G.2(b)** Consider the quenching of an organic fluorescent species with  $\tau_0 = 3.5$  ns by a d-metal ion with  $k_Q = 2.5 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Predict the

## Problems

**20G.1** In an experiment to measure the quantum yield of a photochemical reaction, the absorbing substance was exposed to 320 nm radiation from a 87.5 W source for 28.0 min. The intensity of the transmitted radiation was 0.257 that of the incident radiation. As a result of irradiation, 0.324 mol of the absorbing substance decomposed. Determine the quantum yield.

**20G.2†** Ultraviolet radiation photolyses  $\text{O}_3$  to  $\text{O}_2$  and O. Determine the rate at which ozone is consumed by 305 nm radiation in a layer of the stratosphere of thickness 1.0 km. The quantum yield is 0.94 at 220 K, the concentration about  $8 \text{ nmol dm}^{-3}$ , the molar absorption coefficient  $260 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$ , and the flux of 305 nm radiation about  $1 \times 10^{14} \text{ photons cm}^{-2} \text{ s}^{-1}$ . Data from W.B. DeMore et al., *Chemical kinetics and photochemical data for use in stratospheric modeling: Evaluation Number 11*, JPL Publication 94–26 (1994).

**20G.3** Dansyl chloride, which absorbs maximally at 330 nm and fluoresces maximally at 510 nm, can be used to label amino acids in fluorescence microscopy and FRET studies. Tabulated below is the variation of the fluorescence intensity of an aqueous solution of dansyl chloride with time after excitation by a short laser pulse (with  $I_0$  the initial fluorescence intensity). The ratio of intensities is equal to the ratio of the rates of photon emission.

$t/\text{ns}$	5.0	10.0	15.0	20.0
$I_t/I_0$	0.45	0.21	0.11	0.05

- (a) Calculate the observed fluorescence lifetime of dansyl chloride in water.  
 (b) The fluorescence quantum yield of dansyl chloride in water is 0.70. What is the fluorescence rate constant?

**20G.4** When benzophenone is exposed to ultraviolet radiation it is excited into a singlet state. This singlet changes rapidly into a triplet, which phosphoresces. Triethylamine acts as a quencher for the triplet. In an experiment in the solvent methanol, the phosphorescence intensity varied with amine concentration as shown below. A time-resolved laser spectroscopy experiment had also shown that the half-life of the fluorescence in the absence of quencher is 29  $\mu\text{s}$ . What is the value of  $k_Q$ ?

$[Q]/(\text{mmol dm}^{-3})$	1.0	5.0	10.0
$I_t/(\text{arbitrary units})$	0.41	0.25	0.16

**20G.5** An electronically excited state of Hg can be quenched by  $\text{N}_2$  according to  $\text{Hg}^*(\text{g}) + \text{N}_2(\text{g}, \nu=0) \rightarrow \text{Hg}(\text{g}) + \text{N}_2(\text{g}, \nu=1)$  in which energy transfer from  $\text{Hg}^*$  excites  $\text{N}_2$  vibrationally. Fluorescence lifetime measurements of samples of Hg with and without  $\text{N}_2$  present are summarized below (for  $T=300 \text{ K}$ ):

concentration of quencher required to decrease the fluorescence intensity of the organic species to 75 per cent of the unquenched value.

$p_{\text{N}_2} = 0.0 \text{ atm}$					
Relative fluorescence intensity	1.000	0.606	0.360	0.22	0.135
$t/\mu\text{s}$	0.0	5.0	10.0	15.0	20.0
$p_{\text{N}_2} = 9.74 \times 10^{-4} \text{ atm}$					
Relative fluorescence intensity	1.000	0.585	0.342	0.200	0.117
$t/\mu\text{s}$	0.0	3.0	6.0	9.0	12.0

You may assume that all gases are perfect. Determine the rate constant for the energy transfer process.

**20G.6** An amino acid on the surface of an enzyme was labelled covalently with 1.5-I AEDANS and it is known that the active site contains a tryptophan residue. The fluorescence quantum yield of tryptophan decreased by 15 per cent due to quenching by 1.5-I AEDANS. What is the distance between the active site and the surface of the enzyme?

**20G.7** The Förster theory of resonance energy transfer and the basis for the FRET technique can be tested by performing fluorescence measurements on a series of compounds in which an energy donor and an energy acceptor are covalently linked by a rigid molecular linker of variable and known length. L. Stryer and R.P. Haugland (*Proc. Natl. Acad. Sci. USA* 58, 719 (1967)) collected the following data on a family of compounds with the general composition dansyl-(1-prolyl) $_n$ -naphthyl, in which the distance  $R$  between the naphthyl donor and the dansyl acceptor was varied from 1.2 nm to 4.6 nm by increasing the number of prolyl units in the linker:

$R/\text{nm}$	1.2	1.5	1.8	2.8	3.1	3.4	3.7	4.0	4.3	4.6
$\eta_{\text{T}}$	0.99	0.94	0.97	0.82	0.74	0.65	0.40	0.28	0.24	0.16

Are the data described adequately by eqn 20G.10? If so, what is the value of  $R_0$  for the naphthyl–dansyl pair?

**20G.8** The first step in plant photosynthesis is absorption of light by chlorophyll molecules bound to proteins known as 'light-harvesting complexes', where the fluorescence of a chlorophyll molecule is quenched by nearby chlorophyll molecules. Given that for a pair of chlorophyll  $a$  molecules  $R_0 = 5.6 \text{ nm}$ , by what distance should two chlorophyll  $a$  molecules be separated to shorten the fluorescence lifetime from 1 ns (a typical value for monomeric chlorophyll  $a$  in organic solvents) to 10 ps?

## TOPIC 20H Enzymes

### Discussion questions

**20H.1** Discuss the features, advantages, and limitations of the Michaelis–Menten mechanism of enzyme action.

**20H.2** A plot of the rate of an enzyme-catalysed reaction against temperature has a maximum, in an apparent deviation from the behaviour predicted by the Arrhenius equation (Topic 20D). Suggest an interpretation.

**20H.3** Distinguish between competitive, non-competitive, and uncompetitive inhibition of enzymes. Discuss how these modes of inhibition may be detected experimentally.

**20H.4** Some enzymes are inhibited by high concentrations of their own products. Sketch a plot of reaction rate against concentration of substrate for an enzyme that is prone to product inhibition.

## Exercises

20H.1(a) Consider the base-catalysed reaction

Deduce the rate law.

20H.1(b) Consider the acid-catalysed reaction

Deduce the rate law.

20H.2(a) The enzyme-catalysed conversion of a substrate at 25 °C has a Michaelis constant of 0.046 mol dm<sup>-3</sup>. The rate of the reaction is

1.04 mmol dm<sup>-3</sup> s<sup>-1</sup> when the substrate concentration is 0.105 mol dm<sup>-3</sup>. What is the maximum velocity of this reaction?

20H.2(b) The enzyme-catalysed conversion of a substrate at 25 °C has a Michaelis constant of 0.032 mol dm<sup>-3</sup>. The rate of the reaction is 0.205 mmol dm<sup>-3</sup> s<sup>-1</sup> when the substrate concentration is 0.875 mol dm<sup>-3</sup>. What is the maximum velocity of this reaction?

20H.3(a) Consider an enzyme-catalysed reaction that follows Michaelis–Menten kinetics with  $K_M = 3.0$  mmol dm<sup>-3</sup>. What concentration of a competitive inhibitor characterized by  $K_I = 20$  μmol dm<sup>-3</sup> will reduce the rate of formation of product by 50 per cent when the substrate concentration is held at 0.10 mmol dm<sup>-3</sup>?

20H.3(b) Consider an enzyme-catalysed reaction that follows Michaelis–Menten kinetics with  $K_M = 0.75$  mmol dm<sup>-3</sup>. What concentration of a competitive inhibitor characterized by  $K_I = 0.56$  mmol dm<sup>-3</sup> will reduce the rate of formation of product by 75 per cent when the substrate concentration is held at 0.10 mmol dm<sup>-3</sup>?

## Problems

20H.1 Michaelis and Menten derived their rate law by assuming a rapid pre-equilibrium of E, S, and ES. Derive the rate law in this manner, and identify the conditions under which it becomes the same as that based on the steady-state approximation (eqn 20H.1).

20H.2 (a) Use the Michaelis–Menten equation (eqn 20H.1) to generate two families of curves showing the dependence of  $v$  on  $[S]$ : one in which  $K_M$  varies but  $v_{\max}$  is constant, and another in which  $v_{\max}$  varies but  $K_M$  is constant. (b) Use eqn 20H.7 to explore the effect of competitive, uncompetitive, and non-competitive inhibition on the shapes of the plots of  $v$  against  $[S]$  for constant  $K_M$  and  $v_{\max}$ . Use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book.

20H.3 For many enzymes, the mechanism of action involves the formation of two intermediates:

Show that the rate of formation of product has the same form as that shown in eqn 20H.1, but with  $v_{\max}$  and  $K_M$  given by

$$v_{\max} = \frac{k_b k_c [\text{E}]_0}{k_b + k_c} \quad \text{and} \quad K_M = \frac{k_c (k'_a + k_b)}{k_a (k_b + k_c)}$$

20H.4 The enzyme-catalysed conversion of a substrate at 25 °C has a Michaelis constant of 90 μmol dm<sup>-3</sup> and a maximum velocity of 22.4 μmol dm<sup>-3</sup> s<sup>-1</sup> when the enzyme concentration is 1.60 nmol dm<sup>-3</sup>. (a) Calculate  $k_{\text{cat}}$  and  $\eta$ . (b) Is the enzyme 'catalytically perfect'?

20H.5 The following results were obtained for the action of an ATPase on ATP at 20 °C, when the concentration of the ATPase was 20 nmol dm<sup>-3</sup>:

[ATP]/(μmol dm <sup>-3</sup> )	0.60	0.80	1.4	2.0	3.0
$v$ /(μmol dm <sup>-3</sup> s <sup>-1</sup> )	0.81	0.97	1.30	1.47	1.69

Determine the Michaelis constant, the maximum velocity of the reaction, the turnover number, and the catalytic efficiency of the enzyme.

20H.6 Some enzymes are inhibited by high concentrations of their own substrates. (a) Show that when substrate inhibition is important the reaction rate  $v$  is given by

$$v = \frac{v_{\max}}{1 + K_M/[S]_0 + [S]_0/K_I}$$

where  $K_I$  is the equilibrium constant for dissociation of the inhibited enzyme–substrate complex. (b) What effect does substrate inhibition have on a plot of  $1/v$  against  $1/[S]_0$ ?

## Integrated activities

20.1 Autocatalysis is the catalysis of a reaction by the products. For example, for a reaction  $\text{A} \rightarrow \text{P}$  it may be found that the rate law is  $v = k_r[\text{A}][\text{P}]$  and the reaction rate is proportional to the concentration of P. The reaction gets started because there are usually other reaction routes for the formation of some P initially, which then takes part in the autocatalytic reaction proper. (a) Integrate the rate equation for an autocatalytic reaction of the form  $\text{A} \rightarrow \text{P}$ , with rate law  $v = k_r[\text{A}][\text{P}]$ , and show that

$$\frac{[\text{P}]}{[\text{P}]_0} = \frac{(1+b)e^{at}}{1+be^{at}}$$

where  $a = ([\text{A}]_0 + [\text{P}]_0)k_r$  and  $b = [\text{P}]_0/[\text{A}]_0$ . *Hint:* Starting with the expression  $v = -d[\text{A}]/dt = k_r[\text{A}][\text{P}]$ , write  $[\text{A}] = [\text{A}]_0 - x$ ,  $[\text{P}] = [\text{P}]_0 + x$  and then write the expression for the rate of change of either species in terms of  $x$ . To integrate the resulting expression, use integration by the method of partial fractions

(The chemist's toolbox 20B.1). (b) Plot  $[P]/[P]_0$  against  $at$  for several values of  $b$ . Discuss the effect of autocatalysis on the shape of a plot of  $[P]/[P]_0$  against  $t$  by comparing your results with those for a first-order process, in which  $[P]/[P]_0 = 1 - e^{-k_1 t}$ . (c) Show that for the autocatalytic process discussed in parts (a) and (b), the reaction rate reaches a maximum at  $t_{\max} = -(1/a) \ln b$ . (d) An autocatalytic reaction  $A \rightarrow P$  is observed to have the rate law  $d[P]/dt = k_r[A]^2[P]$ . Solve the rate law for initial concentrations  $[A]_0$  and  $[P]_0$ . Calculate the time at which the rate reaches a maximum. (e) Another reaction with the stoichiometry  $A \rightarrow P$  has the rate law  $d[P]/dt = k_r[A][P]^2$ ; integrate the rate law for initial concentrations  $[A]_0$  and  $[P]_0$ . Calculate the time at which the rate reaches a maximum.

**20.2** Many biological and biochemical processes involve autocatalytic steps (Problem 20.1). In the SIR model of the spread and decline of infectious diseases the population is divided into three classes; the 'susceptibles',  $S$ , who can catch the disease, the 'infectives',  $I$ , who have the disease and can transmit it, and the 'removed class',  $R$ , who have either had the disease and recovered, are dead, are immune, or isolated. The model mechanism for this process implies the following rate laws:

$$\frac{dS}{dt} = -rSI \quad \frac{dI}{dt} = rSI - aI \quad \frac{dR}{dt} = aI$$

Which are the autocatalytic steps of this mechanism? Find the conditions on the ratio  $a/r$  that decide whether the disease will spread (an epidemic) or die out. Show that a constant population is built into this system, namely that  $S + I + R = N$ , meaning that the time scales of births, deaths by other causes, and migration are assumed large compared to that of the spread of the disease.

**20.3\*** J. Czarnowski and H.J. Schuhmacher (*Chem. Phys. Lett.* 17, 235 (1972)) suggested the following mechanism for the thermal decomposition of  $F_2O$  in the reaction  $2 F_2O(g) \rightarrow 2 F_2(g) + O_2(g)$ :

(a) Using the steady-state approximation, show that this mechanism is consistent with the experimental rate law  $-d[F_2O]/dt = k_r[F_2O]^2 + k'_r[F_2O]^{3/2}$ . (b) The experimentally determined Arrhenius parameters in the range 501–583 K are  $A = 7.8 \times 10^{13} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ,  $E_a/R = 1.935 \times 10^4 \text{ K}$  for  $k_r$ , and  $A = 2.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ,  $E_a/R = 1.691 \times 10^4 \text{ K}$  for  $k'_r$ . At 540 K,  $\Delta_r H^\ominus(F_2O) = +24.41 \text{ kJ mol}^{-1}$ ,  $D(F-F) = 160.6 \text{ kJ mol}^{-1}$ , and  $D(O-O) = 498.2 \text{ kJ mol}^{-1}$ . Estimate the bond dissociation energies of the first and second F–O bonds in  $F_2O$  and the Arrhenius activation energy of reaction 2.

**20.4** Express the root mean square deviation  $\{\langle M^2 \rangle - \langle M \rangle^2\}^{1/2}$  of the molar mass of a condensation polymer in terms of the fraction  $p$ , and deduce its time-dependence.

**20.5** Calculate the ratio of the mean cube molar mass to the mean square molar mass in terms of (a) the fraction  $p$ , (b) the chain length.

**20.6** Conventional equilibrium considerations do not apply when a reaction is being driven by light absorption. Thus the steady-state concentration of products and reactants might differ significantly from equilibrium values. For instance, suppose the reaction  $A \rightarrow B$  is driven by light absorption, and that its rate is  $I_a$ , but that the reverse reaction  $B \rightarrow A$  is bimolecular and second order with a rate  $k_r[B]^2$ . What is the stationary state concentration of  $B$ ? Why does this 'photostationary state' differ from the equilibrium state?

**20.7** The photochemical chlorination of chloroform in the gas phase has been found to follow the rate law  $d[CCL_3]/dt = k_r[Cl_2]^{1/2}I_a^{1/2}$ . Devise a mechanism that leads to this rate law when the chlorine pressure is high.

# CHAPTER 21

## Reaction dynamics

Now we are at the heart of chemistry. In this chapter we examine the details of what happens to molecules at the climax of reactions. Extensive changes of structure are taking place and energies the size of dissociation energies are being redistributed among bonds: old bonds are being ripped apart and new bonds are being formed.

As may be imagined, the calculation of the rates of such processes from first principles is very difficult. Nevertheless, like so many intricate problems, the broad features can be established quite simply. Only when we enquire more deeply do the complications emerge. Here we look at several approaches to the calculation of a rate constant for elementary bimolecular processes, ranging from electron transfer to chemical reactions involving bond breakage and formation. Although a great deal of information can be obtained from gas-phase reactions, many reactions of interest take place in condensed phases, and we also see to what extent their rates can be predicted.

### 21A Collision theory

This Topic explores ‘collision theory’, the simplest quantitative account of reaction rates. The treatment can be used only for the discussion of reactions between simple species in the gas phase.

### 21B Diffusion-controlled reactions

In this Topic we see that reactions in solution are classified into two types: ‘diffusion-controlled’ and ‘activation-controlled’. The former can be expressed quantitatively in terms of the diffusion equation.

### 21C Transition-state theory

This Topic discusses ‘transition-state theory’, in which it is assumed that the reactant molecules form a complex that can be discussed in terms of the population of its energy levels. The

theory inspires a thermodynamic approach to reaction rates, in which the rate constant is expressed in terms of thermodynamic parameters. This approach is useful for parameterizing the rates of reactions in solution.

### 21D The dynamics of molecular collisions

The highest level of sophistication in the theoretical study of chemical reactions is in terms of potential energy surfaces and the motion of molecules on these surfaces. As we see in this Topic, such an approach gives an intimate picture of the events that occur when reactions occur and is open to experimental study.

### 21E Electron transfer in homogeneous systems

In this Topic we use transition-state theory to examine the transfer of electrons in homogeneous systems, including those involving proteins.

### 21F Processes at electrodes

Electron transfer processes on the surface of electrodes are difficult to describe theoretically, but in this Topic we develop a useful phenomenological approach that lends insight into useful experimental techniques and technological applications of electrochemistry.

### What is the impact of this material?

The economic consequences of electron transfer reactions are almost incalculable. Most of the modern methods of generating

electricity are inefficient, and in *Impact* I21.1 we see how the development of special electrochemical cells known as ‘fuel cells’ could revolutionize our production and deployment of energy.

To read more about the impact of this material, scan the QR code, or go to [bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-21-1.html](https://bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-21-1.html)

### ► Why do you need to know this material?

A major component of chemistry is the study of the mechanisms of chemical reactions. One of the earliest approaches, which continues to give insight into the details of mechanisms, is collision theory.

### ► What is the key idea?

According to collision theory, in a bimolecular gas-phase reaction, a reaction takes place on the collision of reactants provided their relative kinetic energy exceeds a threshold value and certain steric requirements are fulfilled.

### ► What do you need to know already?

This Topic draws on the kinetic theory of gases (Topic 1B) and extends the account of unimolecular reactions (Topic 20F). The latter uses combinatorial arguments like those described in Topic 15A.

In this Topic we consider the bimolecular elementary reaction

where P denotes products. Our aim is to calculate the second-order rate constant  $k_r$  and to justify the form of the Arrhenius expression (Topic 20D):

$$k_r = A e^{-E_a/RT} \quad \text{Arrhenius expression} \quad (21A.1b)$$

where  $A$  is the ‘pre-exponential factor’ and  $E_a$  is the ‘activation energy’. The model is then improved by examining how the energy of a collision is distributed over all the bonds in the reactant molecule. This improvement helps to account for the value of the rate constant  $k_b$  that appears in the Lindemann theory of unimolecular reactions (Topic 20F).

## 21A.1 Reactive encounters

We can anticipate the general form of the expression for  $k_r$  in eqn 21A.1a by considering the physical requirements for reaction. We can expect the rate  $\nu$  to be proportional to the rate of collisions, and therefore to the mean speed of the molecules,  $\nu_{\text{mean}} \propto (T/M)^{1/2}$  where  $M$  is some combination of the molar masses of A and B; we also expect the rate to be proportional to their collision cross-section,  $\sigma$ , (Topic 1B) and to the number densities  $\mathcal{N}_A$  and  $\mathcal{N}_B$  of A and B:

$$\nu \propto \sigma (T/M)^{1/2} \mathcal{N}_A \mathcal{N}_B \propto \sigma (T/M)^{1/2} [A][B]$$

However, a collision will be successful only if the kinetic energy exceeds a minimum value which we denote  $E'$ . This requirement suggests that the rate should also be proportional to a Boltzmann factor of the form  $e^{-E'/RT}$  representing the fraction of collisions with at least the minimum required energy  $E'$ . Therefore,

$$\nu \propto \sigma (T/M)^{1/2} e^{-E'/RT} [A][B]$$

and we can anticipate, by writing the reaction rate in the form given in eqn 21A.1, that

$$k_r \propto \sigma (T/M)^{1/2} e^{-E'/RT}$$

At this point, we begin to recognize the form of the Arrhenius equation, eqn 21A.1b, and identify the minimum kinetic energy  $E'$  with the activation energy  $E_a$  of the reaction. This identification, however, should not be regarded as precise, since collision theory is only a rudimentary model of chemical reactivity.

Not every collision will lead to reaction even if the energy requirement is satisfied, because the reactants may need to collide in a certain relative orientation. This ‘steric requirement’ suggests that a further factor,  $P$ , should be introduced, and that

$$k_r \propto P\sigma(T/M)^{1/2} e^{-E^*/RT} \quad (21A.2)$$

As we shall see in detail below, this expression has the form predicted by collision theory. It reflects three aspects of a successful collision:

$$k_r \propto \overbrace{P}^{\text{Steric requirement}} \overbrace{\sigma(T/M)^{1/2}}^{\text{Encounter rate}} \overbrace{e^{-E^*/RT}}^{\text{Minimum energy requirement}}$$

### (a) Collision rates in gases

We have anticipated that the reaction rate, and hence  $k_r$ , depends on the frequency with which molecules collide. The **collision density**,  $Z_{AB}$ , is the number of (A,B) collisions in a region of the sample in an interval of time divided by the volume of the region and the duration of the interval. The frequency of collisions of a single molecule in a gas was calculated in Topic 1B (eqn 1B.11a,  $z = \sigma v \mathcal{N}_A$ ). As shown in the following *Justification*, that result can be adapted to deduce that

$$Z_{AB} = \sigma \left( \frac{8kT}{\pi\mu} \right)^{1/2} N_A^2 [A][B] \quad \text{KMT} \quad \text{Collision density} \quad (21A.3a)$$

where  $\sigma$  is the collision cross-section (Fig. 21A.1)

$$\sigma = \pi d^2 \quad d = \frac{1}{2}(d_A + d_B) \quad \text{Collision cross-section} \quad (21A.3b)$$

$d_A$  and  $d_B$  are the diameters of A and B, respectively, and  $\mu$  is the reduced mass,

$$\mu = \frac{m_A m_B}{m_A + m_B} \quad \text{Reduced mass} \quad (21A.3c)$$

**Figure 21A.1** The collision cross-section for two molecules can be regarded to be the area within which the projectile molecule (A) must enter around the target molecule (B) in order for a collision to occur. If the diameters of the two molecules are  $d_A$  and  $d_B$ , the radius of the target area is  $d = \frac{1}{2}(d_A + d_B)$  and the cross-section is  $\pi d^2$ .

For like molecules  $\mu = \frac{1}{2}m_A$  and at a molar concentration  $[A]$

$$Z_{AA} = \frac{1}{2}\sigma \left( \frac{16kT}{\pi m_A} \right)^{1/2} N_A^2 [A]^2 = \sigma \left( \frac{4kT}{\pi m_A} \right)^{1/2} N_A^2 [A]^2 \quad (21A.3d)$$

The (blue) factor of  $\frac{1}{2}$  is included to avoid double counting of collisions in this instance. If the collision density is required in terms of the pressure of each gas  $J$ , then we use  $[J] = n_J/V = p_J/RT$ .

#### Brief illustration 21A.1 Collision density

Collision densities may be very large. For example, in nitrogen at 25 °C and 1.0 bar, when  $[N_2] \approx 40 \text{ mol m}^{-3}$ , with  $\sigma = 0.43 \text{ nm}^2$  and  $m_{N_2} = 28.02 m_u$  the collision density is

$$Z_{N_2, N_2} = (4.3 \times 10^{-19} \text{ m}^2) \times \left( \frac{4 \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})}{\pi \times 28.02 \times (1.661 \times 10^{-27} \text{ kg})} \right)^{1/2} \\ \times (6.022 \times 10^{23} \text{ mol}^{-1})^2 \times (40 \text{ mol m}^{-3})^2 = 8.4 \times 10^{34} \text{ m}^{-3} \text{ s}^{-1}$$

Even in  $1 \text{ cm}^3$ , there are over  $8 \times 10^{16}$  collisions in each picosecond.

**Self-test 21A.1** Calculate the collision density in molecular hydrogen under the same conditions.

Answer:  $Z_{H_2, H_2} = 2.0 \times 10^{35} \text{ m}^{-3} \text{ s}^{-1}$

#### Justification 21A.1 The collision density

It follows from Topic 1B that the collision frequency,  $z$ , for a single A molecule of mass  $m_A$  in a gas of other A molecules is  $z = \sigma v_{\text{rel}} \mathcal{N}_A$ , where  $\mathcal{N}_A$  is the number density of A molecules and  $v_{\text{rel}}$  is their relative mean speed. As indicated in Topic 1B,  $v_{\text{rel}} = 2^{1/2} v_{\text{mean}}$  with  $v_{\text{mean}} = (8kT/\pi m)^{1/2}$ . For future convenience, it is sensible to introduce  $\mu = \frac{1}{2}m$  (for like molecules of mass  $m$ ), and then to write  $v_{\text{rel}} = (8kT/\pi\mu)^{1/2}$ . This expression also applies to the mean relative speed of dissimilar molecules provided that  $\mu$  is interpreted as their reduced mass.

The total collision density is the collision frequency multiplied by the number density of A molecules:

$$Z_{AA} = \frac{1}{2} z \mathcal{N}_A = \frac{1}{2} \sigma v_{\text{rel}} \mathcal{N}_A^2$$

The factor of  $\frac{1}{2}$  has been introduced to avoid double counting of the collisions (so one A molecule colliding with another A molecule is counted as one collision regardless of their actual identities). For collisions of A and B molecules present at number densities  $\mathcal{N}_A$  and  $\mathcal{N}_B$ , the collision density is

$$Z_{AB} = \sigma v_{\text{rel}} \mathcal{N}_A \mathcal{N}_B$$

The factor of  $\frac{1}{2}$  has been discarded because now we are considering an A molecule colliding with any of the B molecules as a collision. The number density of a species  $J$  is  $\mathcal{N}_J = \mathcal{N}_A [J]$ , where  $[J]$  is their molar concentration and  $\mathcal{N}_A$  is Avogadro's constant. Equation 21A.3 then follows.

### (b) The energy requirement

According to collision theory, the rate of change in the number density,  $\mathcal{N}_A$ , of A molecules is the product of the collision density and the probability that a collision occurs with sufficient energy. The latter condition can be incorporated by writing the collision cross-section  $\sigma$  as a function of the kinetic energy  $\varepsilon$  of approach of the two colliding species, and setting the cross-section,  $\sigma(\varepsilon)$ , equal to zero if the kinetic energy of approach is below a certain threshold value,  $\varepsilon_a$ . Later, we shall identify  $N_A \varepsilon_a$  as  $E_a$ , the (molar) activation energy of the reaction. Then, for a collision between A and B with a specific relative speed of approach  $v_{\text{rel}}$  (not, at this stage, a mean value),

$$\frac{d\mathcal{N}_A}{dt} = -\sigma(\varepsilon)v_{\text{rel}}\mathcal{N}_A\mathcal{N}_B \quad (21A.4a)$$

or, in terms of molar concentrations,

$$\frac{d[A]}{dt} = -\sigma(\varepsilon)v_{\text{rel}}N_A[A][B] \quad (21A.4b)$$

The kinetic energy associated with the relative motion of the two particles takes the form  $\varepsilon = \frac{1}{2}\mu v_{\text{rel}}^2$  when the centre-of-mass coordinates are separated from the internal coordinates of each particle. Therefore the relative speed is given by  $v_{\text{rel}} = (2\varepsilon/\mu)^{1/2}$ . At this point we recognize that a wide range of approach energies  $\varepsilon$  is present in a sample, so we should average the expression just derived over a Boltzmann distribution of energies  $f(\varepsilon)$ , and write

$$\frac{d[A]}{dt} = -\left\{ \int_0^\infty \sigma(\varepsilon)v_{\text{rel}}f(\varepsilon)d\varepsilon \right\} N_A[A][B] \quad (21A.5)$$

and hence recognize the rate constant as

$$k_i = N_A \int_0^\infty \sigma(\varepsilon)v_{\text{rel}}f(\varepsilon)d\varepsilon \quad \text{Rate constant} \quad (21A.6)$$

Now suppose that the reactive collision cross-section is zero below  $\varepsilon_a$ . We show in the following *Justification* that, above  $\varepsilon_a$ ,  $\sigma(\varepsilon)$  varies as

$$\sigma(\varepsilon) = \left(1 - \frac{\varepsilon_a}{\varepsilon}\right)\sigma \quad \text{Energy dependence of } \sigma \quad (21A.7)$$

with the energy-independent  $\sigma$  given by eqn 21A.3b. This form of the energy-dependence for  $\sigma(\varepsilon)$  is broadly consistent with experimental determinations of the reaction between H and D<sub>2</sub> as determined by molecular beam measurements of the kind described in Topic 21D (Fig. 21A.2).

**Figure 21A.2** The variation of the reactive cross-section with energy as expressed by eqn 21A.7. The data points are from experiments on the reaction  $\text{H} + \text{D}_2 \rightarrow \text{HD} + \text{D}$  (K. Tsukiyama et al., *J. Chem. Phys.* **84**, 1934 (1986)).

#### Justification 21A.2 The collision cross-section

Consider two colliding molecules A and B with relative speed  $v_{\text{rel}}$  and relative kinetic energy  $\varepsilon = \frac{1}{2}\mu v_{\text{rel}}^2$  (Fig. 21A.3). Intuitively, we expect that a head-on collision between A and B will be most effective in bringing about a chemical reaction. Therefore,  $v_{\text{rel,A-B}}$ , the magnitude of the relative velocity component parallel to an axis that contains the vector connecting the centres of A and B, must be large. From trigonometry and the definitions of the distances  $a$  and  $d$  and the angle  $\theta$  given in Fig. 21A.3, it follows that

$$v_{\text{rel,A-B}} = v_{\text{rel}} \cos \theta = v_{\text{rel}} \left( \frac{d^2 - a^2}{d^2} \right)^{1/2}$$

**Figure 21A.3** The parameters used in the calculation of the dependence of the collision cross-section on the relative kinetic energy of two molecules A and B.

We assume that only the kinetic energy associated with the head-on component of the collision,  $\varepsilon_{\text{A-B}}$ , can lead to a chemical reaction. After squaring both sides of this equation and multiplying by  $\frac{1}{2}\mu$ , it follows that

$$\varepsilon_{\text{A-B}} = \varepsilon \times \frac{d^2 - a^2}{d^2}$$

The existence of an energy threshold,  $\varepsilon_a$ , for the formation of products implies that there is a maximum value of  $a$ ,  $a_{\max}$ , above which reaction does not occur. Setting  $a = a_{\max}$  and  $\varepsilon_{A-B} = \varepsilon_a$  gives

$$a_{\max}^2 = \left(1 - \frac{\varepsilon_a}{\varepsilon}\right) d^2$$

Substitution of  $\sigma(\varepsilon)$  for  $\pi a_{\max}^2$  and  $\sigma$  for  $\pi d^2$  in the equation above gives eqn 21A.7. Note that the equation can be used only when  $\varepsilon > \varepsilon_a$ .

With the energy dependence of the collision cross-section established, we can evaluate the integral in eqn 21A.6. In the following *Justification* we show that

$$k_r = \sigma N_A \nu_{\text{rel}} e^{-E_a/RT} \quad \text{Collision theory} \quad \text{Rate constant} \quad (21A.8)$$

### Justification 21A.3 The rate constant

The Maxwell–Boltzmann distribution of molecular speeds is eqn 1B.4 of Topic 1B:

$$f(v) dv = 4\pi \left(\frac{\mu}{2\pi kT}\right)^{3/2} v^2 e^{-\mu v^2/2kT} dv$$

(We have replaced  $M/R$  by  $\mu/k$ .) This expression may be written in terms of the kinetic energy,  $\varepsilon$ , by writing  $\varepsilon = \frac{1}{2}\mu v^2$ ; then  $dv = d\varepsilon/(2\mu\varepsilon)^{1/2}$ , when it becomes

$$\begin{aligned} f(v) dv &= 4\pi \left(\frac{\mu}{2\pi kT}\right)^{3/2} \left(\frac{2\varepsilon}{\mu}\right) e^{-\varepsilon/kT} \frac{d\varepsilon}{(2\mu\varepsilon)^{1/2}} \\ &= 2\pi \left(\frac{1}{\pi kT}\right)^{3/2} \varepsilon^{1/2} e^{-\varepsilon/kT} d\varepsilon = f(\varepsilon) d\varepsilon \end{aligned}$$

The integral we need to evaluate is therefore

$$\begin{aligned} \int_0^\infty \sigma(\varepsilon) \overbrace{\nu_{\text{rel}}^{(2\varepsilon/\mu)^{1/2}}} f(\varepsilon) d\varepsilon &= 2\pi \left(\frac{1}{\pi kT}\right)^{3/2} \int_0^\infty \sigma(\varepsilon) \left(\frac{2\varepsilon}{\mu}\right)^{1/2} \varepsilon^{1/2} e^{-\varepsilon/kT} d\varepsilon \\ &= \left(\frac{8}{\pi\mu kT}\right)^{1/2} \left(\frac{1}{kT}\right) \int_0^\infty \varepsilon \sigma(\varepsilon) e^{-\varepsilon/kT} d\varepsilon \end{aligned}$$

To proceed, we introduce the approximation for  $\sigma(\varepsilon)$  in eqn 21A.7 and evaluate

$$\begin{aligned} \int_0^\infty \varepsilon \sigma(\varepsilon) e^{-\varepsilon/kT} d\varepsilon &\stackrel{\sigma=0 \text{ for } \varepsilon < \varepsilon_a}{=} \sigma \int_{\varepsilon_a}^\infty \varepsilon \left(1 - \frac{\varepsilon_a}{\varepsilon}\right) e^{-\varepsilon/kT} d\varepsilon \\ &= \sigma \left\{ \int_{\varepsilon_a}^\infty \varepsilon e^{-\varepsilon/kT} d\varepsilon - \int_{\varepsilon_a}^\infty \varepsilon_a e^{-\varepsilon/kT} d\varepsilon \right\} \end{aligned}$$

$$\stackrel{\text{Integral E.1}}{=} (kT)^2 \sigma e^{-\varepsilon_a/kT}$$

It follows that

$$\int_0^\infty \sigma(\varepsilon) \nu_{\text{rel}} f(\varepsilon) d\varepsilon = \sigma \left(\frac{8kT}{\pi\mu}\right)^{1/2} e^{-\varepsilon_a/kT}$$

as in eqn 21A.8 (with  $\varepsilon_a/kT = E_a/RT$ ).

Equation 21A.8 has the Arrhenius form  $k_r = Ae^{-E_a/RT}$  provided the exponential temperature dependence dominates the weak square-root temperature dependence of the pre-exponential factor. It follows that we can identify (within the constraints of collision theory) the activation energy,  $E_a$ , with the minimum kinetic energy along the line of approach that is needed for reaction, and that the pre-exponential factor is a measure of the rate at which collisions occur in the gas.

The simplest procedure for calculating  $k_r$  is to use for  $\sigma$  the values obtained for non-reactive collisions (for example, typically those obtained from viscosity measurements) or from tables of molecular radii. If the collision cross-sections of A and B are  $\sigma_A = \pi d_A^2$  and  $\sigma_B = \pi d_B^2$ , then an approximate value of the AB cross-section can be estimated from  $\sigma = \pi d^2$ , with  $d = \frac{1}{2}(d_A + d_B)$ . That is,

$$\sigma \approx \frac{1}{4}(\sigma_A^{1/2} + \sigma_B^{1/2})^2$$

### Brief illustration 21A.2 The rate constant

To estimate the rate constant for the reaction  $\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$  at 628 K we first calculate the reduced mass using  $m(\text{H}_2) = 2.016m_u$  and  $m(\text{C}_2\text{H}_4) = 28.05m_u$ . A straightforward calculation gives  $\mu = 3.123 \times 10^{-27}$  kg. It then follows that

$$\left(\frac{8kT}{\pi\mu}\right)^{1/2} = \left(\frac{8 \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (628 \text{ K})}{\pi \times (3.123 \times 10^{-27} \text{ kg})}\right)^{1/2} = 2.65 \dots \text{ km s}^{-1}$$

From Table 1B.1,  $\sigma(\text{H}_2) = 0.27 \text{ nm}^2$  and  $\sigma(\text{C}_2\text{H}_4) = 0.64 \text{ nm}^2$ , giving  $\sigma(\text{H}_2, \text{C}_2\text{H}_4) \approx 0.44 \text{ nm}^2$ . The activation energy, Table 20D.1, is large:  $180 \text{ kJ mol}^{-1}$ . Therefore,

$$k_r = (4.4 \times 10^{-19} \text{ m}^2) \times (2.65 \dots \times 10^3 \text{ m s}^{-1}) \times (6.022 \times 10^{23} \text{ mol}^{-1}) \times e^{-(1.80 \times 10^5 \text{ J mol}^{-1}) / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (628 \text{ K})}$$

$$= \overbrace{7.04 \dots \times 10^8 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}}^A \times e^{-34.4 \dots} = 7.5 \times 10^{-7} \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

or  $7.5 \times 10^{-4} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ .

**Self-test 21A.2** Evaluate the rate constant for the reaction  $\text{NO} + \text{Cl}_2 \rightarrow \text{NOCl} + \text{Cl}$  at 298 K from  $\sigma(\text{NO}) = 0.42 \text{ nm}^2$  and  $\sigma(\text{Cl}_2) = 0.93 \text{ nm}^2$  and data in Table 1B.1.

Answer:  $2.7 \times 10^{-4} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

### (c) The steric requirement

Table 21A.1 compares some values of the pre-exponential factor calculated from the collisional data in Table 1B.1 with values obtained from Arrhenius plots. One of the reactions shows fair agreement between theory and experiment, but for others there are major discrepancies. In some cases the experimental values are orders of magnitude smaller than those calculated, which suggests that the collision energy is not the only criterion for reaction and that some other feature, such as the relative orientation of the colliding species, is important. Moreover, one reaction in the table has a pre-exponential factor larger than theory, which seems to indicate that the reaction occurs more quickly than the particles collide!

The disagreement between experiment and theory can be eliminated by introducing a **steric factor**,  $P$ , and expressing the **reactive cross-section**,  $\sigma^*$ , as a multiple of the collision cross-section,  $\sigma^* = P\sigma$  (Fig. 21A.4). Then the rate constant becomes

$$k_r = P\sigma N_A \left( \frac{8kT}{\pi\mu} \right)^{1/2} e^{-E_a/RT} \quad (21A.9)$$

This expression has the form we anticipated in eqn 21A.2. The steric factor is normally found to be several orders of magnitude smaller than 1.

Table 21A.1\* Arrhenius parameters for gas-phase reactions

	$A/(\text{dm}^3 \text{mol}^{-1} \text{s}^{-1})$		$E_a/(\text{kJ mol}^{-1})$	$P$
	Experiment	Theory		
$2 \text{NOCl} \rightarrow 2 \text{NO} + 2 \text{Cl}$	$9.4 \times 10^9$	$5.9 \times 10^{10}$	102	0.16
$2 \text{ClO} \rightarrow \text{Cl}_2 + \text{O}_2$	$6.3 \times 10^7$	$2.5 \times 10^{10}$	0	$2.5 \times 10^{-3}$
$\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$	$1.24 \times 10^6$	$7.4 \times 10^{11}$	180	$1.7 \times 10^{-6}$
$\text{K} + \text{Br}_2 \rightarrow \text{KBr} + \text{Br}$	$1.0 \times 10^{12}$	$2.1 \times 10^{11}$	0	4.8

\* More values are given in the *Resource section*.

Figure 21A.4 The collision cross-section is the target area that results in simple deflection of the projectile molecule; the reactive cross-section is the corresponding area for chemical change to occur on collision.

#### Brief illustration 21A.3 The steric factor

It is found experimentally that the pre-exponential factor for the reaction  $\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$  at 628 K is  $1.24 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . In *Brief illustration 21A.2* we calculated the result that can be expressed as  $A = 7.04 \dots \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . It follows that the steric factor for this reaction is

$$P = \frac{A_{\text{experimental}}}{A_{\text{calculated}}} = \frac{1.24 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}}{7.04 \dots \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}} \approx 1.8 \times 10^{-6}$$

The very small value of  $P$  is one reason why catalysts are needed to bring this reaction about at a reasonable rate. As a general guide, the more complex the reactant molecules, the smaller the value of  $P$ .

**Self-test 21A.3** It is found for the reaction  $\text{NO} + \text{Cl}_2 \rightarrow \text{NOCl} + \text{Cl}$  that  $A = 4.0 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at 298 K. Estimate the  $P$  factor for the reaction (see *Self-test 21A.2*).

Answer: 0.019

An example of a reaction for which it is possible to estimate the steric factor is  $\text{K} + \text{Br}_2 \rightarrow \text{KBr} + \text{Br}$ , with the experimental value  $P = 4.8$ . In this reaction, the distance of approach at which reaction occurs appears to be considerably larger than the distance needed for deflection of the path of the approaching molecules in a non-reactive collision. It has been proposed that the reaction proceeds by a **harpoon mechanism**. This brilliant name is based on a model of the reaction which pictures the K atom as approaching a  $\text{Br}_2$  molecule, and when the two are close enough an electron (the harpoon) flips across from K to  $\text{Br}_2$ . In place of two neutral particles there are now two ions, so there is a Coulombic attraction between them: this attraction is the line on the harpoon. Under its influence the ions move together (the line is wound in), the reaction takes place, and  $\text{KBr} + \text{Br}$  emerge. The harpoon extends the cross-section for the reactive encounter, and the reaction rate is significantly underestimated by taking for the collision cross-section the value for simple mechanical contact between K and  $\text{Br}_2$ .

#### Example 21A.1 Estimating a steric factor

Estimate the value of  $P$  for the harpoon mechanism by calculating the distance at which it becomes energetically favourable for the electron to leap from K to  $\text{Br}_2$ . Take the sum of the radii of the reactants (treating them as spherical) to be 400 pm.

**Method** Begin by identifying all the contributions to the energy of interaction between the colliding species. There are three contributions to the energy of the process  $\text{K} + \text{Br}_2 \rightarrow \text{K}^+ + \text{Br}_2^-$ . The first is the ionization energy,  $I$ , of K. The second is the electron affinity,  $E_{\text{ea}}$ , of  $\text{Br}_2$ . The third is the

Coulombic interaction energy between the ions when they have been formed: when their separation is  $R$ , this energy is  $-e^2/4\pi\epsilon_0 R$ . The electron flips across when the sum of these three contributions changes from positive to negative (that is, when the sum is zero) and becomes energetically favourable.

**Answer** The net change in energy when the transfer occurs at a separation  $R$  is

$$E = I - E_{\text{ea}} - \frac{e^2}{4\pi\epsilon_0 R}$$

The ionization energy  $I$  is larger than  $E_{\text{ea}}$ , so  $E$  becomes negative only when  $R$  has decreased to less than some critical value  $R^*$  given by

$$R = \frac{e^2}{4\pi\epsilon_0(I - E_{\text{ea}})}$$

When the particles are at this separation, the harpoon shoots across from K to  $\text{Br}_2$ , so we can identify the reactive cross-section as  $\sigma^* = \pi R^{*2}$ . This value of  $\sigma^*$  implies that the steric factor is

$$P = \frac{\sigma^*}{\sigma} = \frac{R^{*2}}{d^2} = \left( \frac{e^2}{4\pi\epsilon_0 d(I - E_{\text{ea}})} \right)^2$$

where  $d = R(\text{K}) + R(\text{Br}_2)$ , the sum of the radii of the spherical reactants. With  $I = 420 \text{ kJ mol}^{-1}$  (corresponding to 0.70 aJ),  $E_{\text{ea}} \approx 250 \text{ kJ mol}^{-1}$  (corresponding to 0.42 aJ), and  $d = 400 \text{ pm}$ , we find  $P = 4.2$ , in good agreement with the experimental value (4.8).

**Self-test 21A.4** Estimate the value of  $P$  for the harpoon reaction between Na and  $\text{Cl}_2$  for which  $d \approx 350 \text{ pm}$ ; take  $E_{\text{ea}} \approx 230 \text{ kJ mol}^{-1}$ .

Answer: 2.2

*Example 21A.1* illustrates two points about steric factors. First, the concept of a steric factor is not wholly useless because in some cases its numerical value can be estimated. Second, and more pessimistically, most reactions are much more complex than  $\text{K} + \text{Br}_2$ , and we cannot expect to obtain  $P$  so easily.

## 21A.2 The RRK model

The steric factor  $P$  can also be estimated for unimolecular gas-phase reactions (Topic 20F), by a calculation based on the **Rice–Ramsperger–Kassel model** (RRK model), which was proposed in 1926 by O.K. Rice and H.C. Ramsperger and almost simultaneously by L.S. Kassel. The model has been elaborated, largely by R.A. Marcus, into the ‘RRKM model’. Here we outline Kassel’s original approach to the RRK model; the details are set out in the following *Justification*. The essential feature

of the model is that although a molecule might have enough energy to react, that energy is distributed over all the modes of motion of the molecule, and reaction will occur only when enough of that energy has migrated into a particular location (such as a particular bond) in the molecule. This distribution effect leads to a  $P$  factor of the form

$$P = \left( 1 - \frac{E^*}{E} \right)^{s-1} \quad \text{RRK theory} \quad (21A.10a)$$

where  $s$  is the number of modes of motion over which the energy  $E$  may be dissipated and  $E^*$  is the energy required for the bond of interest to break. The resulting **Kassel form** of the unimolecular rate constant for the decay of  $\text{A}^*$  to products is

$$k_b(E) = \left( 1 - \frac{E^*}{E} \right)^{s-1} k_b \quad \text{for } E \geq E^* \quad \text{Kassel form} \quad (21A.10b)$$

where  $k_b$  is the rate constant used in the original Lindemann theory for the decomposition of the activated intermediate (eqn 20F.8 of Topic 20F).

### Justification 21A.4 The RRK model of unimolecular reactions

To set up the RRK model, we suppose that a molecule consists of  $s$  identical harmonic oscillators, each of which has frequency  $\nu$ . In practice, of course, the vibrational modes of a molecule have different frequencies, but assuming that they are all the same is a reasonable first approximation. Next, we suppose that the vibrations are excited to a total energy  $E = nh\nu$  and then set out to calculate the number of ways  $N$  in which the energy can be distributed over the oscillators.

We can represent the  $n$  quanta as follows:

These quanta must be put in  $s$  containers (the  $s$  oscillators), which can be represented by inserting  $s-1$  walls, denoted by  $|$ . One such distribution is

The total number of arrangements of each quantum and wall (of which there are  $n+s-1$  in all) is  $(n+s-1)!$  where, as usual,  $x! = x(x-1)\dots 1$ . However, the  $n!$  arrangements of the  $n$  quanta are indistinguishable, as are the  $(s-1)!$  arrangements of the  $s-1$  walls. Therefore, to find  $N$  we must divide  $(n+s-1)!$  by these two factorials. It follows that

$$N = \frac{(n+s-1)!}{n!(s-1)!}$$

The distribution of the energy throughout the molecule means that it is too sparsely spread over all the modes for any particular bond to be sufficiently highly excited to undergo dissociation. We suppose that a bond will break only if it is excited to at least an energy  $E^* = n^*h\nu$ . Therefore, we isolate one critical oscillator as the one that undergoes dissociation if it has *at least*  $n^*$  of the quanta, leaving up to  $n - n^*$  quanta to be accommodated in the remaining  $s - 1$  oscillators (and therefore with  $s - 2$  walls in the partition in place of the  $s - 1$  walls we used above). For example, consider 28 quanta distributed over six oscillators, with excitation by at least six quanta required for dissociation. Then all the following partitions will result in dissociation:

(The leftmost partition is the critical oscillator.) However, these partitions are equivalent to

and we see that we have the problem of permuting  $28 - 6 = 22$  (in general,  $n - n^*$ ) quanta and five (in general,  $s - 1$ ) walls, and therefore a total of 27 (in general,  $n - n^* + s - 1$ ) objects. Therefore, the calculation is exactly like the one above for  $N$ , except that we have to find the number of distinguishable permutations of  $n - n^*$  quanta in  $s$  containers (and therefore  $s - 1$  walls). The number  $N^*$  is therefore obtained from the expression for  $N$  by replacing  $n$  by  $n - n^*$  and is

$$N^* = \frac{(n - n^* + s - 1)!}{(n - n^*)!(s - 1)!}$$

From the preceding discussion we conclude that the probability that one specific oscillator will have undergone sufficient excitation to dissociate is the ratio  $N^*/N$ , which is

$$P = \frac{N^*}{N} = \frac{n!(n - n^* + s - 1)!}{(n - n^*)!(n + s - 1)!}$$

This equation is still awkward to use, even when written out in terms of its factors:

$$P = \frac{n(n-1)(n-2)\dots 1}{(n-n^*)(n-n^*-1)\dots 1} \times \frac{(n-n^*+s-1)(n-n^*+s-2)\dots 1}{(n+s-1)(n+s-2)\dots 1}$$

$$= \frac{(n-n^*+s-1)(n-n^*+s-2)\dots(n-n^*+1)}{(n+s-1)(n+s-2)\dots(n+2)(n+1)}$$

However, because  $s - 1$  is small (in the sense  $s - 1 \ll n - n^*$ ), we can approximate this expression by

$$P = \frac{\overbrace{(n-n^*)(n-n^*)\dots(n-n^*)}^{s-1 \text{ factors}}}{\underbrace{(n)(n)\dots(n)}_{s-1 \text{ factors}}} = \left(\frac{n-n^*}{n}\right)^{s-1}$$

An alternative derivation of this expression for  $P$  is developed in Problem 21A.7. Because the energy of the excited molecule is  $E = nh\nu$  and the critical energy is  $E^* = n^*h\nu$ , this expression may be written

$$P = \left(1 - \frac{E^*}{E}\right)^{s-1}$$

as in eqn 21A.10.

The energy dependence of the rate constant given by eqn 21A.10b is shown in Fig. 21A.5 for various values of  $s$ . We see that the rate constant is smaller at a given excitation energy if  $s$  is large, as it takes longer for the excitation energy to migrate through all the oscillators of a large molecule and accumulate in the critical mode. As  $E$  becomes very large, however, the term in parentheses approaches 1, and  $k_b(E)$  becomes independent of the energy and the number of oscillators in the molecule, as there is now enough energy to accumulate immediately in the critical mode regardless of the size of the molecule.

Figure 21A.5 The energy dependence of the rate constant given by eqn 21A.10b for three values of  $s$ .

#### Brief illustration 21A.4 The RRK model

In *Brief illustration 21A.3* we calculated a value of  $P = 1.8 \times 10^{-6}$  for the reaction  $\text{H}_2 + \text{C}_2\text{H}_4 \rightarrow \text{C}_2\text{H}_6$ . Although this is not a unimolecular process, it is interesting to analyse it on the basis of the RRK theory because in some sense the collision energy must accumulate in a region where bonds are broken and

formed. Thus,  $C_2H_4$  has six atoms and therefore  $s=12$  vibrational modes. We can estimate the ratio  $E^*/E$  by solving

$$\left(1 - \frac{E^*}{E}\right)^{11} = 1.8 \times 10^{-6} \quad \text{or} \quad \frac{E^*}{E} = 1 - (1.8 \times 10^{-6})^{1/11} = 0.70$$

This result suggests in one interpretation that the energy needed to proceed in the reaction (identified here with the energy to break the carbon-carbon bond in  $C_2H_4$ ) is typically

70 per cent of the energy of a typical collision. If all eight atoms are taken to be involved in sharing the energy of the collision, the ratio works out as 0.54.

**Self-test 21A.5** Apply the same analysis to the reaction in Self-test 21A.3, where it is found that  $P=0.019$  for  $NO + Cl_2 \rightarrow NOCl + Cl$ . Take the number of atoms in the complex to be 4, so  $s=6$ .

Answer: 0.55

## Checklist of concepts

- 1. In **collision theory**, it is supposed that the rate is proportional to the collision frequency, a steric factor, and the fraction of collisions that occur with at least the kinetic energy  $E_a$  along their lines of centres.
- 2. The **collision density** is the number of collisions in a region of the sample in an interval of time divided by the volume of the region and the duration of the interval.
- 3. The **activation energy** is the minimum kinetic energy along the line of approach of reactant molecules that is required for reaction.
- 4. The **steric factor** is an adjustment that takes into account the orientational requirements for a successful collision.
- 5. For unimolecular reactions, the steric factor can be computed by using the **RRK model**.

## Checklist of equations

Property	Equation	Comment	Equation number
Collision density	$Z_{AB} = \sigma(8kT/\pi\mu)^{1/2} N_A^2 [A][B]$	Unlike molecules, KMT (kinetic molecular theory)	21A.3a

### ► Why do you need to know this material?

Most chemical reactions take place in solution and for a thorough grasp of chemistry it is important to understand what controls their rates and how those rates can be modified.

### ► What is the key idea?

There are two limiting types of chemical reaction mechanism in solution: diffusion control and activation control.

### ► What do you need to know already?

This Topic makes use of the steady-state approximation (Topic 20E) and draws on the formulation and solution of the diffusion equation (Topic 19C). At one point it uses the Stokes–Einstein relation (Topic 19B).

To consider reactions in solution we have to imagine processes that are entirely different from those in gases. No longer are there collisions of molecules hurtling through space; now there is the jostling of one molecule through a dense but mobile collection of molecules making up the fluid environment.

## 21B.1 Reactions in solution

Encounters between reactants in solution occur in a very different manner from encounters in gases. The encounters of reactant molecules dissolved in solvent are considerably

less frequent than in a gas. However, because a molecule also migrates only slowly away from a location, two reactant molecules that encounter each other stay near each other for much longer than in a gas. This lingering of one molecule near another on account of the hindering presence of solvent molecules is called the **cage effect**. Such an **encounter pair** may accumulate enough energy to react even though it does not have enough energy to do so when it first forms. The activation energy of a reaction is a much more complicated quantity in solution than in a gas because the encounter pair is surrounded by solvent and we need to consider the energy of the entire local assembly of reactant and solvent molecules.

### (a) Classes of reaction

The complicated overall process can be divided into simpler parts by setting up a simple kinetic scheme. We suppose that the rate of formation of an encounter pair AB is first order in each of the reactants A and B:

As we shall see,  $k_d$  (where the d signifies diffusion) is determined by the diffusional characteristics of A and B. The encounter pair can break up without reaction or it can go on to form products P. If we suppose that both processes are pseudo-first-order reactions (with the solvent perhaps playing a role), then we can write

The concentration of AB can now be found from the equation for the net rate of change of concentration of AB:

$$\frac{d[AB]}{dt} = k_d[A][B] - k'_d[AB] - k_a[AB] = 0$$

where we have applied the steady-state approximation (Topic 20E). This expression solves to

$$[AB] = \frac{k_d[A][B]}{k_a + k'_d}$$

The rate of formation of products is therefore

$$\frac{d[P]}{dt} = k_a[AB] = k_r[A][B] \quad k_r = \frac{k_a k_d}{k_a + k'_d} \quad (21B.1)$$

Two limits can now be distinguished. If the rate of separation of the unreacted encounter pair is much slower than the rate at which it forms products, then  $k'_d \ll k_a$  and the effective rate constant is

$$k_r \approx \frac{k_a k_d}{k'_d} = k_d \quad \text{Diffusion-controlled limit} \quad (21B.2a)$$

In this **diffusion-controlled limit**, the rate of reaction is governed by the rate at which the reactant molecules diffuse through the solvent. Because the combination of radicals involves very little activation energy, radical and atom recombination reactions are often diffusion-controlled. An **activation-controlled reaction** arises when a substantial activation energy is involved in the reaction  $AB \rightarrow P$ . Then  $k_a \ll k'_d$  and

$$k_r \approx \frac{k_a k_d}{k'_d} = k_a K \quad \text{Activation-controlled limit} \quad (21B.2b)$$

where  $K$  is the equilibrium constant for  $A+B \rightleftharpoons AB$ . In this limit, the reaction proceeds at the rate at which energy accumulates in the encounter pair from the surrounding solvent. Some experimental data are given in Table 21B.1.

### (b) Diffusion and reaction

The rate of a diffusion-controlled reaction is calculated by considering the rate at which the reactants diffuse together. As shown in the following *Justification*, the rate constant for a reaction in which the two molecules react if they come within a distance  $R^*$  of one another is

$$k_d \approx 4\pi R^* D N_A \quad (21B.3)$$

where  $D$  is the sum of the diffusion coefficients of the two reactant species in the solution.

#### Brief illustration 21B.1 Diffusion control 1

The order of magnitude of  $R^*$  is  $10^{-7}$  m (100 nm) and that of  $D$  for a species in water is  $10^{-9}$  m<sup>2</sup> s<sup>-1</sup>. It follows from eqn 21B.3 that

$$k_d \approx 4\pi \times (10^{-7} \text{ m}) \times (10^{-9} \text{ m}^2 \text{ s}^{-1}) \times (6.022 \times 10^{23}) \approx 10^9 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

which corresponds to  $10^{12}$  dm<sup>3</sup> mol<sup>-1</sup> s<sup>-1</sup>. An indication that a reaction is diffusion-controlled is therefore that its rate constant is of the order of  $10^{12}$  dm<sup>3</sup> mol<sup>-1</sup> s<sup>-1</sup>.

**Self-test 21B.1** Estimate the rate constant for a diffusion-controlled reaction in benzene ( $D \approx 2 \times 10^{-9}$  m<sup>2</sup> s<sup>-1</sup>), taking  $R^* \approx 100$  nm.

Answer:  $1.5 \times 10^{12}$  dm<sup>3</sup> mol<sup>-1</sup> s<sup>-1</sup>

**Table 21B.1\*** Arrhenius parameters for solvolysis reactions in solution

	Solvent	$A/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	$E_a/(\text{kJ mol}^{-1})$
(CH <sub>3</sub> ) <sub>3</sub> CCl	Water	$7.1 \times 10^{16}$	100
	Ethanol	$3.0 \times 10^{13}$	112
	Chloroform	$1.4 \times 10^4$	45
CH <sub>3</sub> CH <sub>2</sub> Br	Ethanol	$4.3 \times 10^{11}$	90

\* More values are given in the *Resource section*.

#### Justification 21B.1 Solution of the radial diffusion equation

The general form of the diffusion equation (Topic 19A) corresponding to motion in three dimensions is  $D_B \nabla^2[B](r,t) = \partial[B](r,t)/\partial t$ ; therefore, the concentration of B when the system has reached a steady state ( $\partial[B](r,t)/\partial t = 0$ ) satisfies  $\nabla^2[B](r) = 0$ , with the concentration of B now depending only on location not time. For a spherically symmetrical system,  $\nabla^2$  can be replaced by radial derivatives alone (see Table 7B.1), so the equation satisfied by  $[B](r)$ , as  $[B](r)$  can now be written, is

$$\frac{d^2[B](r)}{dr^2} + \frac{2}{r} \frac{d[B](r)}{dr} = 0$$

The general solution of this equation is

$$[B](r) = a + \frac{b}{r}$$

as may be verified by substitution. We need two boundary conditions to pin down the values of the two constants ( $a$  and  $b$ ). One condition is that  $[B](r)$  has its bulk value  $[B]$  as  $r \rightarrow \infty$ . The second condition is that the concentration of B is zero at  $r = R^*$ , the distance at which reaction occurs. It follows that  $a = [B]$  and  $b = -R^*[B]$ , and hence that (for  $r \geq R^*$ )

$$[B](r) = \left(1 - \frac{R^*}{r}\right)[B]$$

Figure 21B.1 illustrates the variation of concentration expressed by this equation.

The rate of reaction is the (molar) flux,  $J$ , of the reactant B towards A multiplied by the area of the spherical surface of radius  $R^*$  through which B must pass:

$$\text{Rate of reaction} = 4\pi R^{*2} J$$

From Fick's first law (eqn 19C.3 of Topic 19C,  $J = -D\partial[J]/\partial x$ ), the flux of B towards A is proportional to the concentration gradient, so at a radius  $R^*$ :

$$J = D_B \left( \frac{d[B](r)}{dr} \right)_{r=R^*} = -D_B [B] R^* \left( -\frac{1}{r^2} \right)_{r=R^*} = \frac{D_B [B]}{R^*}$$

**Figure 21B.1** The concentration profile for reaction in solution when a molecule B diffuses towards another reactant molecule and reacts if it reaches  $R^*$ .

(A sign change has been introduced because we are interested in the flux towards decreasing values of  $r$ .) It follows that

$$\text{Rate of reaction} = 4\pi R^* D_B [B]$$

The rate of the diffusion-controlled reaction is equal to the average flow of B molecules to all the A molecules in the sample. If the bulk concentration of A is  $[A]$ , the number of A molecules in the sample of volume  $V$  is  $N_A[A]V$ ; the global flow of all B to all A is therefore  $4\pi R^* D_B N_A [A][B]V$ . Because it is unrealistic to suppose that all A molecules are stationary; we replace  $D_B$  by the sum of the diffusion coefficients of the two species and write  $D = D_A + D_B$ . Then the rate of change of concentration of AB is

$$\frac{d[AB]}{dt} = 4\pi R^* D N_A [A][B]$$

Hence, the diffusion-controlled rate constant is as given in eqn 21B.3.

We can take eqn 21B.3 further by incorporating the Stokes-Einstein equation (eqn 19B.19 of Topic 19B,  $D_j = kT/6\pi\eta R_j$ ) relating the diffusion constant and the hydrodynamic radius  $R_A$  and  $R_B$  of each molecule in a medium of viscosity  $\eta$ . As this relation is approximate, little extra error is introduced if we write  $R_A = R_B = \frac{1}{2}R^*$ , which leads to

$$k_d = \frac{8RT}{3\eta} \quad \text{Diffusion-controlled rate constant} \quad (21B.4)$$

(The  $R$  in this equation is the gas constant.) The radii have cancelled because, although the diffusion constants are smaller when the radii are large, the reactive collision radius is larger and the particles need travel a shorter distance to meet. In this approximation, the rate constant is independent of the identities of the reactants, and depends only on the temperature and the viscosity of the solvent.

### Brief illustration 21B.2 Diffusion control 2

The rate constant for the recombination of I atoms in hexane at 298 K, when the viscosity of the solvent is 0.326 cP (with  $1 \text{ P} = 10^{-1} \text{ kg m}^{-1} \text{ s}^{-1}$ ) is

$$k_d = \frac{8 \times (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (298 \text{ K})}{3 \times (3.26 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1})} = 2.0 \times 10^7 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

where we have used  $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$ . Because  $1 \text{ m}^3 = 10^3 \text{ dm}^3$ , this result corresponds to  $2.0 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The experimental value is  $1.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , so the agreement is very good considering the approximations involved.

**Self-test 21B.2** Evaluate a typical rate constant for a reaction taking place in ethanol at 20 °C, for which the viscosity is 1.06 cP.

Answer:  $6.1 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$

## 21B.2 The material-balance equation

The diffusion of reactants plays an important role in many chemical processes, such as the diffusion of  $\text{O}_2$  molecules into red blood corpuscles and the diffusion of a gas towards a catalyst. We can catch a glimpse of the kinds of calculations involved by considering the diffusion equation (Topic 19C) generalized to take into account the possibility that the diffusing, convecting molecules are also reacting.

### (a) The formulation of the equation

Consider a small volume element in a chemical reactor (or a biological cell). The net rate at which J molecules enter the region by diffusion and convection is given by eqn 19C.10 of Topic 19C, which we repeat here:

$$\frac{\partial[J]}{\partial t} = D \frac{\partial^2[J]}{\partial x^2} - \nu \frac{\partial[J]}{\partial x} \quad \text{Diffusion equation} \quad (21B.5)$$

where  $\nu$  is the velocity of the convective flow of J and  $[J]$  in general depends on both position and time. The net rate of change of molar concentration due to chemical reaction is

$$\frac{\partial[J]}{\partial t} = -k_r[J]$$

if we suppose that J disappears by a pseudofirst-order reaction. Therefore, the overall rate of change of the concentration of J is

$$\frac{\partial[J]}{\partial t} = D \frac{\partial^2[J]}{\partial x^2} - \nu \frac{\partial[J]}{\partial x} - \overline{k_r}[J] \quad \text{Material-balance equation} \quad (21B.6)$$

Equation 21B.6 is called the **material-balance equation**. If the rate constant is large, then  $[J]$  will decline rapidly. However, if the diffusion constant is large, then the decline can be replenished as  $J$  diffuses rapidly into the region. The convection term, which may represent the effects of stirring, can sweep material either into or out of the region according to the signs of  $v$  and the concentration gradient  $\partial[J]/\partial x$ .

### (b) Solutions of the equation

The material-balance equation is a second-order partial differential equation and is far from easy to solve in general. Some idea of how it is solved can be obtained by considering the special case in which there is no convective motion (as in an unstirred reaction vessel):

$$\frac{\partial[J]}{\partial t} = D \frac{\partial^2[J]}{\partial x^2} - k_r[J] \quad (21B.7)$$

As may be verified by substitution (Problem 21B.1), if the solution of this equation in the absence of reaction (that is, for  $k_r=0$ ) is  $[J]$ , then the solution  $[J]^*$  in the presence of reaction ( $k_r>0$ ) is

$$[J]^* = [J]e^{-k_r t} \quad \text{Diffusion with reaction} \quad (21B.8)$$

**Figure 21B.2** The concentration profiles for a diffusing, reacting system (for example, a column of solution) in which one reactant is initially in a layer at  $x=0$ . In the absence of reaction (grey lines), the concentration profiles are the same as in Fig. 19C.3.

An example of a solution of the diffusion equation in the absence of reaction is that given in Topic 19C for a system in which initially a layer of  $n_0 N_A$  molecules is spread over a plane of area  $A$ :

$$[J] = \frac{n_0 e^{-x^2/4Dt}}{A(\pi Dt)^{1/2}} \quad (21B.9)$$

When this expression is substituted into eqn 21B.8, we obtain the concentration of  $J$  as it diffuses away from its initial surface layer and undergoes reaction in the overlying solution (Fig. 21B.2).

#### Brief illustration 21B.3 Reaction with diffusion

Suppose 1.0 g of iodine (3.9 mmol  $I_2$ ) is spread over a surface of area  $5.0 \text{ cm}^2$  under a column of hexane ( $D=4.1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ ). As it diffuses upwards it reacts with a pseudofirst-order rate constant  $k_r=4.0 \times 10^{-5} \text{ s}^{-1}$ . By substituting these values into

$$[J]^* = \frac{n_0 e^{-x^2/4Dt - k_r t}}{A(\pi Dt)^{1/2}}$$

we can construct the following table:

$[J]^*/(\text{mmol dm}^{-3})$	$x$		
$T$	1 mm	5 mm	1 cm
100 s	3.72	0	0
1000 s	1.96	0.45	0.005
10 000 s	0.46	0.40	0.25

**Self-test 21B.3** What is the value of  $[J]$  at 15 000 s at the same three locations?

Answer: 0.31, 0.28, 0.21  $\text{mmol dm}^{-3}$

Even this relatively simple example has led to an equation that is difficult to solve, and only in some special cases can the full material balance equation be solved analytically. Most modern work on reactor design and cell kinetics uses numerical methods to solve the equation, and detailed solutions for realistic environments, such as vessels of different shapes (which influence the boundary conditions on the solutions) and with a variety of inhomogeneously distributed reactants, can be obtained reasonably easily.

## Checklist of concepts

1. A reaction in solution may be **diffusion-controlled** if its rate is controlled by the rate at which reactant molecules encounter each other in solution.
2. The rate of an **activation-controlled reaction** is controlled by the rate at which the encounter pair accumulates sufficient energy.

- 3. The **material-balance equation** relates the overall rate of change of the concentration of a species to its rates of diffusion, convection and reaction.
- 4. The **cage effect**, the lingering of one reactant molecule near another due to the hindering presence of solvent molecules, results in the formation of an **encounter pair** of reactant molecules.

### ► Why do you need to know this material?

Transition-state theory provides a way to relate the rate constant of reactions to models of the cluster of atoms that is proposed to be formed when reactants come together. It provides a link between information about the structures of reactants and the rate constant for their reaction.

### ► What is the key idea?

Reactants come together to form an activated complex that decays into products.

### ► What do you need to know already?

This Topic makes use of two strands: one is the relation between equilibrium constants and partition functions (Topic 15F); the other is the relation between equilibrium constants and thermodynamic functions, such as the Gibbs energy, enthalpy, and entropy of reaction (Topic 6A). You need to be aware of the Arrhenius equation for the temperature dependence of the rate constant (Topic 20D).

In **transition-state theory** (which is also widely referred to as *activated complex theory*), the notion of the transition state is used in conjunction with concepts of statistical thermodynamics to provide a more detailed calculation of rate constants than that presented by collision theory (Topic 21A). Transition-state theory has the advantage that a quantity corresponding to the steric factor appears automatically, and  $P$  does not need to be grafted on to an equation as an afterthought; it is an attempt to identify the principal features governing the size of a rate constant in terms of a model of the events that take place during the reaction. There are several approaches to the formulation of transition-state theory; here we present the simplest.

## 21C.1 The Eyring equation

In the course of a chemical reaction that begins with a collision between molecules of A and molecules of B, the potential energy of the system typically changes in a manner shown in Fig. 21C.1. Although the illustration displays an exothermic reaction, a potential barrier is also common for endothermic reactions. As the reaction event proceeds, A and B come into contact, distort, and begin to exchange or discard atoms.

### (a) The formulation of the equation

The **reaction coordinate** is a representation of the atomic displacements, such as changes in interatomic distances and bond angles, that are directly involved in the formation of products from reactants. The potential energy rises to a maximum and the cluster of atoms that corresponds to the region close to the maximum is called the **activated complex**. After the maximum, the potential energy falls as the atoms rearrange in the cluster and reaches a value characteristic of the products. The climax of the reaction is at the peak of the potential energy, which can be identified with the activation energy  $E_a$ ; however, as in collision theory, this identification should be regarded as approximate and we clarify it later. Here two reactant molecules have come to such a degree of closeness and distortion that a small further distortion will send them in the direction of products. This crucial configuration is called the **transition state** of the reaction. Although some molecules entering the transition state might revert to reactants, if they pass through this configuration then it is inevitable that products will emerge from the encounter.

**Figure 21C.1** A potential energy profile for an exothermic reaction. The height of the barrier between the reactants and products is the activation energy of the reaction.

*A note on good practice* The terms *activated complex* and *transition state* are often used as synonyms; however, it is best to preserve the distinction, with the former referring to the cluster of atoms and the latter to their critical configuration.

Transition state theory pictures a reaction between A and B as proceeding through the formation of an activated complex,  $C^\ddagger$ , in a rapid pre-equilibrium (Fig. 21C.2):

where we have replaced the activity of each species by  $p/p^\ominus$ . When we express the partial pressures,  $p_j$ , in terms of the molar concentrations,  $[J]$ , by using  $p_j = RT[J]$ , the concentration of activated complex is related to the (dimensionless) equilibrium constant by

$$[C^\ddagger] = \frac{RT}{p^\ominus} K^\ddagger [A][B] \quad (21C.2)$$

The activated complex falls apart by unimolecular decay into products, P, with a rate constant  $k^\ddagger$ :

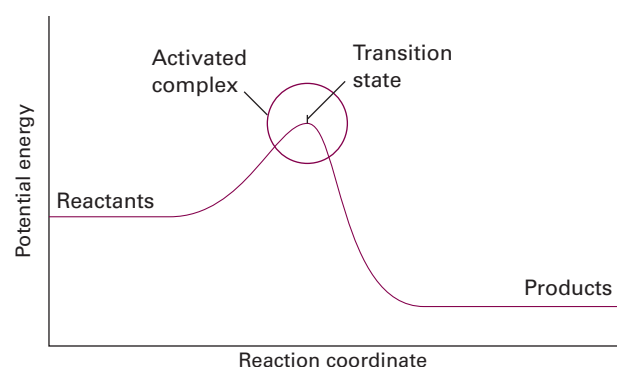

It follows that

$$\nu = k_r [A][B] \quad k_r = \frac{RT}{p^\ominus} k^\ddagger K^\ddagger \quad (21C.4)$$

Our task is to calculate the unimolecular rate constant  $k^\ddagger$  and the equilibrium constant  $K^\ddagger$ .

### (b) The rate of decay of the activated complex

An activated complex can form products if it passes through the transition state. As the reactant molecules approach the

**Figure 21C.2** A reaction profile (for an exothermic reaction). The horizontal axis is the reaction coordinate, and the vertical axis is potential energy. The activated complex is the region near the potential maximum, and the transition state corresponds to the maximum itself.

activated complex region, some bonds are forming and shortening while others are lengthening and breaking; therefore, along the reaction coordinate, there is a vibration-like motion of the atoms in the activated complex. If this motion occurs with a frequency  $\nu^\ddagger$ , then the frequency with which the cluster of atoms forming the complex approaches the transition state is also  $\nu^\ddagger$ . However, it is possible that not every oscillation along the reaction coordinate takes the complex through the transition state. For instance, the centrifugal effect of rotations might also be an important contribution to the break-up of the complex, and in some cases the complex might be rotating too slowly or rotating rapidly but about the wrong axis. Therefore, we suppose that the rate of passage of the complex through the transition state is proportional to the vibrational frequency along the reaction coordinate, and write

$$k^\ddagger = \kappa \nu^\ddagger \quad (21C.5)$$

where  $\kappa$  (kappa) is the **transmission coefficient**. In the absence of information to the contrary,  $\kappa$  is assumed to be about 1.

#### Brief illustration 21C.1 The transmission coefficient

Typical molecular vibration wavenumbers of small molecules occur at wavenumbers of the order of  $10^3 \text{ cm}^{-1}$  (C–H bends, for example, occur in the range  $1340\text{--}1465 \text{ cm}^{-1}$ ) and therefore occur at frequencies of the order of  $10^{13} \text{ Hz}$ . If we suppose that the loosely bound cluster vibrates at one or two orders of magnitude lower frequency, then  $\nu^\ddagger \approx 10^{11}\text{--}10^{12} \text{ Hz}$ . These figures suggest that  $\nu^\ddagger \approx 10^{11}\text{--}10^{12} \text{ s}^{-1}$ , with  $\kappa$  perhaps reducing that value further.

**Self-test 21C.1** Estimate the change in  $\nu^\ddagger$  that would occur if  $^1\text{H}$  is replaced by  $^2\text{H}$  in a C–H group at the site of reaction. Assume that the C atom is immobile.

$$\text{Answer: } \nu^\ddagger \rightarrow \nu^\ddagger / 2^{1/2}$$

### (c) The concentration of the activated complex

Topic 15F explains how to calculate equilibrium constants from structural data. Equation 15F.10 of that Topic ( $K$  in terms of the standard molar partition functions  $q_j^\ominus$ ) can be used directly, which in this case gives

$$K^\ddagger = \frac{N_A q_{C^\ddagger}^\ominus}{q_A^\ominus q_B^\ominus} e^{-\Delta E_0/RT} \quad (21C.6)$$

with

$$\Delta E_0 = E_0(C^\ddagger) - E_0(A) - E_0(B) \quad (21C.7)$$

Note that the units of  $N_A$  and the  $q_j^\ominus$  are  $\text{mol}^{-1}$ , so  $K^\ddagger$  is dimensionless (as is appropriate for an equilibrium constant).

In the final step of this part of the calculation, we focus attention on the partition function of the activated complex. We have already assumed that a vibration of the activated complex  $C^\ddagger$  tips it through the transition state. The partition function for this vibration is (see eqn 15B.15 of Topic 15B, which is essentially the following):

$$q = \frac{1}{1 - e^{-h\nu^\ddagger/kT}}$$

where  $\nu^\ddagger$  is its frequency (the same frequency that determines  $k^\ddagger$ ). This frequency is much lower than for an ordinary molecular vibration because the oscillation corresponds to the complex falling apart (Fig. 21C.3), so the force constant is very low.

**Figure 21C.3** In an elementary depiction of the activated complex close to the transition state, there is a broad, shallow dip in the potential energy surface along the reaction coordinate. The complex vibrates harmonically and almost classically in this well. However, this depiction is an oversimplification, for in many cases there is no dip at the top of the barrier, and the curvature of the potential energy, and therefore the force constant, is negative. Formally, the vibrational frequency is then imaginary. We ignore this problem here.

Therefore, provided that  $h\nu^\ddagger/kT \ll 1$ , the exponential may be expanded and the partition function reduces to

$$q = \frac{1}{1 - (1 - h\nu^\ddagger/kT + \dots)} \approx \frac{kT}{h\nu^\ddagger}$$

We can therefore write

$$q_{C^\ddagger}^\ominus = \frac{kT}{h\nu^\ddagger} \bar{q}_{C^\ddagger} \quad (21C.8)$$

where  $\bar{q}_{C^\ddagger}$  denotes the partition function for all the other modes of the complex. The constant  $K^\ddagger$  is therefore

$$K^\ddagger = \frac{kT}{h\nu^\ddagger} \bar{K}^\ddagger \quad \bar{K}^\ddagger = \frac{N_A \bar{q}_{C^\ddagger}^\ominus}{q_A^\ominus q_B^\ominus} e^{-\Delta E_0/RT} \quad (21C.9)$$

with  $\bar{K}^\ddagger$  a kind of equilibrium constant, but with one vibrational mode of  $C^\ddagger$  discarded.

#### Brief illustration 21C.2 The discarded mode

Consider the case of two structureless particles A and B colliding to give an activated complex that resembles a diatomic molecule. The activated complex is a diatomic cluster. It has one vibrational mode, but that mode corresponds to motion along the reaction coordinate and therefore does not appear in  $\bar{q}_{C^\ddagger}^\ominus$ . It follows that the standard molar partition function of the activated complex has only rotational and translational contributions.

**Self-test 21C.2** Which mode would be discarded for a reaction in which the activated complex is modelled as a linear triatomic cluster?

Answer: Antisymmetric stretch

### (d) The rate constant

We can now combine all the parts of the calculation into

$$k_r = \frac{RT}{p^\ominus} k^\ddagger K^\ddagger = \kappa \nu^\ddagger \frac{kT}{h\nu^\ddagger} \frac{RT}{p^\ominus} \bar{K}^\ddagger$$

At this stage the unknown frequencies  $\nu^\ddagger$  (in blue) cancel, and after writing  $\bar{K}_c^\ddagger = (RT/p^\ominus) \bar{K}^\ddagger$ , we obtain the **Eyring equation**:

$$k_r = \kappa \frac{kT}{h} \bar{K}_c^\ddagger \quad \text{Eyring equation} \quad (21C.10)$$

The factor  $\bar{K}_c^\ddagger$  is given by eqn 21C.9 and the definition  $\bar{K}_c^\ddagger = (RT/p^\ominus) \bar{K}^\ddagger$  in terms of the partition functions of A, B, and  $C^\ddagger$ , so in principle we now have an explicit expression for calculating the second-order rate constant for a bimolecular reaction

in terms of the molecular parameters for the reactants and the activated complex and the quantity  $\kappa$ .

The partition functions for the reactants can normally be calculated quite readily by using either spectroscopic information about their energy levels or the approximate expressions set out in Table 15C.1. The difficulty with the Eyring equation, however, lies in the calculation of the partition function of the activated complex:  $C^\ddagger$  is difficult to investigate spectroscopically (but see the following section), and in general we need to make assumptions about its size, shape, and structure. We shall illustrate what is involved in one simple but significant case.

### Example 21C.1 Analysing the collision of structureless particles

Consider the case of two structureless (and different) particles A and B colliding to give an activated complex that resembles a diatomic molecule and deduce an expression for the rate constant of the reaction  $A+B \rightarrow \text{Products}$ .

**Method** Because the reactants  $J=A, B$  are structureless ‘atoms’, the only contributions to their partition functions are the translational terms. The activated complex is a diatomic cluster of mass  $m_{C^\ddagger} = m_A + m_B$  and moment of inertia  $I$ . It has one vibrational mode but, as explained in *Brief illustration* 21C.2, that mode corresponds to motion along the reaction coordinate. It follows that the standard molar partition function of the activated complex has only rotational and translational contributions. Expressions for the relevant partition functions are given in Topic 15B.

**Answer** The translational partition functions are

$$q_j^\ominus = \frac{V_m^\ominus}{\Lambda_j^3} \quad \Lambda_j = \frac{h}{(2\pi m_j kT)^{1/2}} \quad V_m^\ominus = \frac{RT}{p^\ominus}$$

with  $J=A, B$ , and  $C^\ddagger$  and with  $m_{C^\ddagger} = m_A + m_B$ . The expression for the partition function of the activated complex is

$$q_{C^\ddagger}^\ominus = \frac{2IkT}{\hbar^2} \frac{V_m^\ominus}{\Lambda_{C^\ddagger}^3}$$

where we have used the high-temperature form of the rotational partition function (Topic 15B). By substituting these expressions into the Eyring equation, we find that the rate constant is

$$\begin{aligned} k_r &= \kappa \frac{kT}{h} \frac{RT}{p^\ominus} \left( \frac{N_A \Lambda_A^3 \Lambda_B^3}{\Lambda_{C^\ddagger}^3 V_m^\ominus} \right) \frac{2IkT}{\hbar^2} e^{-\Delta E_0/RT} \\ &= \kappa \frac{kT}{h} N_A \left( \frac{\Lambda_A \Lambda_B}{\Lambda_{C^\ddagger}} \right)^3 \frac{2IkT}{\hbar^2} e^{-\Delta E_0/RT} \end{aligned}$$

The moment of inertia of a diatomic molecule of bond length  $r$  is  $\mu r^2$ , where  $\mu = m_A m_B / (m_A + m_B)$ , so after introducing the

expressions for the thermal wavelengths and cancelling common terms, we find (Problem 21C.3)

$$k_r = \kappa N_A \left( \frac{8kT}{\pi\mu} \right)^{1/2} \pi r^2 e^{-\Delta E_0/RT}$$

Finally, by identifying  $\kappa \pi r^2$  as the reactive cross-section  $\sigma^*$ , we arrive at precisely the same expression as that obtained from simple collision theory (eqn 21A.9):

$$k_r = N_A \left( \frac{8kT}{\pi\mu} \right)^{1/2} \sigma^* e^{-\Delta E_0/RT}$$

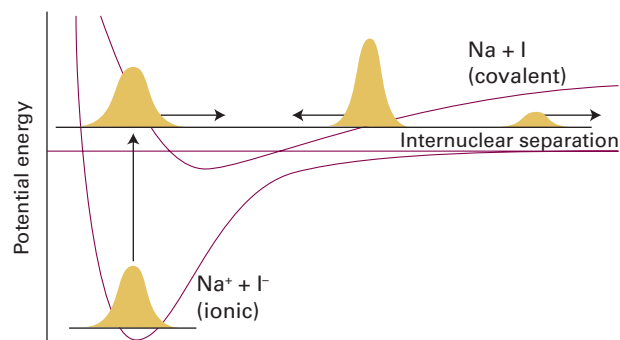

**Self-test 21C.3** What additional factors would be present if the reaction were  $AB+C \rightarrow \text{Products}$  through a linear activated complex?

Answer: Rotation and vibration of AB, bends and symmetric stretch of the activated complex

### (e) Observation and manipulation of the activated complex

The development of femtosecond pulsed lasers has made it possible to make observations on species that have such short lifetimes that in a number of respects they resemble an activated complex, which often survive for only a few picoseconds. In a typical experiment designed to detect an activated complex, a femtosecond laser pulse is used to excite a molecule to a dissociative state, and then the system is exposed to a second femtosecond pulse at an interval after the dissociating pulse. The frequency of the second pulse is set at an absorption of one of the free fragmentation products, so the intensity of its absorption is a measure of the abundance of the dissociation product. For example, when ICN is dissociated by the first pulse, the emergence of CN from the photoactivated state can be monitored by watching the growth of the free CN absorption (or, more commonly, its laser-induced fluorescence). In this way it has been found that the CN signal remains zero until the fragments have separated by about 600 pm, which takes about 205 fs.

Some sense of the progress that has been made in the study of the intimate mechanism of chemical reactions can be obtained by considering the decay of the ion pair  $\text{Na}^+\text{I}^-$ . As shown in Fig. 21C.4, excitation of the ionic species with a femtosecond laser pulse forms an excited state that corresponds to a covalently bonded NaI molecule. The system can be described with two potential energy surfaces, one largely ‘ionic’ and another ‘covalent’, which cross at an internuclear separation of 693 pm. A short laser pulse is composed of a wide range of frequencies, which excite many vibrational states of NaI simultaneously. Consequently, the electronically excited complex exists as a superposition of states, or a localized wavepacket, which oscillates between the ‘covalent’ and ‘ionic’ potential energy

**Figure 21C.4** Excitation of the ion pair  $\text{Na}^+\text{I}^-$  forms an excited state with covalent character. Also shown is migration between a 'covalent' surface (upper curve) and an 'ionic' surface (lower curve) of the wavepacket formed by laser excitation.

surfaces, as shown in Fig. 21C.4. The complex can also dissociate, shown as movement of the wavepacket towards very long internuclear separation along the dissociative surface. However, not every outward-going swing leads to dissociation because there is a chance that the I atom can be harpooned again, in which case it fails to make good its escape. The dynamics of the system is probed by a second laser pulse with a frequency that corresponds to the absorption frequency of the free Na product or to the frequency at which Na absorbs when it is a part of the complex. The latter frequency depends on the  $\text{Na}\cdots\text{I}$  distance, so an absorption (in practice, a laser-induced fluorescence) is obtained each time the wavepacket returns to that separation.

### Brief illustration 21C.3 Femtosecond analysis

A typical set of results is shown in Fig. 21C.5. The bound Na absorption intensity shows up as a series of pulses that recur in about 1 ps, showing that the wavepacket oscillates with about

**Figure 21C.5** Femtosecond spectroscopic results for the reaction in which sodium iodide separates into Na and I. The lower curve is the absorption of the electronically excited complex and the upper curve is the absorption of free Na atoms. (Adapted from A.H. Zewail, *Science* **242**, 1645 (1988).)

that period. The decline in intensity shows the rate at which the complex can dissociate as the two atoms swing away from each other. The free Na absorption also grows in an oscillating manner, showing the periodicity of wavepacket oscillation, each swing of which gives it a chance to dissociate. The precise period of the oscillation in NaI is 1.25 ps. The complex survives for about ten oscillations. In contrast, although the oscillation frequency of NaBr is similar, it barely survives one oscillation.

**Self-test 21C.4** Confirm the assumption in transition-state theory that the vibrational frequency of the dissociative mode of the activated complex is very low by calculating the vibrational wavenumber corresponding to the 1.25 ps period of oscillation in NaI.

Answer:  $27\text{ cm}^{-1}$

Femtosecond spectroscopy has also been used to examine analogues of the activated complex involved in bimolecular reactions. Thus, a molecular beam can be used to produce a complex held together by van der Waals interactions (a 'van der Waals molecule'), such as  $\text{IH}\cdots\text{OCO}$ . The HI bond can be dissociated by a femtosecond pulse, and the H atom is ejected towards the O atom of the neighbouring  $\text{CO}_2$  molecule to form HOCO. Hence, the van der Waals molecule is a source of a species that resembles the activated complex of the reaction

The probe pulse is tuned to the OH radical, which enables the evolution of  $[\text{HOCO}]^\ddagger$  to be studied in real time.

The techniques used for the spectroscopic detection of transition states can also be used to control the outcome of a chemical reaction by direct manipulation of the activated complex. Consider the reaction  $\text{I}_2 + \text{Xe} \rightarrow \text{XeI}^* + \text{I}$ , which occurs by a harpoon mechanism with an activated complex denoted as  $[\text{Xe}^+\cdots\text{I}^-\cdots\text{I}]$ . The reaction can be initiated by exciting  $\text{I}_2$  to an electronic state at least  $52\,460\text{ cm}^{-1}$  above the ground state and then followed by measuring the time dependence of the chemiluminescence of  $\text{XeI}^*$ . To exert control over the yield of the product, a pair of femtosecond pulses can be used to induce the reaction. The first pulse excites the  $\text{I}_2$  molecule to a low energy and unreactive electronic state. We already know that excitation by a femtosecond pulse generates a wavepacket that can be treated as a particle travelling across the potential energy surface. In this case, the wavepacket does not have enough energy to react, but excitation by another laser pulse with the appropriate wavelength can provide the necessary additional energy. It follows that activated complexes with different geometries can be prepared by varying the time delay between the two pulses, as the partially localized wavepacket will be at different locations on the potential energy surface as it evolves after being formed by the first pulse. Because the reaction occurs by the

harpoon mechanism, the product yield is expected to be optimal if the second pulse is applied when the wavepacket is at a point where the  $\text{Xe}\cdots\text{I}_2$  distance is just right for electron transfer from Xe to  $\text{I}_2$  to occur. This type of control of the  $\text{I}_2 + \text{Xe}$  reaction has been demonstrated.

## 21C.2 Thermodynamic aspects

The statistical thermodynamic version of transition state theory rapidly runs into difficulties because only in some cases is anything known about the structure of the activated complex. However, the concepts that it introduces, principally that of an equilibrium between the reactants and the activated complex, have motivated a more general, empirical approach in which the activation process is expressed in terms of thermodynamic functions.

### (a) Activation parameters

If we accept that  $\bar{K}^\ddagger$  is an equilibrium constant (despite one mode of  $\text{C}^\ddagger$  having been discarded), we can express it in terms of a **Gibbs energy of activation**,  $\Delta^\ddagger G$ , through the definition

$$\Delta^\ddagger G = -RT \ln \bar{K}^\ddagger \quad \text{Definition} \quad \text{Gibbs energy of activation} \quad (21C.11)$$

All the  $\Delta^\ddagger X$  in this section are *standard* thermodynamic quantities,  $\Delta^\ddagger X^\ominus$ , but we shall omit the standard state sign to avoid overburdening the notation. Then the rate constant becomes

$$k_r = \kappa \frac{kT}{h} \frac{RT}{p^\ominus} e^{-\Delta^\ddagger G/RT} \quad (21C.12)$$

Because  $G = H - TS$ , the Gibbs energy of activation can be divided into an **entropy of activation**,  $\Delta^\ddagger S$ , and an **enthalpy of activation**,  $\Delta^\ddagger H$ , by writing

$$\Delta^\ddagger G = \Delta^\ddagger H - T\Delta^\ddagger S \quad \text{Definition} \quad \text{Entropy and enthalpy of activation} \quad (21C.13)$$

When eqn 21C.13 is used in eqn 21C.12 and  $\kappa$  is absorbed into the entropy term, we obtain

$$k_r = B e^{\Delta^\ddagger S/R} e^{-\Delta^\ddagger H/RT} \quad B = \frac{kT}{h} \frac{RT}{p^\ominus} \quad (21C.14)$$

The formal definition of activation energy (eqn 20D.2 of Topic 20D,  $E_a = RT^2(\partial \ln k_r / \partial T)$ ), then gives  $E_a = \Delta^\ddagger H + 2RT$ , so<sup>1</sup>

$$k_r = e^2 B e^{\Delta^\ddagger S/R} e^{-E_a/RT} \quad (21C.15a)$$

<sup>1</sup> For reactions of the type  $A + B \rightarrow P$  in the gas phase,  $E_a = \Delta^\ddagger H + 2RT$ . For such reactions in solution,  $E_a = \Delta^\ddagger H + RT$ .

from which it follows that the Arrhenius factor  $A$  can be identified as

$$A = e^2 B e^{\Delta^\ddagger S/R} \quad \text{Transition-state theory} \quad \text{A-factor} \quad (21C.15b)$$

The entropy of activation is negative because throughout the system reactant species are combining to form reactive pairs. However, if there is a reduction in entropy below what would be expected for the simple encounter of A and B, then the Arrhenius factor  $A$  will be smaller than that expected on the basis of simple collision theory. Indeed, we can identify that *additional* reduction in entropy,  $\Delta^\ddagger S_{\text{steric}}$ , as the origin of the steric factor of collision theory, and write

$$P = e^{\Delta^\ddagger S_{\text{steric}}/R} \quad \text{Transition-state theory} \quad \text{P-factor} \quad (21C.15c)$$

Thus, the more complex the steric requirements of the encounter, the more negative the value of  $\Delta^\ddagger S_{\text{steric}}$ , and the smaller the value of  $P$ .

### Brief illustration 21C.4 Activation parameters

The reaction of propylxanthate ion in acetic acid buffer solutions can be represented by the equation  $A^- + H^+ \rightarrow P$ . Near 30 °C,  $A = 2.05 \times 10^{13} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . To evaluate the entropy of activation at 30 °C we first note that because the reaction is in solution the  $e^2$  of eqn 21C.15 should be replaced by  $e$  (see footnote 1), and then use eqn 21C.15b in the form

$$\Delta^\ddagger S = R \ln \frac{A}{eB} \quad \text{with } B = \frac{kT}{h} \frac{RT}{p^\ominus} = 1.592 \times 10^{14} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

Therefore,

$$\begin{aligned} \Delta^\ddagger S &= R \ln \frac{2.05 \times 10^{13} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}}{e \times (1.592 \times 10^{14} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1})} = R \ln 0.047 \dots \\ &= -25.4 \text{ J K}^{-1} \text{ mol}^{-1} \end{aligned}$$

**Self-test 21C.5** The reaction  $A^- + H^+ \rightarrow P$  in solution has  $A = 6.92 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Evaluate the entropy of activation at 25 °C.

Answer:  $-34.1 \text{ J K}^{-1} \text{ mol}^{-1}$

Gibbs energies, enthalpies, and entropies of activation (and volumes and heat capacities of activation) are widely used to report experimental reaction rates, especially for organic reactions in solution. They are encountered when relationships between equilibrium constants and rates of reaction are explored using **correlation analysis**, in which  $\ln K$  (which is equal to  $-\Delta_r G^\ominus/RT$ ) is plotted against  $\ln k_r$  (which is proportional to  $-\Delta^\ddagger G/RT$ ). In many cases the correlation is linear, signifying that as the reaction becomes thermodynamically more

**Figure 21C.6** For a related series of reactions, as the magnitude of the standard reaction Gibbs energy increases, so the activation barrier decreases and the rate constant increases. The approximate linear correlation between  $\Delta^\ddagger G$  and  $\Delta_r G^\ominus$  is the origin of linear free energy relations.

favourable, its rate constant increases (Fig. 21C.6). This linear correlation is the origin of the alternative name **linear free energy relation** (LFER).

### (b) Reactions between ions

The full statistical thermodynamic theory is very complicated to apply because the solvent plays a role in the activated complex. The thermodynamic version of transition-state theory simplifies the discussion of reactions in solution and is applicable to non-ideal systems. In the thermodynamic approach we combine the rate law

$$\frac{d[\text{P}]}{dt} = k^\ddagger [\text{C}^\ddagger]$$

with the thermodynamic equilibrium constant (Topic 6A)

$$K = \frac{a_{\text{C}^\ddagger}}{a_{\text{A}} a_{\text{B}}} = K_\gamma \frac{[\text{C}^\ddagger] c^\ominus}{[\text{A}][\text{B}]} \quad K_\gamma = \frac{\gamma_{\text{C}^\ddagger}}{\gamma_{\text{A}} \gamma_{\text{B}}}$$

Then

$$\frac{d[\text{P}]}{dt} = k_{\text{r}} [\text{A}][\text{B}] \quad k_{\text{r}} = \frac{k^\ddagger K}{K_\gamma c^\ominus} \quad (21\text{C.16a})$$

If  $k_{\text{r}}^\ominus$  is the rate constant when the activity coefficients are 1 (that is,  $k_{\text{r}}^\ominus = k^\ddagger K / c^\ominus$ ), we can write

$$k_{\text{r}} = \frac{k_{\text{r}}^\ominus}{K_\gamma} \quad \log k_{\text{r}} = \log k_{\text{r}}^\ominus - \log K_\gamma \quad (21\text{C.16b})$$

At low concentrations the activity coefficients can be expressed in terms of the ionic strength,  $I$ , of the solution by using the

**Figure 21C.7** Experimental tests of the kinetic salt effect for reactions in water at 298 K. The ion types are shown as spheres, and the slopes of the lines are those given by the Debye–Hückel limiting law and eqn 21C.18.

Debye–Hückel limiting law (Topic 5F, particularly eqn 5F.8,  $\log \gamma_{\pm} = -A|z_+ z_-| I^{1/2}$ ). However, we need the expressions for the individual ions rather than the mean value, and so write  $\log \gamma_{\pm} = -A z_+^2 I^{1/2}$  and

$$\log \gamma_{\text{A}} = -A z_{\text{A}}^2 I^{1/2} \quad \log \gamma_{\text{B}} = -A z_{\text{B}}^2 I^{1/2} \quad (21\text{C.17a})$$

with  $A = 0.509$  in aqueous solution at 298 K and  $z_{\text{A}}$  and  $z_{\text{B}}$  the (signed) charge numbers of A and B, respectively. Because the activated complex forms from reaction of one of the ions of A with one of the ions of B, the charge number of the activated complex is  $z_{\text{A}} + z_{\text{B}}$  where  $z_j$  is positive for cations and negative for anions. Therefore

$$\log \gamma_{\text{C}^\ddagger} = -A(z_{\text{A}} + z_{\text{B}})^2 I^{1/2} \quad (21\text{C.17b})$$

Inserting these relations into eqn 21C.16b results in

$$\begin{aligned} \log k_{\text{r}} &= \log k_{\text{r}}^\ominus - A\{z_{\text{A}}^2 + z_{\text{B}}^2 - (z_{\text{A}} + z_{\text{B}})^2\} I^{1/2} \\ &= \log k_{\text{r}}^\ominus + 2A z_{\text{A}} z_{\text{B}} I^{1/2} \end{aligned} \quad (21\text{C.18})$$

Equation 21C.18 expresses the **kinetic salt effect**, the variation of the rate constant of a reaction between ions with the ionic strength of the solution (Fig. 21C.7). If the reactant ions have the same sign (as in a reaction between cations or between anions), then increasing the ionic strength by the addition of inert ions increases the rate constant. The formation of a single, highly charged ionic complex from two less highly charged ions is favoured by a high ionic strength because the new ion has a denser ionic atmosphere and interacts with that atmosphere more strongly. Conversely, ions of opposite charge react more slowly in solutions of high ionic strength. Now the charges cancel and the complex has a less favourable interaction with its atmosphere than the separated ions.

**Example 21C.2** Analysing the kinetic salt effect

The rate constant for the base ( $\text{OH}^-$ ) hydrolysis of  $[\text{CoBr}(\text{NH}_3)_5]^{2+}$  varies with ionic strength as tabulated below. What can be deduced about the charge of the activated complex in the rate-determining stage? We cannot assume without more evidence that it is a bimolecular process with an activated complex of charge +1.

$I$	0.0050	0.0100	0.0150	0.0200	0.0250	0.0300
$k_r/k_r^\circ$	0.718	0.631	0.562	0.515	0.475	0.447

**Method** According to eqn 21C.18, a plot of  $\log(k_r/k_r^\circ)$  against  $I^{1/2}$  will have a slope of  $1.02z_A z_B$ , from which we can infer the charges of the ions involved in the formation of the activated complex.

**Answer** Form the following table:

$I$	0.0050	0.0100	0.0150	0.0200	0.0250	0.0300
$I^{1/2}$	0.071	0.100	0.122	0.141	0.158	0.173
$\log(k_r/k_r^\circ)$	-0.14	-0.20	-0.25	-0.29	-0.32	-0.35

These points are plotted in Fig. 21C.8. The slope of the (least squares) straight line is  $-2.04$ , indicating that  $z_A z_B = -2$ . Because  $z_A = -1$  for the  $\text{OH}^-$  ion, if that ion is involved in the formation of the activated complex, then the charge number of the second ion is +2. This analysis suggests that the pentaamminebromidocobalt(III) cation  $[\text{CoBr}(\text{NH}_3)_5]^{2+}$  participates in the formation of the activated complex and that the charge of the activated complex is  $-1 + 2 = +1$ . Although we do not pursue the point here, you should be aware that the rate constant is also influenced by the relative permittivity of the medium.

**Figure 21C.8** The experimental ionic strength dependence of the rate constant of a hydrolysis reaction: the slope gives information about the charge types involved in the activated complex of the rate determining step. See Example 21C.2.

**Self-test 21C.6** An ion of charge number +1 is known to be involved in the activated complex of a reaction. Deduce the charge number of the other ion from the following data:

$I$	0.0050	0.0100	0.0150	0.0200	0.0250	0.0300
$k_r/k_r^\circ$	0.930	0.902	0.884	0.867	0.853	0.841

Answer:  $-1$

**21C.3 The kinetic isotope effect**

The postulation of a plausible reaction mechanism requires careful analysis of many experiments designed to determine the fate of atoms during the formation of products. Observation of the **kinetic isotope effect**, a decrease in the rate of a chemical reaction upon replacement of one atom in a reactant by a heavier isotope, facilitates the identification of bond-breaking events in the rate-determining step. A **primary kinetic isotope effect** is observed when the rate-determining step requires the scission of a bond involving the isotope. A **secondary kinetic isotope effect** is the reduction in reaction rate even though the bond involving the isotope is not broken to form product. In both cases, the effect arises from the change in activation energy that accompanies the replacement of an atom by a heavier isotope on account of changes in the zero-point vibrational energies. We now explore the primary kinetic isotope effect in some detail.

Consider a reaction in which a C–H bond is cleaved. If scission of this bond is the rate-determining step (Topic 20E), then the reaction coordinate corresponds to the stretching of the C–H bond and the potential energy profile is shown in Fig. 21C.9. On deuteration, the dominant change is the reduction of the zero-point energy of the bond (because the deuterium atom is heavier). The whole reaction profile is not lowered, however, because the relevant vibration in the activated complex has a very low force constant, so there is little zero-point energy associated with the reaction coordinate in either form of the activated complex. We show in the following *Justification*, that, as a consequence of this reduction, the activation energy change upon deuteration is

$$E_a(\text{C-D}) - E_a(\text{C-H}) = \frac{1}{2} N_A \hbar \omega(\text{C-H}) \left\{ 1 - \left( \frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} \right\} \quad (21\text{C.19})$$

where  $\omega$  is the relevant vibrational frequency (in radians per second),  $\mu$  is the relevant effective mass, and

$$\frac{k_r(\text{C-D})}{k_r(\text{C-H})} = e^{-\zeta} \quad \text{with} \quad \zeta = \frac{\hbar \omega(\text{C-H})}{2kT} \left\{ 1 - \left( \frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} \right)^{1/2} \right\} \quad (21\text{C.20})$$

**Figure 21C.9** Changes in the reaction profile when a C–H bond undergoing cleavage is deuterated. In this figure the C–H and C–D bonds are modelled as harmonic oscillators. The only significant change is in the zero-point energy of the reactants, which is lower for C–D than for C–H. As a result, the activation energy is greater for C–D cleavage than for C–H cleavage.

Note that  $\zeta > 0$  ( $\zeta$  is zeta) because  $\mu_{\text{CD}} > \mu_{\text{CH}}$  and that  $k_{\text{r}}(\text{C–D})/k_{\text{r}}(\text{C–H}) < 1$ , meaning that, as expected from Fig. 21C.9, the rate constant decreases upon deuteration. We also conclude that  $k_{\text{r}}(\text{C–D})/k_{\text{r}}(\text{C–H})$  decreases with decreasing temperature.

#### Justification 21C.1 The primary kinetic isotope effect

We assume that, to a good approximation, a change in the activation energy arises only from the change in zero-point energy of the stretching vibration, so, from Fig. 21C.9,

$$\begin{aligned} E_{\text{a}}(\text{C–D}) - E_{\text{a}}(\text{C–H}) &= N_{\text{A}} \left\{ \frac{1}{2} \hbar \omega(\text{C–H}) - \frac{1}{2} \hbar \omega(\text{C–D}) \right\} \\ &= \frac{1}{2} N_{\text{A}} \hbar \{ \omega(\text{C–H}) - \omega(\text{C–D}) \} \end{aligned}$$

where  $\omega$  is the relevant vibrational frequency. From Topic 12D, we know that  $\omega(\text{C–D}) = (\mu_{\text{CH}}/\mu_{\text{CD}})^{1/2} \omega(\text{C–H})$ , where  $\mu$  is the relevant effective mass. Making this substitution in the equation above gives eqn 21C.19.

If we assume further that the pre-exponential factor does not change upon deuteration, then the rate constants for the two species should be in the ratio

$$\frac{k_{\text{r}}(\text{C–D})}{k_{\text{r}}(\text{C–H})} = e^{-\{E_{\text{a}}(\text{C–D}) - E_{\text{a}}(\text{C–H})\}/RT} = e^{-\{E_{\text{a}}(\text{C–D}) - E_{\text{a}}(\text{C–H})\}/N_{\text{A}}kT}$$

where we used  $R = N_{\text{A}}k$ . Equation 21C.20 follows after using eqn 21C.19 for  $E_{\text{a}}(\text{C–D}) - E_{\text{a}}(\text{C–H})$  in this expression.

#### Brief illustration 21C.5 The primary kinetic isotope effect

From infrared spectra, the fundamental vibrational wavenumber  $\tilde{\nu}$  for stretching of a C–H bond is about  $3000 \text{ cm}^{-1}$ . To convert this wavenumber to an angular frequency,  $\omega = 2\pi\nu$ , we use  $\omega = 2\pi c\tilde{\nu}$  and it follows that

$$\begin{aligned} \omega &= 2\pi \times (2.998 \times 10^{10} \text{ cm s}^{-1}) \times (3000 \text{ cm}^{-1}) \\ &= 5.65 \dots \times 10^{14} \text{ s}^{-1} \end{aligned}$$

The ratio of effective masses is

$$\begin{aligned} \frac{\mu_{\text{CH}}}{\mu_{\text{CD}}} &= \left( \frac{m_{\text{C}}m_{\text{H}}}{m_{\text{C}} + m_{\text{H}}} \right) \times \left( \frac{m_{\text{C}} + m_{\text{D}}}{m_{\text{C}}m_{\text{D}}} \right) \\ &= \left( \frac{12.01 \times 1.0078}{12.01 + 1.0078} \right) \times \left( \frac{12.01 + 2.0140}{12.01 \times 2.0140} \right) = 0.539 \dots \end{aligned}$$

Now we can use eqn 21C.20, to calculate

$$\begin{aligned} \zeta &= \frac{(1.055 \times 10^{-34} \text{ J s}) \times (5.65 \dots \times 10^{14} \text{ s}^{-1})}{2 \times (1.381 \times 10^{-23} \text{ J K}^{-1}) \times (298 \text{ K})} \times (1 - 0.539 \dots)^{1/2} \\ &= 1.92 \dots \end{aligned}$$

and

$$\frac{k_{\text{r}}(\text{C–D})}{k_{\text{r}}(\text{C–H})} = e^{-1.92 \dots} = 0.146$$

We conclude that at room temperature C–H cleavage should be about seven times faster than C–D cleavage, other conditions being equal. However, experimental values of  $k_{\text{r}}(\text{C–D})/k_{\text{r}}(\text{C–H})$  can differ significantly from those predicted by eqn 21C.20 on account of the severity of the assumptions in the model.

**Self-test 21C.7** The bromination of a deuterated hydrocarbon at 298 K proceeds 6.4 times more slowly than the bromination of the undeuterated material. What value of the force constant for the cleaved bond can account for this difference?

$$k_{\text{f}} = 450 \text{ N m}^{-1}, \text{ which is consistent with } k_{\text{f}}(\text{C–H})$$

**Figure 21C.10** A proton can tunnel through the activation energy barrier that separates reactants from products, so the effective height of the barrier is reduced and the rate of the proton transfer reaction increases. The effect is represented by drawing the wavefunction of the proton near the barrier. Proton tunnelling is important only at low temperatures, when most of the reactants are trapped on the left of the barrier.

In some cases, substitution of deuterium for hydrogen results in values of  $k_r(\text{C-D})/k_r(\text{C-H})$  that are too low to be accounted for by eqn 21C.20, even when more complete models are used to predict ratios of rate constants. Such abnormal kinetic isotope effects are evidence for a path in which quantum mechanical tunnelling of hydrogen atoms takes place through the activation barrier (Fig 21C.10). The probability of tunnelling through a barrier decreases as the mass of the particle increases

(Topic 8A), so deuterium tunnels less efficiently through a barrier than hydrogen and its reactions are correspondingly slower. Quantum mechanical tunnelling can be the dominant process in reactions involving hydrogen atom or proton transfer when the temperature is so low that very few reactant molecules can overcome the activation energy barrier. We see in Topic 21E that because  $m_e$  is so small, tunnelling is also a very important contributor to the rates of electron transfer reactions.

## Checklist of concepts

- 1. In transition-state theory, it is supposed that an **activated complex** is in equilibrium with the reactants.
- 2. The rate at which the activated complex forms products depends on the rate at which it passes through a **transition state**.
- 3. The rate constant may be parameterized in terms of the **Gibbs energy, entropy, and enthalpy of activation**.
- 4. The **kinetic salt effect** is the effect of an added inert salt on the rate of a reaction between ions.
- 5. The **kinetic isotope effect** is the decrease in the rate constant of a chemical reaction upon replacement of one atom in a reactant by a heavier isotope.

## Checklist of equations

Property	Equation	Comment	Equation number
'Equilibrium constant' for activated complex formation	$\bar{K}^\ddagger = \left( N_A \bar{q}_{\text{C}^\ddagger} / q_{\text{A}} q_{\text{B}} \right) e^{-\Delta E_0 / RT}$	Assume equilibrium; one vibrational mode of $\text{C}^\ddagger$ discarded	21C.9
Eyring equation	$k_r = \kappa (kT/h) \bar{K}_c^\ddagger$	Transition-state theory	21C.10
Gibbs energy of activation	$\Delta^\ddagger G = -RT \ln \bar{K}^\ddagger$	Definition	21C.11
Enthalpy and entropy of activation	$\Delta^\ddagger G = \Delta^\ddagger H - T\Delta^\ddagger S$	Definition	21C.13
Parameterization	$k_r = e^n B e^{\Delta^\ddagger S / R} e^{-E_a / RT}$	$n=2$ for gas-phase reactions; $n=1$ for solution	21C.15a
A-factor	$A = e^n B e^{\Delta^\ddagger S / R}$		21C.15b
P-factor	$P = e^{\Delta^\ddagger S_{\text{steric}} / R}$		21C.15c
Kinetic salt effect	$\log k_r = \log k_r^\circ + 2A z_A z_B I^{1/2}$	Assumes Debye-Hückel limiting law valid	21C.18
Primary kinetic isotope effect	$k_r(\text{C-D})/k_r(\text{C-H}) = e^{-\zeta}$ , $\zeta = (\hbar\omega(\text{C-H})/2kT) \times \{1 - (\mu_{\text{CH}}/\mu_{\text{CD}})^{1/2}\}$	Cleavage of a C-H/D bond in the rate-determining step	21C.20

### ► Why do you need to know this material?

Chemists need to be interested in the details of chemical reactions, and there is no more detailed approach than that involved in the study of the dynamics of reactive encounters, when one molecule collides with another and atoms exchange partners.

### ► What is the key idea?

The rates of reactions in the gas phase can be investigated by exploring the trajectories of molecules on potential energy surfaces.

### ► What do you need to know already?

This Topic builds on the concept of rate constant (Topic 20A) and in one part of the discussion uses the concept of partition function (Topic 15B). The discussion of potential energy surfaces is qualitative, but the underlying calculations are those of self-consistent field theory (Topic 10E).

The investigation of the dynamics of the collisions between reactant molecules is the most detailed level of the examination of the factors that govern the rates of reactions. There are two approaches: an experimental one that uses molecular beams and a theoretical one that uses the results of computations. In this Topic we describe both approaches and the link between them.

## 21D.1 Molecular beams

**Molecular beams**, which consist of collimated, narrow streams of molecules travelling through an evacuated vessel, allow collisions between molecules in preselected states (for example, specific rotational and vibrational states) to be studied, and can be used to identify the states of the products of a reactive collision. Information of this kind is essential if a full picture of the reaction is to be built, because the rate constant is an average over events in which reactants in different initial states evolve into products in their final states.

### (a) Techniques

The basic arrangement of a molecular beam experiment is shown in Fig. 21D.1. If the pressure of vapour in the source is increased so that the mean free path of the molecules in the emerging beam is much shorter than the diameter of the pin-hole, many collisions take place even outside the source. The net effect of these collisions, which give rise to **hydrodynamic**

**Figure 21D.1** The basic arrangement of a molecular beam apparatus. The atoms or molecules emerge from a heated source, and pass through the velocity selector, a rotating series of slotted discs, such as that discussed in Topic 1B. The scattering occurs from the target gas (which might take the form of another beam), and the flux of particles entering the detector set at some angle is recorded.

**flow**, is to transfer momentum into the direction of the beam. The molecules in the beam then travel with very similar speeds, so further downstream few collisions take place between them. This condition is called **molecular flow**. Because the spread in speeds is so small, the molecules are effectively in a state of very low translational temperature (Fig. 21D.2). The translational temperature may reach as low as 1 K. Such jets are called **supersonic** because the average speed of the molecules in the jet is much greater than the speed of sound in the jet.

A supersonic jet can be converted into a more parallel **supersonic beam** if it is 'skimmed' in the region of hydrodynamic flow and the excess gas pumped away. A skimmer consists of a conical nozzle shaped to avoid any supersonic shock waves spreading back into the gas and so increasing the translational temperature (Fig. 21D.3). A jet or beam may also be formed by using helium or neon as the principal gas, and injecting molecules of interest into it in the hydrodynamic region of flow.

The low translational temperature of the molecules is reflected in their low rotational and vibrational temperatures. In this context, a rotational or vibrational temperature means the temperature that should be used in the Boltzmann distribution to reproduce the observed populations of the states. However, as rotational states equilibrate more slowly than translational states, and vibrational states equilibrate even more slowly, the rotational and vibrational populations of the species correspond to somewhat higher temperatures, of the order of 10 K for rotation and 100 K for vibrations.

The target gas may be either a bulk sample or another molecular beam. The detectors may consist of a chamber fitted with a sensitive pressure gauge, a bolometer (a detector that responds to the incident energy by making use of the temperature-dependence of resistance), or an ionization detector, in which the incoming molecule is first ionized and then detected electronically. The rotational and vibrational state of the scattered molecules may also be determined spectroscopically.

## (b) Experimental results

The primary experimental information from a molecular beam experiment is the fraction of the molecules in the incident

Figure 21D.2 The shift in the mean speed and the width of the distribution brought about by use of a supersonic nozzle.

Figure 21D.3 A supersonic nozzle skims off some of the molecules of the beam and leads to a beam with well-defined velocity.

beam that are scattered into a particular direction. The fraction is normally expressed in terms of  $dI$ , the rate at which molecules are scattered into a cone (described by a solid angle  $d\Omega$ ) that represents the area covered by the 'eye' of the detector (Fig. 21D.4). This rate is reported as the **differential scattering cross-section**,  $\sigma$ , the constant of proportionality between the value of  $dI$  and the intensity,  $I$ , of the incident beam, the number density of target molecules,  $\mathcal{N}$ , and the infinitesimal path length  $dx$  through the sample:

$$dI = \sigma I \mathcal{N} dx \quad \text{Definition} \quad \text{Differential scattering cross-section} \quad (21D.1)$$

The value of  $\sigma$  (which has the dimensions of area) depends on the **impact parameter**,  $b$ , the initial perpendicular separation of the paths of the colliding molecules (Fig. 21D.5), and the details of the intermolecular potential.

The role of the impact parameter is most easily seen by considering the impact of two hard spheres (Fig. 21D.6). If  $b=0$ ,

Figure 21D.4 The definition of the solid angle,  $d\Omega$ , for scattering.

Figure 21D.5 The definition of the impact parameter,  $b$ , as the perpendicular separation of the initial paths of the particles.

**Figure 21D.6** Three typical cases for the collisions of two hard spheres: (a)  $b=0$ , giving backward scattering; (b)  $b > R_A + R_B$ , giving forward scattering; (c)  $0 < b < R_A + R_B$ , leading to scattering into one direction on a ring of possibilities. (The target molecule is taken to be so heavy that it remains virtually stationary.)

the projectile is on a trajectory that leads to a head-on collision, so the only scattering intensity is detected when the detector is at  $\theta=\pi$ . When the impact parameter is so great that the spheres do not make contact ( $b > R_A + R_B$ ), there is no scattering and the scattering cross-section is zero at all angles except  $\theta=0$ . Glancing blows, with  $0 < b \leq R_A + R_B$ , lead to scattering intensity in cones around the forward direction

The scattering pattern of real molecules, which are not hard spheres, depends on the details of the intermolecular potential, including the anisotropy that is present when the molecules are non-spherical. The scattering also depends on the relative speed of approach of the two particles: a very fast particle might pass through the interaction region without much deflection, whereas a slower one on the same path might be temporarily captured and undergo considerable deflection (Fig. 21D.7). The variation of the scattering cross-section with the relative speed of approach should therefore give information about the strength and range of the intermolecular potential.

**Figure 21D.7** The extent of scattering may depend on the relative speed of approach as well as the impact parameter. The dark central zone represents the repulsive core; the fuzzy outer zone represents the long-range attractive potential.

A further point is that the outcome of collisions is determined by quantum, not classical, mechanics. The wave nature of the particles can be taken into account, at least to some extent, by drawing all classical trajectories that take the projectile particle from source to detector, and then considering the effects of interference between them.

Two quantum mechanical effects are of great importance. A particle with a certain impact parameter might approach the attractive region of the potential in such a way that the particle is deflected towards the repulsive core (Fig. 21D.8), which then repels it out through the attractive region to continue its flight in the forward direction. Some molecules, however, also travel in the forward direction because they have impact parameters so large that they are undeflected. The wavefunctions of the particles that take the two types of path interfere, and the intensity in the forward direction is modified. The effect is called **quantum oscillation**. The same phenomenon accounts for the optical ‘glory effect’, in which a bright halo can sometimes be seen surrounding an illuminated object. (The coloured rings around the shadow of an aircraft cast on clouds by the Sun, and often seen in flight, are an example of an optical glory.)

The second quantum effect we need consider is the observation of a strongly enhanced scattering in a non-forward direction. This effect is called **rainbow scattering** because the same mechanism accounts for the appearance of an optical rainbow. The origin of the phenomenon is illustrated in Fig. 21D.9. As the impact parameter decreases, there comes a stage at which the scattering angle passes through a maximum and the interference between the paths results in a strongly scattered beam. The **rainbow angle**,  $\theta_r$ , is the angle for which  $d\theta/db=0$  and the scattering is strong.

Another phenomenon that can occur in certain beams is the capturing of one species by another. The vibrational temperature in supersonic beams is so low that **van der Waals molecules** may be formed, which are complexes of the form AB in which A and B are held together by van der Waals forces or hydrogen bonds. Large numbers of such molecules have been studied spectroscopically, including ArHCl, (HCl)<sub>2</sub>, ArCO<sub>2</sub>, and (H<sub>2</sub>O)<sub>2</sub>. More recently, van der Waals clusters of water molecules have been pursued as far as (H<sub>2</sub>O)<sub>6</sub>. The study of their

**Figure 21D.8** Two paths leading to the same destination will interfere quantum mechanically; in this case they give rise to quantum oscillations in the forward direction.

**Figure 21D.9** The interference of paths leading to rainbow scattering. The rainbow angle,  $\theta_r$ , is the maximum scattering angle reached as  $b$  is decreased. Interference between the numerous paths at that angle modifies the scattering intensity markedly.

spectroscopic properties gives detailed information about the intermolecular potentials involved.

## 21D.2 Reactive collisions

Detailed experimental information about the intimate processes that occur during reactive encounters comes from molecular beams, especially **crossed molecular beams** (Fig. 21D.10). The detector for the products of the collision of molecules in the two beams can be moved to different angles to observe so the angular distribution of the products. Because the molecules in the incoming beams can be prepared with different energies (for example, with different translational energies by using rotating sectors and supersonic nozzles, with different vibrational energies by using selective excitation with lasers, and with different orientations by using electric fields), it is possible to study the dependence of the success of collisions on these variables and to study how they affect the properties of the product molecules.

**Figure 21D.10** In a crossed-beam experiment, state-selected molecules are generated in two separate sources, and are directed perpendicular to one another. The detector responds to molecules (which may be product molecules if a chemical reaction occurs) scattered into a chosen direction.

### (a) Probes of reactive collisions

One method for examining the energy distribution in the products is **infrared chemiluminescence**, in which vibrationally excited molecules emit infrared radiation as they return to their ground states. By studying the intensities of the infrared emission spectrum, the populations of the vibrational states of the products may be determined (Fig. 21D.11). Another method makes use of **laser-induced fluorescence**. In this technique, a laser is used to excite a product molecule from a specific vibration–rotation level; the intensity of the fluorescence from the upper state is monitored and interpreted in terms of the population of the initial vibration–rotation state. When the molecules being studied do not fluoresce efficiently, versions of Raman spectroscopy (Topic 12A) can be used to monitor the progress of reaction. **Multiphoton ionization** (MPI) techniques are also good alternatives for the study of weakly fluorescing molecules. In MPI, the absorption by a molecule of several photons from one or more pulsed lasers results in ionization if the total photon energy is greater than the ionization energy of the molecule.

The angular distribution of products can be determined by **reaction product imaging**. In this technique, product ions are accelerated by an electric field towards a phosphorescent screen and the light emitted from specific spots where the ions struck the screen is imaged by a charge-coupled device (CCD). An important variant of MPI is **resonant multiphoton ionization** (REMPI), in which one or more photons promote a molecule to an electronically excited state and then additional photons are used to generate ions from the excited state. The power of REMPI lies in the fact that the experimenter can choose which reactant or product to study by tuning the laser frequency to the electronic absorption band of a specific molecule.

### (b) State-to-state reaction dynamics

The concept of collision cross-section is introduced in connection with collision theory in Topic 21A, where it is shown

**Figure 21D.11** Infrared chemiluminescence from CO produced in the reaction  $\text{O} + \text{CS} \rightarrow \text{CO} + \text{S}$  arises from the non-equilibrium populations of the vibrational states of CO and the radiative relaxation to equilibrium.

that the second-order rate constant,  $k_r$ , can be expressed as a Boltzmann-weighted average of the reactive cross-section and the relative speed of approach of the colliding reactant molecules. We shall write eqn 21A.6 of that Topic ( $k_r = N_A \int_0^\infty \sigma(\varepsilon) v_{\text{rel}} f(\varepsilon) d\varepsilon$ ) as

$$k_r = \langle \sigma v_{\text{rel}} \rangle N_A \quad (21D.2)$$

where the angle brackets denote a Boltzmann average. Molecular beam studies provide a more sophisticated version of this quantity, for they provide the **state-to-state cross-section**,  $\sigma_{nn'}$ , and hence the **state-to-state rate constant**,  $k_{nn'}$  for the reactive transition from initial state  $n$  of the reactants to final state  $n'$  of the products:

$$k_{nn'} = \langle \sigma_{nn'} v_{\text{rel}} \rangle N_A \quad \text{State-to-state rate constant} \quad (21D.3)$$

The rate constant  $k_r$  is the sum of the state-to-state rate constants over all final states (because a reaction is successful whatever the final state of the products) and over a Boltzmann-weighted sum of initial states (because the reactants are initially present with a characteristic distribution of populations at a temperature  $T$ ):

$$k_r = \sum_{n,n'} k_{nn'}(T) f_n(T) \quad (21D.4)$$

where  $f_n(T)$  is the Boltzmann factor at a temperature  $T$ . It follows that if we can determine or calculate the state-to-state cross-sections for a wide range of approach speeds and initial and final states, then we have a route to the calculation of the rate constant for the reaction.

#### Brief illustration 21D.1 The state-to-state rate constant

Suppose a harmonic oscillator collides with another oscillator of the same effective mass and force constant. If the state-to-state rate constant for the excitation of the latter's vibration is  $k_{vv'} = k_r^\circ \delta_{vv'}$  for all the states  $v$  and  $v'$ , implying that an excitation can flow only from any level to the same level of the second oscillator, then at a temperature  $T$ , when  $f_v(T) = e^{-v h \nu / kT} / q$ , where  $q$  is the molecular vibrational partition function (Topic 15B,  $q = 1 / (1 - e^{-h \nu / kT})$ ), the overall rate constant is

$$k_r = \frac{k_r^\circ}{q} \sum_{v,v'} \delta_{vv'} e^{-v h \nu / kT} = \frac{k_r^\circ}{q} \sum_{v'} \overbrace{e^{-v' h \nu / kT}}^q = k_r^\circ$$

**Self-test 21D.1** Now suppose that  $k_{vv'} = k_r^\circ \delta_{vv'} e^{-\lambda v}$ , implying that the transfer becomes less efficient as the vibrational quantum number increases. Evaluate  $k_r$ .

$$\text{Answer: } k_r = k_r^\circ (1 - e^{-h \nu / kT}) / (1 - e^{-(\lambda + h \nu / kT)})$$

## 21D.3 Potential energy surfaces

One of the most important concepts for discussing beam results and calculating the state-to-state collision cross-section is the **potential energy surface** of a reaction, the potential energy as a function of the relative positions of all the atoms taking part in the reaction. Potential energy surfaces may be constructed from experimental data and from results of quantum chemical calculations (Topic 10E). The theoretical method requires the systematic calculation of the energies of the system in a large number of geometrical arrangements. Special computational techniques, such as those described in Topic 10E, are used to take into account electron correlation, which arises from interactions between electrons as they move closer to and farther from each other in a molecule or molecular cluster. Techniques that incorporate electron correlation accurately are very time consuming and, consequently, only reactions between relatively simple particles, such as the reactions  $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$  and  $\text{H} + \text{H}_2\text{O} \rightarrow \text{OH} + \text{H}_2$ , currently are amenable to this type of theoretical treatment. An alternative is to use semi-empirical methods, in which results of calculations and experimental parameters are used to construct the potential energy surface.

To illustrate the features of a potential energy surface, consider the collision between an H atom and an  $\text{H}_2$  molecule. Detailed calculations show that the approach of an atom  $\text{H}_A$  along the  $\text{H}_B\text{--H}_C$  axis requires less energy for reaction than any other approach, so initially we confine our attention to that collinear approach. Two parameters are required to define the nuclear separations: the  $\text{H}_A\text{--H}_B$  separation  $R_{AB}$  and the  $\text{H}_B\text{--H}_C$  separation  $R_{BC}$ .

At the start of the encounter  $R_{AB}$  is effectively infinite and  $R_{BC}$  is the  $\text{H}_2$  equilibrium bond length. At the end of a successful reactive encounter  $R_{AB}$  is equal to the equilibrium bond length and  $R_{BC}$  is infinite. The total energy of the three-atom system depends on their relative separations, and can be found by doing an electronic structure calculation. The plot of the total energy of the system against  $R_{AB}$  and  $R_{BC}$  gives the potential energy surface of this collinear reaction (Fig. 21D.12). This surface is normally depicted as a contour diagram (Fig. 21D.13).

**Figure 21D.12** The potential energy surface for the  $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$  reaction when the atoms are constrained to be collinear.

**Figure 21D.13** The contour diagram (with contours of equal potential energy) corresponding to the surface in Fig. 21D.12.  $R_e$  marks the equilibrium bond length of an  $H_2$  molecule (strictly, it relates to the arrangement when the third atom is at infinity).

When  $R_{AB}$  is very large, the variation in potential energy represented by the surface as  $R_{BC}$  changes is that of an isolated  $H_2$  molecule as its bond length is altered. A section through the surface at  $R_{AB} = \infty$ , for example, is the same as the  $H_2$  bonding potential energy curve. At the edge of the diagram where  $R_{BC}$  is very large, a section through the surface is the molecular potential energy curve of an isolated  $H_A H_B$  molecule.

#### Brief illustration 21D.2 A potential energy surface

The bimolecular reaction  $H + O_2 \rightarrow OH + O$  plays an important role in combustion processes. The reaction can be characterized in terms of the  $HO_2$  potential energy surface and the two distances for collinear approach  $R_{HO_A}$  and  $R_{O_A O_B}$ . When  $R_{HO_A}$  is very large, the variation of the  $HO_2$  potential energy with  $R_{O_A O_B}$  is that of an isolated dioxygen molecule as its bond length is changed. Similarly, when  $R_{O_A O_B}$  is very large, a section through the potential energy surface is the molecular potential energy curve of an isolated OH radical.

**Self-test 21D.2** Repeat the analysis for  $H + OD \rightarrow OH + D$ .

Answer:  $R_{HO}$  at infinity: OD potential energy curve;  
 $R_{OD}$  at infinity: OH potential energy curve

The actual path of the atoms in the course of the encounter depends on their total energy, the sum of their kinetic and potential energies. However, we can obtain an initial idea of the paths available to the system by identifying paths that correspond to least potential energy. For example, consider the changes in potential energy as  $H_A$  approaches  $H_B H_C$ . If the  $H_B-H_C$  bond length is constant during the initial approach of  $H_A$ , then the potential energy of the  $H_3$  cluster rises along the path marked A in Fig. 21D.14. We see that the potential energy reaches a high value as  $H_A$  is pushed into the molecule and then decreases sharply as  $H_C$  breaks off and separates to a great distance. An alternative reaction path can be imagined (B) in

**Figure 21D.14** Various trajectories through the potential energy surface shown in Fig. 21D.13. Path A corresponds to a route in which  $R_{BC}$  is held constant as  $H_A$  approaches; path B corresponds to a route in which  $R_{BC}$  lengthens at an early stage during the approach of  $H_A$ ; path C is the route along the floor of the potential valley.

which the  $H_B-H_C$  bond length increases while  $H_A$  is still far away. Both paths, although feasible if the molecules have sufficient initial kinetic energy, take the three atoms to regions of high potential energy in the course of the encounter.

The path of least potential energy is the one marked C, corresponding to  $R_{BC}$  lengthening as  $H_A$  approaches and begins to form a bond with  $H_B$ . The  $H_B-H_C$  bond relaxes at the demand of the incoming atom, and the potential energy climbs only as far as the saddle-shaped region of the surface, to the saddle point marked  $C^\ddagger$ . The encounter of least potential energy is one in which the atoms take route C up the floor of the valley, through the saddle point, and down the floor of the other valley as  $H_C$  recedes and the new  $H_A-H_B$  bond achieves its equilibrium length. This path is the reaction coordinate.

We can now make contact with the transition-state theory of reaction rates (Topic 21C). In terms of trajectories on potential surfaces with a total energy close to the saddle point energy, the transition state can be identified with a critical geometry such that every trajectory that goes through this geometry goes on to react (Fig. 21D.15). Most trajectories on potential energy

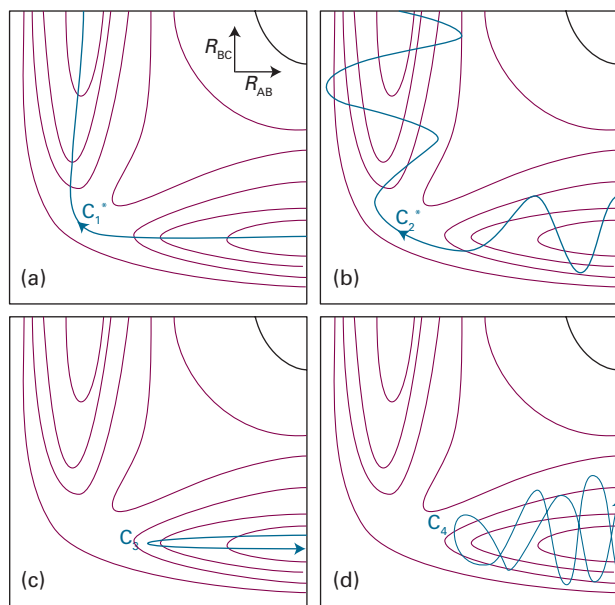

**Figure 21D.15** The transition state is a set of configurations (here, marked by the purple line across the saddle point) through which successful reactive trajectories must pass.

surfaces do not go directly over the saddle point and therefore, to result in a reaction, they require a total energy significantly higher than the saddle point energy. As a result, the experimentally determined activation energy is often significantly higher than the calculated saddle-point energy.

## 21D.4 Some results from experiments and calculations

Although quantum mechanical tunnelling can play an important role in reactivity, particularly in hydrogen atom and electron transfer reactions, initially we can consider the classical trajectories of particles over surfaces. From this viewpoint, to travel successfully from reactants to products, the incoming molecules must possess enough kinetic energy to be able to climb to the saddle point of the potential surface. Therefore, the shape of the surface can be explored experimentally by changing the relative speed of approach (by selecting the beam velocity) and the degree of vibrational excitation and observing whether reaction occurs and whether the products emerge in a vibrationally excited state (Fig. 21D.16). For example, one question that can be answered is whether it is better to smash

**Figure 21D.16** Some successful (\*) and unsuccessful encounters. (a)  $C_1^*$  corresponds to the path along the foot of the valley; (b)  $C_2^*$  corresponds to an approach of A to a vibrating BC molecule, and the formation of a vibrating AB molecule as C departs. (c)  $C_3$  corresponds to A approaching a non-vibrating BC molecule, but with insufficient translational kinetic energy; (d)  $C_4$  corresponds to A approaching a vibrating BC molecule, but still the energy, and the phase of the vibration, is insufficient for reaction.

the reactants together with a lot of translational kinetic energy or to ensure instead that they approach in highly excited vibrational states. Thus, is trajectory  $C_2^*$ , where the  $H_B H_C$  molecule is initially vibrationally excited, more efficient at leading to reaction than the trajectory  $C_1^*$ , in which the total energy is the same but reactants have a high translational kinetic energy?

### (a) The direction of attack and separation

Figure 21D.17 shows the results of a calculation of the potential energy as an H atom approaches an  $H_2$  molecule from different angles, the  $H_2$  bond being allowed to relax to the optimum length in each case. The potential barrier is least for collinear attack, as we assumed earlier. (But we must be aware that other lines of attack are feasible and contribute to the overall rate.) In contrast, Fig. 21D.18 shows the potential energy changes that occur as a Cl atom approaches an HI molecule. The lowest barrier occurs for approaches within a cone of half-angle  $30^\circ$  surrounding the H atom. The relevance of this result to the calculation of the steric factor of collision theory should be noted: not every collision is successful, because they do not all lie within the reactive cone.

**Figure 21D.17** An indication of how the anisotropy of the potential energy changes as H approaches  $H_2$  with different angles of attack. The collinear attack has the lowest potential barrier to reaction. The surface indicates the potential energy profile along the reaction coordinate for each configuration.

**Figure 21D.18** The potential energy barrier for the approach of Cl to HI. In this case, successful encounters occur only when Cl approaches within a cone surrounding the H atom.

If the collision is sticky, so that when the reactants collide they orbit around each other, the products can be expected to emerge in random directions because all memory of the approach direction has been lost. A rotation takes about 1 ps, so if the collision is over in less than that time the complex will not have had time to rotate and the products will be thrown off in a specific direction. In the collision of K and  $I_2$ , for example, most of the products are thrown off in the forward direction (forward and backward directions refer to directions in a centre-of-mass coordinate system with the origin at the centre of mass of the colliding reactants and collision occurring when molecules are at the origin.) This product distribution is consistent with the harpoon mechanism (Topic 20A) because the transition takes place at long range. In contrast, the collision of K with  $CH_3I$  leads to reaction only if the molecules approach each other very closely. In this mechanism, K effectively bumps into a brick wall, and the KI product bounces out in the backward direction. The detection of this anisotropy in the angular distribution of products gives an indication of the distance and orientation of approach needed for reaction, as well as showing that the event is complete in less than about 1 ps.

### (b) Attractive and repulsive surfaces

Some reactions are very sensitive to whether the energy has been pre-digested into a vibrational mode or left as the relative translational kinetic energy of the colliding molecules. For example, if two HI molecules are hurled together with more than twice the activation energy of the reaction, then no reaction occurs if all the energy is solely translational. For  $F + HCl \rightarrow Cl + HF$ , for example, the reaction is about five times more efficient when the HCl is in its first vibrational excited state than when, although HCl has the same total energy, it is in its vibrational ground state.

The origin of these requirements can be found by examining the potential energy surface. Figure 21D.19 shows an **attractive**

**Figure 21D.19** An attractive potential energy surface. A successful encounter ( $C^*$ ) involves high translational kinetic energy and results in a vibrationally excited product.

**Figure 21D.20** A repulsive potential energy surface. A successful encounter ( $C^*$ ) involves initial vibrational excitation and the products have high translational kinetic energy. A reaction that is attractive in one direction is repulsive in the reverse direction.

**surface** in which the saddle point occurs early in the reaction coordinate. Figure 21D.20 shows a **repulsive surface** in which the saddle point occurs late. A surface that is attractive in one direction is repulsive in the reverse direction.

Consider first the attractive surface. If the original molecule is vibrationally excited, then a collision with an incoming molecule takes the system along  $C$ . This path is bottled up in the region of the reactants, and does not take the system to the saddle point. If, however, the same amount of energy is present solely as translational kinetic energy, then the system moves along  $C^*$  and travels smoothly over the saddle point into products. We can therefore conclude that reactions with attractive potential energy surfaces proceed more efficiently if the energy is in relative translational motion. Moreover, the potential surface shows that once past the saddle point the trajectory runs up the steep wall of the product valley, and then rolls from side to side as it falls to the foot of the valley as the products separate. In other words, the products emerge in a vibrationally excited state.

Now consider the repulsive surface. On trajectory  $C$  the collisional energy is largely in translation. As the reactants approach, the potential energy rises. Their path takes them up the opposing face of the valley, and they are reflected back into the reactant region. This path corresponds to an unsuccessful encounter, even though the energy is sufficient for reaction. On  $C^*$  some of the energy is in the vibration of the reactant molecule and the motion causes the trajectory to weave from side to side up the valley as it approaches the saddle point. This motion may be sufficient to tip the system round the corner to the saddle point and then on to products. In this case, the product molecule is expected to be in an unexcited vibrational state. Reactions with repulsive potential surfaces can therefore be expected to proceed more efficiently if the excess energy is present as vibrations. This is the case with the  $H + Cl_2 \rightarrow HCl + Cl$  reaction, for instance.

**Brief illustration 21D.3** Attractive and repulsive surfaces

The reaction  $\text{H} + \text{Cl}_2 \rightarrow \text{HCl} + \text{Cl}$  has a repulsive potential surface. Of the following four reactive processes,  $\text{H} + \text{Cl}_2(\nu) \rightarrow \text{HCl}(\nu') + \text{Cl}$ , which we denote  $(\nu, \nu')$ , all at the same total energy, (a) (0,0), (b) (2,0), (c) (0,2), (d) (2,2), reaction (b) is most probable with reactants vibrationally excited and products vibrationally unexcited.

**Self-test 21D.3** Which of the four reactive processes of the reaction  $\text{HCl}(\nu) + \text{Cl} \rightarrow \text{H} + \text{Cl}_2(\nu')$ , all at the same total energy, (a) (0,0), (b) (2,0), (c) (0,2), (d) (2,2), is most probable?

Answer: (0,2); attractive surface

**(c) Classical trajectories**

A clear picture of the reaction event can be obtained by using classical mechanics to calculate the trajectories of the atoms taking place in a reaction from a set of initial conditions, such as velocities, relative orientations, and internal energies of the reacting particles. The initial values used for the internal energy reflect the quantization of electronic, vibrational, and rotational energies in molecules but the features of quantum mechanics are not used explicitly in the calculation of the trajectory.

Figure 21D.21 shows the result of such a calculation of the positions of the three atoms in the reaction  $\text{H} + \text{H}_2 \rightarrow \text{H}_2 + \text{H}$ , the horizontal coordinate now being time and the vertical coordinate the separations. This illustration shows clearly the vibration of the original molecule and the approach of the attacking atom. The reaction itself, the switch of partners, takes place very rapidly and is an example of a **direct mode process**. The newly formed molecule shakes, but quickly settles down to steady, harmonic vibration as the expelled atom

**Figure 21D.21** The calculated trajectories for a reactive encounter between A and a vibrating BC molecule leading to the formation of a vibrating AB molecule. This direct-mode reaction is between H and  $\text{H}_2$  (M. Karplus et al., *J. Chem. Phys.* **43**, 3258 (1965)).

**Figure 21D.22** An example of the trajectories calculated for a complex-mode reaction,  $\text{KCl} + \text{NaBr} \rightarrow \text{KBr} + \text{NaCl}$ , in which the collision cluster has a long lifetime (P. Brumer and M. Karplus, *Faraday Disc. Chem. Soc.* **55**, 80 (1973)).

departs. In contrast, Fig. 21D.22 shows an example of a **complex mode process**, in which the activated complex survives for an extended period. The reaction in the figure is the exchange reaction  $\text{KCl} + \text{NaBr} \rightarrow \text{KBr} + \text{NaCl}$ . The tetratomic activated complex survives for about 5 ps, during which time the atoms make about 15 oscillations before dissociating into products.

**(d) Quantum mechanical scattering theory**

Classical trajectory calculations do not recognize the fact that the motion of atoms, electrons, and nuclei is governed by quantum mechanics. The concept of trajectory then fades and is replaced by the unfolding of a wavefunction that represents initially the reactants and finally products.

Complete quantum mechanical calculations of trajectories and rate constants are very onerous because it is necessary to take into account all the allowed electronic, vibrational, and rotational states populated by each atom and molecule in the system at a given temperature. It is common to define a 'channel' as a group of molecules in well-defined quantum mechanically allowed states. Then, at a given temperature, there are many channels that represent the reactants and many channels that represent possible products, with some transitions between channels being allowed but others not allowed. Furthermore, not every transition leads to a chemical reaction. For example, the process  $\text{H}_2^* + \text{OH} \rightarrow \text{H}_2 + \text{OH}^*$ , where the asterisk denotes an excited state, amounts to energy transfer between  $\text{H}_2$  and  $\text{OH}$ , whereas the process  $\text{H}_2^* + \text{OH} \rightarrow \text{H}_2\text{O} + \text{H}$  represents a chemical reaction. What complicates a quantum mechanical calculation of rate constants even in this simple four-atom system is that many reacting channels present at a given temperature can lead to the desired products  $\text{H}_2\text{O} + \text{H}$ , which themselves may be formed as many distinct channels.

The **cumulative reaction probability**,  $\bar{P}(E)$ , at a fixed total energy  $E$  is then written as

$$\bar{P}(E) = \sum_{i,j} P_{ij}(E) \quad \text{Cumulative reaction probability} \quad (21D.5)$$

where  $P_{i,j}(E)$  is the probability for a transition between a reacting channel  $i$  and a product channel  $j$  and the summation is over all possible transitions that lead to product. It is then possible to show that the rate constant is given by

$$k_r(T) = \frac{\int_0^\infty \bar{P}(E) e^{-E/kT} dE}{hQ_R(T)} \quad \text{Rate constant} \quad (21D.6)$$

where  $Q_R(T)$  is the partition function density (the partition function divided by the volume) of the reactants at the temperature  $T$ . The significance of eqn 21D.6 is that it provides a direct connection between an experimental quantity, the rate constant, and a theoretical quantity,  $\bar{P}(E)$ .

## Checklist of concepts

- 1. A **molecular beam** is a collimated, narrow stream of molecules travelling through an evacuated vessel.
- 2. In a molecular beam, the scattering pattern of real molecules depends on quantum mechanical effects and the details of the intermolecular potential.
- 3. A **van der Waals molecule** is a complex of the form AB in which A and B are held together by van der Waals forces or hydrogen bonds.
- 4. Techniques for the study of reactive collisions include **infrared chemiluminescence**, **laser-induced fluorescence**, **multiphoton ionization (MPI)**, **reaction product imaging**, and **resonant multiphoton ionization (REMPI)**.
- 5. A **potential energy surface** maps the potential energy as a function of the relative positions of all the atoms taking part in a reaction.
- 6. In an **attractive surface**, the saddle point (the highest point) occurs early on the reaction coordinate.
- 7. In a **repulsive surface**, the saddle point occurs late on the reaction coordinate.

## Checklist of equations

Property	Equation	Comment	Equation number
Rate of molecular scattering	$dI = \sigma I N dx$	$\sigma$ is the differential scattering cross section	21D.1
Rate constant	$k_r = \langle \sigma v_{rel} \rangle N_A$		21D.2
State-to-state rate constant	$k_{nn'} = \langle \sigma_{nn'} v_{rel} \rangle N_A$		21D.3
Overall rate constant	$k_r = \sum_{n,n'} k_{nn'}(T) f_n(T)$		21D.4
Cumulative reaction probability	$\bar{P}(E) = \sum_{i,j} P_{ij}(E)$		21D.5
Rate constant	$k_r(T) = \int_0^\infty \bar{P}(E) e^{-E/kT} dE / hQ_R(T)$	$Q_R(T)$ is the partition function density	21D.6

### ► Why do you need to know this material?

Electron transfer reactions between protein-bound cofactors or between proteins play an important role in a variety of biological processes. Electron transfer is also important in homogeneous, non-biological catalysis (especially biomimetic systems).

### ► What is the key idea?

The rate constant of electron transfer in a donor–acceptor complex depends on the distance between electron donor and acceptor, the standard reaction Gibbs energy, and the energy needed to reach a particular arrangement of atoms.

### ► What do you need to know already?

This Topic makes use of transition-state theory (Topic 21C). It also uses the concept of tunnelling (Topic 8A), the steady-state approximation (Topic 20E), and the Franck–Condon principle (Topic 13A).

Here we apply the concepts of transition state theory and quantum theory to the study of a deceptively simple process, electron transfer between molecules in homogeneous systems. We

describe a theoretical approach to the calculation of rate constants and discuss the theory in the light of experimental results on a variety of systems, including protein complexes. We shall see that relatively simple expressions can be used to predict the rates of electron transfer with reasonable accuracy.

## 21E.1 The electron transfer rate law

Consider electron transfer from a donor species D to an acceptor species A in solution. The overall reaction is

In the first step of the mechanism, D and A must diffuse through the solution and on meeting form a complex DA:

We suppose that in the complex D and A are separated by  $d$ , the distance between their outer surfaces. Next, electron transfer occurs within the DA complex to yield  $D^+A^-$ :

The complex  $D^+A^-$  can also break apart and the ions diffuse through the solution:

We show in the following *Justification* that on the basis of this model

$$\frac{1}{k_r} = \frac{1}{k_a} + \frac{k'_a}{k_a k_{et}} \left( 1 + \frac{k'_{et}}{k_d} \right) \quad \text{Electron transfer rate constant} \quad (21E.3)$$

### Justification 21E.1 The rate constant for electron transfer in solution

We begin by identifying the rate of the overall reaction (eqn 21E.1) with the rate of formation of separated ions:

$$v = k_r[D][A] = k_d[D^+A^-]$$

There are two reaction intermediates, DA and  $D^+A^-$ , and we apply the steady-state approximation (Topic 20E) to both. From

$$\frac{d[D^+A^-]}{dt} = k_{et}[DA] - k'_{et}[D^+A^-] - k_d[D^+A^-] = 0$$

it follows that

$$[DA] = \frac{k'_{et} + k_d}{k_{et}} [D^+A^-]$$

and from

$$\frac{d[DA]}{dt} = k_a[D][A] - k'_a[DA] - k_{et}[DA] + k'_{et}[D^+A^-] = 0$$

it follows that

$$\begin{aligned} k_a[D][A] & \overbrace{-k'_a[DA] - k_{et}[DA]}^{(k'_{et} + k_d)/k_{et}[D^+A^-]} + k'_{et}[D^+A^-] \\ & = k_a[D][A] - \left\{ \frac{(k'_a + k_{et})(k'_{et} + k_d)}{k_{et}} - k'_{et} \right\} [D^+A^-] \\ & = k_a[D][A] - \frac{1}{k_{et}} (k'_a k'_{et} + k'_a k_d + k_d k_{et}) [D^+A^-] = 0 \end{aligned}$$

therefore

$$[D^+A^-] = \frac{k_a k_{et}}{k'_a k'_{et} + k'_a k_d + k_d k_{et}} [D][A]$$

When this expression is multiplied by  $k_d$ , the resulting equation has the form of the rate of electron transfer,  $v = k_r[D][A]$ , with  $k_r$  given by

$$k_r = \frac{k_a k_{et} k_d}{k'_a k'_{et} + k'_a k_d + k_d k_{et}}$$

To obtain eqn 21E.3, divide the numerator and denominator on the right-hand side of this expression by  $k_d k_{et}$  and solve for the reciprocal of  $k_r$ .

To gain insight into eqn 21E.3 and the factors that determine the rate of electron transfer reactions in solution, we assume that the main decay route for  $D^+A^-$  is dissociation of the complex into separated ions, and therefore that  $k_d \gg k'_{et}$ . It follows that

$$\frac{1}{k_r} \approx \frac{1}{k_a} \left( 1 + \frac{k'_a}{k_{et}} \right)$$

- When  $k_{et} \gg k'_a$ ,  $k_r \approx k_a$  and the rate of product formation is controlled by diffusion of D and A in solution, which favours formation of the DA complex.
- When  $k_{et} \ll k'_a$ ,  $k_r \approx (k_a/k'_a)k_{et} = Kk_{et}$ , where  $K$  is the equilibrium constant for the diffusive encounter. The process is controlled by  $k_{et}$  and therefore the activation energy of electron transfer in the DA complex.

Physical interpretation

## 21E.2 The rate constant

This analysis can be taken further by introducing the implication from transition-state theory (Topic 21C) that, at a given temperature,  $k_{et} \propto e^{-\Delta^\ddagger G/RT}$ , where  $\Delta^\ddagger G$  is the Gibbs energy of activation. Our remaining task, therefore, is to find expressions for the proportionality constant and  $\Delta^\ddagger G$ .

Our discussion concentrates on the following two key aspects of the theory of electron transfer processes, which was developed independently by R.A. Marcus, N.S. Hush, V.G. Levich, and R.R. Dogonadze:

- Electrons are transferred by tunnelling through a potential energy barrier, the height of which is partly determined by the ionization energies of the DA and  $D^+A^-$  complexes. Electron tunnelling influences the magnitude of the proportionality constant in the expression for  $k_{et}$ .
- The complex DA and the solvent molecules surrounding it undergo structural rearrangements prior to electron transfer. The energy associated with these rearrangements and the standard reaction Gibbs energy determine  $\Delta^\ddagger G$ .

According to the Franck–Condon principle (Topic 13A), electronic transitions are so fast that they can be regarded as taking place in a stationary nuclear framework. This principle also applies to an electron transfer process in which an electron migrates from one energy surface, representing the dependence of the energy of DA on its geometry, to another representing the energy of  $D^+A^-$ . We can represent the potential energy (and the Gibbs energy) surfaces of the two complexes (the reactant complex, DA, and the product complex,  $D^+A^-$ ) by the parabolas characteristic of harmonic oscillators, with the displacement coordinate corresponding to the changing geometries (Fig. 21E.1). This coordinate represents a collective mode of the donor, acceptor, and solvent.

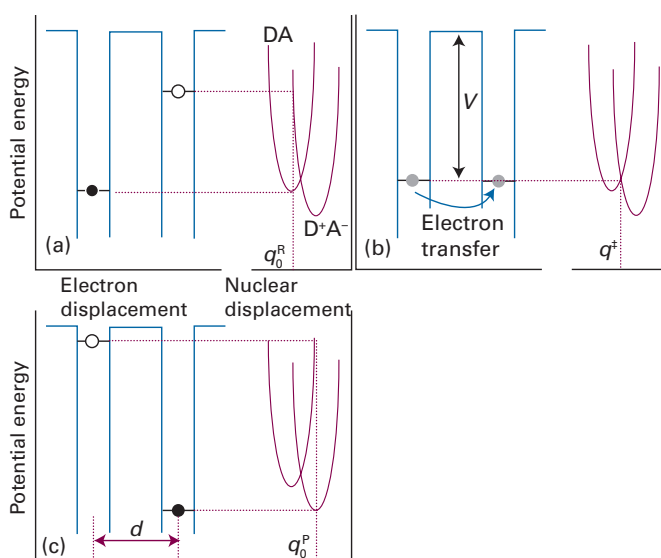

**Figure 21E.1** The Gibbs energy surfaces of the complexes DA and  $D^+A^-$  involved in an electron transfer process are represented by parabolas characteristic of harmonic oscillators, with the displacement coordinate  $q$  corresponding to the changing geometries of the system.

According to the Franck–Condon principle, the nuclei do not have time to move when the system passes from the reactant to the product surface as a result of the transfer of an electron. Therefore, electron transfer can occur only after thermal fluctuations bring the geometry of DA to  $q^\ddagger$  in Fig 21E.1, the value of the nuclear coordinate at which the two parabolas intersect.

### (a) The role of electron tunnelling

The proportionality constant in the expression for  $k_{et}$  is a measure of the rate at which the system will convert from reactants (DA) to products ( $D^+A^-$ ) at  $q^\ddagger$  by electron transfer within the thermally excited DA complex. To understand the process, we must turn our attention to the effect that the rearrangement of nuclear coordinates has on electronic energy levels of DA and  $D^+A^-$  for a given distance  $d$  between D and A (Fig. 21E.2). Initially, the overall energy of DA is lower than that of  $D^+A^-$  (Fig 21E.2a). As the nuclei rearrange to a configuration represented by  $q^\ddagger$  in Fig. 21E.2b, the HOMO of DA and the LUMO of  $D^+A^-$  become degenerate and electron transfer becomes energetically feasible. Over reasonably short distances  $d$ , the main mechanism of electron transfer is tunnelling through the potential energy barrier depicted in Fig 21E.2b. After an electron moves between the two frontier orbitals, the system relaxes to the configuration represented by  $q_0^P$  in Fig 21E.2c. As shown in the illustration, now the energy of  $D^+A^-$  is lower than that of DA, reflecting the thermodynamic tendency for A to remain reduced (as  $A^-$ ) and for D to remain oxidized (as  $D^+$ ).

The tunnelling event responsible for electron transfer is similar to that described in Topic 8A, except that in this case the electron tunnels from an electronic level of DA, with

**Figure 21E.2** (a) At the nuclear configuration denoted by  $q_0^R$ , the electron to be transferred in DA is in an occupied electronic energy level and the lowest unoccupied energy level of  $D^+A^-$  is of too high an energy to be a good electron acceptor. (b) As the nuclei rearrange to a configuration represented by  $q^\ddagger$ , DA and  $D^+A^-$  become degenerate and electron transfer occurs by tunnelling. (c) The system relaxes to the equilibrium nuclear configuration of  $D^+A^-$  denoted by  $q_0^P$ , in which the lowest unoccupied electronic level of DA is higher in energy than the highest occupied electronic level of  $D^+A^-$ . Adapted from R.A. Marcus and N. Sutin, *Biochim. Biophys. Acta* **811**, 265 (1985).

wavefunction  $\psi_{DA}$ , to an electronic level of  $D^+A^-$ , with wavefunction  $\psi_{D^+A^-}$ . The rate of an electronic transition from a level described by the wavefunction  $\psi_{DA}$  to a level described by  $\psi_{D^+A^-}$  is proportional to the square of the integral

$$H_{et} = \int \psi_{DA} \hat{h} \psi_{D^+A^-} d\tau$$

where  $\hat{h}$  is a hamiltonian that describes the coupling of the electronic wavefunctions. The probability of tunnelling through a potential barrier typically has an exponential dependence on the width of the barrier (Topic 8A), which suggests that we should write

$$H_{et}(d)^2 = H_{et}^{\circ 2} e^{-\beta d} \quad (21E.4)$$

where  $d$  is the edge-to-edge distance between D and A,  $\beta$  is a parameter that measures the sensitivity of the electronic coupling matrix element to distance, and  $H_{et}^{\circ}$  is the value of the electronic coupling matrix element when DA and  $D^+A^-$  are in contact ( $d=0$ ).

### Brief illustration 21E.1 The distance dependence of the coupling

The value of  $\beta$  depends on the medium through which the electron must travel from donor to acceptor. In a vacuum,  $28 \text{ nm}^{-1} < \beta < 35 \text{ nm}^{-1}$ , whereas  $\beta \approx 9 \text{ nm}^{-1}$  when the intervening medium is a molecular link between donor and acceptor. Electron transfer between protein-bound cofactors can occur at distances of up to about 2.0 nm, a long distance on a molecular scale, corresponding to about 20 carbon atoms, with the protein providing an intervening medium between donor and acceptor.

**Self-test 21E.1** By how much does  $H_{\text{et}}^2$  change when  $d$  is increased from 1.0 nm to 2.0 nm, with  $\beta \approx 9 \text{ nm}^{-1}$ ?

Answer: Decrease by a factor of 8100

### (b) The reorganization energy

The proportionality constant in  $k_{\text{et}} \propto e^{-\Delta^\ddagger G/RT}$  is proportional to  $H_{\text{et}}(d)^2$ , as expressed by eqn 21E.4. Therefore, we can expect the full expression for  $k_{\text{et}}$  to have the form

$$k_{\text{et}} = CH_{\text{et}}(d)^2 e^{-\Delta^\ddagger G/RT} \quad (21E.5)$$

with  $C$  a constant of proportionality and  $H_{\text{et}}(d)^2$  given by eqn 21E.5. We show in the following *Justification* that the Gibbs energy of activation  $\Delta^\ddagger G$  is

$$\Delta^\ddagger G = \frac{(\Delta_{\text{r}}G^\ominus + \Delta E_{\text{R}})^2}{4\Delta E_{\text{R}}} \quad \text{Gibbs energy of activation} \quad (21E.6)$$

where  $\Delta_{\text{r}}G^\ominus$  is the standard reaction Gibbs energy for the electron transfer process  $\text{DA} \rightarrow \text{D}^+\text{A}^-$ , and  $\Delta E_{\text{R}}$  is the **reorganization energy**, the energy change associated with molecular rearrangements that must take place so that DA can take on the equilibrium geometry of  $\text{D}^+\text{A}^-$ . These molecular rearrangements include the relative reorientation of the D and A molecules in DA and the relative reorientation of the solvent molecules surrounding DA. Equation 21E.6 shows that  $\Delta^\ddagger G = 0$ , with the implication that the reaction is not slowed down by an activation barrier, when  $\Delta_{\text{r}}G^\ominus = -\Delta E_{\text{R}}$ , corresponding to the cancellation of the reorganization energy term by the standard reaction Gibbs energy.

### Justification 21E.2 The Gibbs energy of activation of electron transfer

The simplest way to derive an expression for the Gibbs energy of activation of electron transfer processes is to construct a model in which the surfaces for DA (the ‘reactant complex’, denoted R) and for  $\text{D}^+\text{A}^-$  (the ‘product complex’, denoted P) are described by classical harmonic oscillators with identical

reduced masses  $\mu$  and angular frequencies  $\omega$ , but displaced minima, as shown in Fig. 21E.3. The molar Gibbs energies  $G_{\text{m,R}}(q)$  and  $G_{\text{m,P}}(q)$  of the reactant and product complexes, respectively, may then be written

$$G_{\text{m,R}}(q) = \frac{1}{2} N_{\text{A}} \mu \omega^2 (q - q_0^{\text{R}})^2 + G_{\text{m,R}}(q_0^{\text{R}})$$

$$G_{\text{m,P}}(q) = \frac{1}{2} N_{\text{A}} \mu \omega^2 (q - q_0^{\text{P}})^2 + G_{\text{m,P}}(q_0^{\text{P}})$$

where  $q_0^{\text{R}}$  and  $q_0^{\text{P}}$  are the values of  $q$  at which the minima of the reactant and product parabolas occur, respectively. The standard reaction Gibbs energy for the electron transfer process  $\text{R} \rightarrow \text{P}$  is  $\Delta_{\text{r}}G^\ominus = G_{\text{m,P}}(q_0^{\text{P}}) - G_{\text{m,R}}(q_0^{\text{R}})$ , the difference in standard molar Gibbs energy between the minima of the parabolas. In Fig. 21E.3,  $\Delta_{\text{r}}G^\ominus < 0$ .

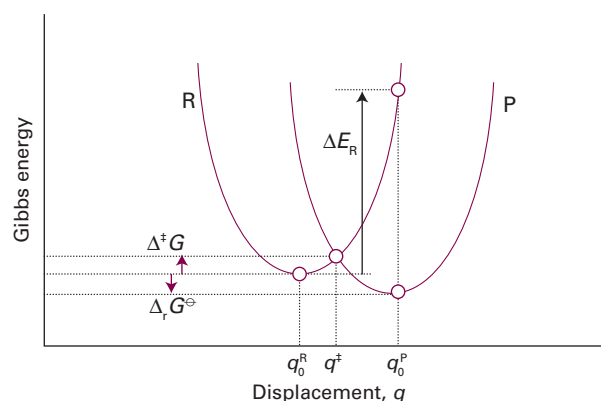

Figure 21E.3 The model system used in *Justification* 21E.2.

The value of  $q$  corresponding to the transition state of the complex,  $q^\ddagger$ , may be written in terms of the parameter  $\alpha$ , the fractional change in  $q$ :

$$q^\ddagger = q_0^{\text{R}} + \alpha(q_0^{\text{P}} - q_0^{\text{R}})$$

We see from Fig. 21E.3 that  $\Delta^\ddagger G = G_{\text{m,R}}(q^\ddagger) - G_{\text{m,R}}(q_0^{\text{R}})$ . It then follows that

$$\Delta^\ddagger G = \frac{1}{2} N_{\text{A}} \mu \omega^2 (q^\ddagger - q_0^{\text{R}})^2 = \frac{1}{2} N_{\text{A}} \mu \omega^2 \{\alpha(q_0^{\text{P}} - q_0^{\text{R}})\}^2$$

We now define the reorganization energy,  $\Delta E_{\text{R}}$ , as

$$\Delta E_{\text{R}} = \frac{1}{2} N_{\text{A}} \mu \omega^2 (q_0^{\text{P}} - q_0^{\text{R}})^2$$

which can be interpreted as  $G_{\text{m,R}}(q_0^{\text{P}}) - G_{\text{m,R}}(q_0^{\text{R}})$  and, consequently, as the (Gibbs) energy required to deform the equilibrium configuration of R to the equilibrium configuration of P (as shown in Fig. 21E.3). Then  $\Delta^\ddagger G = \alpha^2 \Delta E_{\text{R}}$ . Because  $G_{\text{m,R}}(q^\ddagger) = G_{\text{m,P}}(q^\ddagger)$ , it follows that

$$\begin{aligned} \alpha^2 \Delta E_{\text{R}} &= \frac{1}{2} N_{\text{A}} \mu \omega^2 \{(\alpha - 1)(q_0^{\text{P}} - q_0^{\text{R}})\}^2 + \Delta_{\text{r}}G^\ominus \\ &= (\alpha - 1)\Delta E_{\text{R}} + \Delta_{\text{r}}G^\ominus \end{aligned}$$

which implies that

$$\alpha = \frac{1}{2} \left( \frac{\Delta_{\text{r}}G^\ominus}{\Delta E_{\text{R}}} + 1 \right)$$

By inserting this equation into  $\Delta^\ddagger G = \alpha^2 \Delta E_R$ , we obtain eqn 21E.6. We can obtain an identical relation if we allow the harmonic oscillators to have different angular frequencies and hence different curvatures.

The only missing piece of the expression for  $k_{\text{et}}$  is the value of the constant of proportionality  $C$ . Detailed calculation, which we do not repeat here, gives

$$C = \frac{1}{h} \left( \frac{\pi^3}{RT \Delta E_R} \right)^{1/2} \quad (21E.7)$$

Equation 21E.6 has some limitations as might be expected because perturbation theory arguments have been used. For instance, it describes processes with weak electronic coupling between donor and acceptor. Weak coupling is observed when the electroactive species are sufficiently far apart that the tunnelling is an exponential function of distance. An example of a weakly coupled system is the complex of the proteins cytochrome *c* and cytochrome *b*<sub>5</sub>, in which the electroactive haem-bound iron ions shuttle between oxidation states Fe(II) and Fe(III) during electron transfer and are about 1.7 nm apart. Strong coupling is observed when the wavefunctions  $\psi_A$  and  $\psi_D$  overlap very extensively and, as well as other complications, the tunnelling rate is no longer a simple exponential function of distance. Examples of strongly coupled systems are mixed-valence, binuclear d-metal complexes with the general structure  $L_m M^{n+} - B - M^{p+} L_m$ , in which the electroactive metal ions are separated by a bridging ligand B. In these systems,  $d < 1.0$  nm. The weak coupling limit applies to a large number of electron transfer reactions, including those between proteins during metabolism.

Figure 21E.4 The parabolic dependence of  $\ln k_{\text{et}}$  on  $-\Delta_r G^\ominus$  predicted by eqn 21E.9.

The most meaningful experimental tests of the dependence of  $k_{\text{et}}$  on  $d$  are those in which the same donor and acceptor are positioned at a variety of distances, perhaps by covalent attachment to molecular linkers (see 1 in *Brief illustration* 21E.2 for an example). Under these conditions, the term  $e^{-\Delta^\ddagger G/RT}$  becomes a constant and, after taking the natural logarithm of eqn 21E.5 and using eqn 21E.4, we obtain

$$\ln k_{\text{et}} = -\beta d + \text{constant} \quad (21E.8)$$

which implies that a plot of  $\ln k_{\text{et}}$  against  $d$  should be a straight line of slope  $-\beta$ .

The dependence of  $k_{\text{et}}$  on the standard reaction Gibbs energy has been investigated in systems where the edge-to-edge distance and the reorganization energy are constant for a series of reactions. Then, by using eqn 21E.6 for  $\Delta^\ddagger G$ , eqn 21E.5 becomes

$$\ln k_{\text{et}} = -\frac{RT}{4\Delta E_R} \left( \frac{\Delta_r G^\ominus}{RT} \right)^2 - \frac{1}{2} \left( \frac{\Delta_r G^\ominus}{RT} \right) + \text{constant} \quad (21E.9)$$

and a plot of  $\ln k_{\text{et}}$  (or  $\log k_{\text{et}} = \ln k_{\text{et}} / \ln 10$ ) against  $\Delta_r G^\ominus$  (or  $-\Delta_r G^\ominus$ ) is predicted to be shaped like a downward parabola (Fig. 21E.4). Equation 21E.9 implies that the rate constant increases as  $\Delta_r G^\ominus$  decreases but only up to  $-\Delta_r G^\ominus = \Delta E_R$ . Beyond that, the reaction enters the **inverted region**, in which the rate constant decreases as the reaction becomes more exergonic ( $\Delta_r G^\ominus$  becomes more negative). The inverted region has been observed in a series of special compounds in which the electron donor and acceptor are linked covalently to a molecular spacer of known and fixed size (Fig. 21E.5).

Figure 21E.5 Variation of  $\log k_{\text{et}}$  with  $-\Delta_r G^\ominus$  for a series of compounds with the structures given in 1 and as described in *Brief illustration* 21E.2. Based on J.R. Miller, et al., *J. Am. Chem. Soc.* **106**, 3047 (1984).

### Brief illustration 21E.2 The determination of the reorganization energy

Kinetic measurements were conducted in 2-methyltetrahydrofuran and at 296 K for a series of compounds with the structures given in 1. The distance between donor (the reduced biphenyl group) and the acceptor is constant for all compounds in the series because the molecular linker remains the same. Each acceptor has a characteristic standard potential, so it follows that the standard Gibbs energy for the electron transfer process is different for each compound in the series. The line in Fig. 21E.5 is a fit to a version of eqn 21E.9 and the maximum of the parabola occurs at  $-\Delta_r G^\ominus = \Delta E_R = 1.4 \text{ eV} = 1.4 \times 10^2 \text{ kJ mol}^{-1}$ .

**Self-test 21E.2** Some (invented) data on a series of complexes are as follows:

$-\Delta_r G^\ominus/\text{eV}$	0.20	0.60	1.0	1.3	1.6	2.0	2.4
$\log k_{\text{et}}$	8.2	9.7	10.2	10.1	9.4	7.7	5.1

Determine the reorganization energy.

Answer: 1.05 eV

## Checklist of concepts

- 1. Electron transfer can occur only after thermal fluctuations bring the nuclear coordinate to the point at which the donor and acceptor have the same configuration.
- 2. The tunnelling rate is supposed to depend exponentially on the separation of the donor and acceptor.
- 3. The **reorganization energy** is the energy change associated with molecular rearrangements that must take place so that DA can acquire the equilibrium geometry of  $D^+A^-$ .
- 4. In the **inverted region**, the rate constant  $k_{\text{et}}$  decreases as the reaction becomes more exergonic ( $\Delta_r G^\ominus$  becomes more negative).

## Checklist of equations

Property	Equation	Comment	Equation number
Electron transfer rate constant	$1/k_r = 1/k_a + (k'_a/k_a k_{\text{et}})(1 + k'_{\text{et}}/k_d)$	Steady-state assumption	21E.3
Tunnelling probability	$H_{\text{et}}(d)^2 = H_{\text{et}}^{\circ 2} e^{-\beta d}$	Assumed	21E.4
Rate constant	$k_{\text{et}} = CH_{\text{et}}(d)^2 e^{-\Delta^\ddagger G/RT}$	Transition-state theory	21E.5
Gibbs energy of activation	$\Delta^\ddagger G = (\Delta_r G^\ominus + \Delta E_R)^2 / 4\Delta E_R$	Assumes parabolic potential energy	21E.6
Dependence on separation	$\ln k_{\text{et}} = -\beta d + \text{constant}$		21E.8
Dependence on $\Delta_r G^\ominus$	$\ln k_{\text{et}} = a\Delta_r G^{\ominus 2} + b\Delta_r G^\ominus + c$	$a = -1/4\Delta E_R RT, b = -1/2RT, c = \text{constant}$	21E.9

### ► Why do you need to know this material?

A knowledge of the factors that determine the rate of electron transfer at electrodes leads to a better understanding of power production in batteries, and of electron conduction in metals, semiconductors, and nanometre-sized electronic devices, all of which are highly important in modern technology.

### ► What is the key idea?

Transition-state theory can be applied to the description of electron transfer processes at the surface of electrodes.

### ► What do you need to know already?

You need to be familiar with electrochemical cells (Topic 6C), electrode potentials (Topic 6D), and the thermodynamic version of transition-state theory (Topic 21C), particularly the activation Gibbs energy.

As for homogeneous systems (Topic 21E), electron transfer at the surface of an electrode involves electron tunnelling. However, the electrode possesses a nearly infinite number of closely spaced electronic energy levels rather than the small number of discrete levels of a typical complex. Furthermore, specific interactions with the electrode surface give the solute

and solvent special properties that can be very different from those observed in the bulk of the solution. For this reason, we begin with a description of the electrode–solution interface. Then we describe the kinetics of electrode processes that draws on the thermodynamic language inspired by transition-state theory.

## 21F.1 The electrode–solution interface

The most primitive model of the boundary between the solid and liquid phases is as an **electrical double layer**, which consists of a sheet of positive charge at the surface of the electrode and a sheet of negative charge next to it in the solution (or vice versa). We shall see that this arrangement creates an electrical potential difference, called the **Galvani potential difference**, between the bulk of the metal electrode and the bulk of the solution.

More sophisticated models for the electrode–solution interface attempt to describe the gradual changes in the structure of the solution between two extremes, one the charged electrode surface and the other the bulk solution. In the **Helmholtz layer model** of the interface the solvated ions arrange themselves along the surface of the electrode but are held away from it by their hydration spheres (Fig. 21F.1). The location of the sheet

**Figure 21F.1** A simple model of the electrode–solution interface treats it as two rigid planes of charge. One plane, the outer Helmholtz plane (OHP), is due to the ions with their solvating molecules and the other plane is that of the electrode itself. The plot shows the dependence of the electric potential with distance from the electrode surface according to this model. Between the electrode surface and the OHP, the potential varies linearly from  $\phi_M$ , the value in the metal, to  $\phi_S$ , the value in the bulk of the solution.

of ionic charge, which is called the **outer Helmholtz plane** (OHP), is identified as the plane running through the solvated ions. In this simple model, the electrical potential changes linearly within the layer bounded by the electrode surface on one side and the OHP on the other. In a refinement of this model, ions that have discarded their solvating molecules and have become attached to the electrode surface by chemical bonds are regarded as forming the **inner Helmholtz plane** (IHP). The Helmholtz layer model ignores the disrupting effect of thermal motion, which tends to break up and disperse the rigid outer plane of charge. In the **Gouy–Chapman model** of the **diffuse double layer**, the disordering effect of thermal motion is taken into account in much the same way as the Debye–Hückel model describes the ionic atmosphere of an ion (Topic 5F) with the latter's single central ion replaced by an infinite, plane electrode.

Figure 21F.2 shows how the local concentrations of cations and anions differ in the Gouy–Chapman model from their bulk concentrations. Ions of opposite charge cluster close to the electrode and ions of the same charge are repelled from it. The modification of the local concentrations near an electrode implies that it might be misleading to use activity coefficients characteristic of the bulk to discuss the thermodynamic properties of ions near the interface. This is one of the reasons why measurements of the dynamics of electrode processes are almost always done using a large excess of supporting electrolyte (for example, a 1 M solution of a salt, an acid, or a base). Under such conditions, the activity coefficients are almost constant because the inert ions dominate the effects of local changes caused by any reactions taking place. The use of a concentrated solution also minimizes ion migration effects.

Neither the Helmholtz nor the Gouy–Chapman model is a very good representation of the structure of the double layer. The former overemphasizes the rigidity of the local solution; the latter underemphasizes its structure. The two are combined in the

**Figure 21F.2** The Gouy–Chapman model of the electrical double layer treats the outer region as an atmosphere of counter-charge, similar to the Debye–Hückel theory of ion atmospheres. The plot of electrical potential against distance from the electrode surface shows the meaning of the diffuse double layer (see text for details).

**Figure 21F.3** A representation of the Stern model of the electrode–solution interface. The model incorporates the idea of an outer Helmholtz plane near the electrode surface and of a diffuse double layer further away from the surface.

**Stern model**, in which the ions closest to the electrode are constrained into a rigid Helmholtz plane while outside that plane the ions are dispersed as in the Gouy–Chapman model (Fig. 21F.3). Yet another level of sophistication is found in the **Grahame model**, which adds an inner Helmholtz plane to the Stern model.

The potential difference between points in the bulk metal and the bulk solution is the **Galvani potential difference**,  $\Delta\phi$ . Apart from a constant, this Galvani potential difference is the electrode potential that was discussed in Topic 6D. We shall ignore the constant, which cannot be measured anyway, and identify changes in  $\Delta\phi$  with changes in electrode potential.

## 21F.2 The rate of electron transfer

We shall consider a reaction at the electrode in which an ion is reduced by the transfer of a single electron in the rate-determining step. We focus on the **current density**,  $j$ , the electric current flowing through a region of an electrode divided by the area of the region.

### (a) The Butler–Volmer equation

We show in the following *Justification* that an analysis of the effect of the Galvani potential difference at the electrode on the current density leads to the **Butler–Volmer equation**:

$$j = j_0 \{ e^{(1-\alpha)f\eta} - e^{-\alpha f\eta} \} \quad \text{Butler–Volmer equation} \quad (21F.1)$$

where we have written  $f = F/RT$ , with  $F$  as Faraday's constant. The equation contains the following parameters:

- $\eta$  (eta), the **overpotential**:

$$\eta = E' - E \quad \text{Definition} \quad \text{Overpotential} \quad (21F.2)$$

where  $E$  is the electrode potential at equilibrium (when there is no net flow of current), and  $E'$  is the electrode potential when a current is being drawn from the cell.

- $\alpha$ , the **transfer coefficient**, an indication of where the transition state between the reduced and oxidized forms of the electroactive species in solution is reactant-like ( $\alpha=0$ ) or product-like ( $\alpha=1$ ).
- $j_0$ , the **exchange-current density**, the magnitude of the equal but opposite current densities when the electrode is at equilibrium.

### Justification 21F.1 The Butler–Volmer equation

Because an electrode reaction is heterogeneous, we express the rate of charge transfer as the flux of products, the amount of material produced over a region of the electrode surface in an interval of time divided by the area of the region and the duration of the interval.

A first-order heterogeneous rate law has the form

$$\text{Product flux} = k_r[\text{species}]$$

where  $[\text{species}]$  is the molar concentration of the relevant electroactive species in solution close to the electrode, just outside the double layer. The rate constant has dimensions of length/time (with units, for example, of centimetres per second,  $\text{cm s}^{-1}$ ). If the molar concentrations of the oxidized and reduced materials outside the double layer are  $[\text{Ox}]$  and  $[\text{Red}]$ , respectively, then the rate of reduction of Ox,  $\nu_{\text{Ox}}$ , is  $\nu_{\text{Ox}} = k_c[\text{Ox}]$  and the rate of oxidation of Red,  $\nu_{\text{Red}}$ , is  $\nu_{\text{Red}} = k_a[\text{Red}]$ . (The notation  $k_c$  and  $k_a$  is justified below.)

Now consider a reaction at the electrode in which an ion is reduced by the transfer of a single electron in the rate-determining step. The net current density at the electrode is the difference between the current densities arising from the reduction of Ox and the oxidation of Red. Because the redox processes at the electrode involve the transfer of one electron per reaction event, the current densities,  $j$ , arising from the redox processes are the rates  $\nu_{\text{Ox}}$  and  $\nu_{\text{Red}}$  multiplied by the charge transferred per mole of reaction, which is given by Faraday's constant. Therefore, there is a **cathodic current density** of magnitude

$$j_c = Fk_c[\text{Ox}] \quad \text{for } \text{Ox} + e^- \rightarrow \text{Red}$$

arising from the reduction (because, as defined in Topic 6C, the cathode is the site of reduction). There is also an opposing **anodic current density** of magnitude

$$j_a = Fk_a[\text{Red}] \quad \text{for } \text{Red} \rightarrow \text{Ox} + e^-$$

arising from the oxidation (because the anode is the site of oxidation). The net current density at the electrode is the difference

$$j = j_a - j_c = Fk_a[\text{Red}] - Fk_c[\text{Ox}]$$

Note that, when  $j_a > j_c$ , so that  $j > 0$ , the current is anodic (Fig. 21F.4a); when  $j_c > j_a$ , so that  $j < 0$ , the current is cathodic (Fig. 21F.4b).

**Figure 21F.4** The net current density is defined as the difference between the cathodic and anodic contributions. (a) When  $j_a > j_c$ , the net current is anodic, and there is a net oxidation of the species in solution. (b) When  $j_c > j_a$ , the net current is cathodic, and the net process is reduction.

If a species is to participate in reduction or oxidation at an electrode, it must discard any solvating molecules, migrate through the electrode–solution interface, and adjust its hydration sphere as it receives or discards electrons. Likewise, a species already at the inner plane must be detached and migrate into the bulk. Because both processes are activated, we can expect to write their rate constants in the form suggested by transition-state theory (Topic 21C) as

$$k_r = B e^{-\Delta^\ddagger G/RT}$$

where  $\Delta^\ddagger G$  is the activation Gibbs energy and  $B$  is a constant with the same dimensions as  $k_r$ .

When the expressions for  $k_r$ , specifically  $k_c$  and  $k_a$ , are inserted, we obtain

$$j = FB_a[\text{Red}]e^{-\Delta^\ddagger G_a/RT} - FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c/RT}$$

This expression allows the activation Gibbs energies to be different for the cathodic and anodic processes. That they are different is the central feature of the remaining discussion.

Next, we relate  $j$  to the Galvani potential difference, which varies across the electrode–solution interface as shown schematically in Fig. 21F.5. Consider the reduction reaction,  $\text{Ox} + e^- \rightarrow \text{Red}$ , and the corresponding reaction profile. If the transition state of the activated complex is product-like (as represented by the peak of the reaction profile being close to the electrode in Fig. 21F.6), the activation Gibbs energy is changed from  $\Delta^\ddagger G_c(0)$ , the value it has in the absence of a potential difference across the double layer, to  $\Delta^\ddagger G_c = \Delta^\ddagger G_c(0) + F\Delta\phi$ . Thus, if the electrode is more positive than the solution,  $\Delta\phi > 0$ , then more work has to be done to form an activated complex from Ox; in this case the activation Gibbs energy is increased.

**Figure 21F.5** The potential,  $\phi$ , varies linearly between two plane parallel sheets of charge, and its effect on the Gibbs energy of the transition state depends on the extent to which the latter resembles the species at the inner or outer planes.

**Figure 21F.6** When the transition state resembles a species that has undergone reduction, the activation Gibbs energy for the anodic current is almost unchanged, but the full effect applies to the cathodic current. (a) Zero potential difference; (b) nonzero potential difference.

If the transition state is reactant-like (represented by the peak of the reaction profile being close to the outer plane of the double-layer in Fig. 21F.7), then  $\Delta^\ddagger G_c$  is independent of  $\Delta\phi$ . In a real system, the transition state has an intermediate resemblance to these extremes (Fig. 21F.8) and the activation Gibbs energy for reduction may be written as

**Figure 21F.7** When the transition state resembles a species that has undergone oxidation, the activation Gibbs energy for the cathodic current is almost unchanged but the activation Gibbs energy for the anodic current is strongly affected. (a) Zero potential difference; (b) nonzero potential difference.

**Figure 21F.8** When the transition state is intermediate in its resemblance to reduced and oxidized species, as represented here by a peak located at an intermediate position as measured by  $\alpha$  (with  $0 < \alpha < 1$ ), both activation Gibbs energies are affected; here,  $\alpha \approx 0.5$ . (a) Zero potential difference; (b) nonzero potential difference.

$$\Delta^\ddagger G_c = \Delta^\ddagger G_c(0) + \alpha F \Delta\phi$$

The parameter  $\alpha$  lies in the range 0 to 1. Experimentally,  $\alpha$  is often found to be about 0.5.

Now consider the oxidation reaction,  $\text{Red} + e^- \rightarrow \text{Ox}$  and its reaction profile. Similar remarks apply. In this case, Red discards an electron to the electrode, so the extra work is zero if the transition state is reactant-like (represented by a peak close to the electrode). The extra work is the full  $-F\Delta\phi$  if it resembles the product (the peak close to the outer plane). In general, the activation Gibbs energy for this anodic process is

$$\Delta^\ddagger G_a = \Delta^\ddagger G_a(0) - (1 - \alpha) F \Delta\phi$$

The two activation Gibbs energies can now be inserted in the expression for  $j$ , with the result that

$$j = FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT}e^{(1-\alpha)F\Delta\phi/RT} - FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT}e^{-\alpha F\Delta\phi/RT}$$

This is an explicit, if complicated, expression for the net current density in terms of the potential difference.

The appearance of the new expression for  $j$  can be simplified. First, in a purely cosmetic step we write  $f = F/RT$ . Next, we identify the individual cathodic and anodic current densities:

$$j = \overbrace{FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT}e^{(1-\alpha)f\Delta\phi}}^{j_a} - \overbrace{FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT}e^{-\alpha f\Delta\phi}}^{j_c}$$

If the cell is balanced against an external source, the Galvani potential difference,  $\Delta\phi$ , can be identified as the (zero-current) electrode potential,  $E$ , and we can write

$$j_a = FB_a[\text{Red}]e^{-\Delta^\ddagger G_a(0)/RT}e^{(1-\alpha)fE}$$

$$j_c = FB_c[\text{Ox}]e^{-\Delta^\ddagger G_c(0)/RT}e^{-\alpha fE}$$

When these equations apply, there is no net current at the electrode (as the cell is balanced), so the two current densities must be equal. From now on we denote them both as  $j_0$ .

When the cell is producing current (that is, when a load is connected between the electrode being studied and a second counter electrode) the electrode potential changes from its zero-current value,  $E$ , to a new value,  $E'$ , and the difference is the electrode's overpotential,  $\eta = E' - E$ . Hence,  $\Delta\phi$  changes from  $E$  to  $E + \eta$  and the two current densities become

$$j_a = j_0 e^{(1-\alpha)f\eta} \quad j_c = j_0 e^{-\alpha f\eta}$$

Then from  $j = j_a - j_c$  we obtain the Butler–Volmer equation, eqn 21F.1.

Figure 21F.9 shows how eqn 21F.1 predicts the current density to depend on the overpotential for different values of the transfer coefficient. When the overpotential is so small that  $f\eta \ll 1$  (in practice,  $\eta$  less than about 10 mV) the exponentials in eqn 21F.1 can be expanded by using  $e^x = 1 + x + \dots$  to give

$$j = j_0 \left\{ \overbrace{1 + (1-\alpha)f\eta + \dots}^{e^{(1-\alpha)f\eta}} - \overbrace{(1-\alpha f\eta + \dots)}^{e^{-\alpha f\eta}} \right\} \approx j_0 f\eta \quad (21F.3)$$

This equation shows that the current density is proportional to the overpotential, so at low overpotentials the interface behaves like a conductor that obeys Ohm's law. When there is a small positive overpotential the current is anodic ( $j > 0$  when  $\eta > 0$ ), and when the overpotential is small and negative the current is cathodic ( $j < 0$  when  $\eta < 0$ ). The relation can also be reversed to calculate the potential difference that must exist if a current density  $j$  has been established by some external circuit:

$$\eta = \frac{RTj}{Fj_0} \quad (21F.4)$$

The importance of this interpretation will become clear shortly.

Figure 21F.9 The dependence of the current density on the overpotential for different values of the transfer coefficient.

### Brief illustration 21F.1 The current density

The exchange current density of a  $\text{Pt(s)}|\text{H}_2(\text{g})|\text{H}^+(\text{aq})$  electrode at 298 K is  $0.79 \text{ mA cm}^{-2}$ . Therefore, the current density when the overpotential is  $+5.0 \text{ mV}$  is obtained by using eqn 21F.4 and  $f = F/RT = 1/(25.69 \text{ mV})$ :

$$j = j_0 f \eta = \frac{(0.79 \text{ mA cm}^{-2}) \times (5.0 \text{ mV})}{25.69 \text{ mV}} = 0.15 \text{ mA cm}^{-2}$$

The current through an electrode of total area  $5.0 \text{ cm}^2$  is therefore  $0.75 \text{ mA}$ .

**Self-test 21F.1** What would be the current at  $\text{pH} = 2.0$ , the other conditions being the same?

Answer:  $-18 \text{ mA}$  (cathodic)

Some experimental values for the Butler–Volmer parameters are given in Table 21F.1. From them we can see that exchange current densities vary over a very wide range. Exchange currents are generally large when the redox process involves no bond breaking (as in the  $[\text{Fe}(\text{CN})_6]^{3-}$ ,  $[\text{Fe}(\text{CN})_6]^{4-}$  couple) or if only weak bonds are broken (as in  $\text{Cl}_2, \text{Cl}^-$ ). They are generally small when more than one electron needs to be transferred, or when multiple or strong bonds are broken, as in the  $\text{N}_2, \text{N}_3^-$  couple and in redox reactions of organic compounds.

### (b) Tafel plots

When the overpotential is large and positive (in practice,  $\eta \geq 0.12 \text{ V}$ ), corresponding to the electrode being the anode in electrolysis, the second exponential in eqn 21F.1 is much smaller than the first, and may be neglected. Then

$$j = j_0 e^{(1-\alpha)f\eta} \quad (21F.5a)$$

so

$$\ln j = \ln j_0 + (1-\alpha)f\eta \quad (21F.5b)$$

The plot of the logarithm of the current density against the overpotential is called a **Tafel plot**. The slope, which is equal to

Table 21F.1\* Exchange current densities and transfer coefficients at 298 K

Reaction	Electrode	$j_0 / (\text{A cm}^{-2})$	$\alpha$
$2 \text{ H}^+ + 2 \text{ e}^- \rightarrow \text{H}_2$	Pt	$7.9 \times 10^{-4}$	
	Ni	$6.3 \times 10^{-6}$	0.58
	Pb	$5.0 \times 10^{-12}$	
$\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+}$	Pt	$2.5 \times 10^{-3}$	0.58

\* More values are given in the *Resource section*.

$(1-\alpha)f$ , gives the value of  $\alpha$  and the intercept at  $\eta=0$  gives the exchange-current density. If instead the overpotential is large but negative (in practice,  $\eta \leq -0.12$  V), the first exponential in eqn 21F.1 may be neglected. Then

$$j = j_0 e^{-\alpha f \eta} \quad (21F.6a)$$

so

$$\ln j = \ln j_0 - \alpha f \eta \quad (21F.6b)$$

In this case the slope of the Tafel plot is  $-\alpha f$ .

### Example 21F.1 Interpreting a Tafel plot

The data below refer to the anodic current through a platinum electrode of area  $2.0 \text{ cm}^2$  in contact with an  $\text{Fe}^{3+}$ ,  $\text{Fe}^{2+}$  aqueous solution at 298 K. Calculate the exchange-current density and the transfer coefficient for the electrode process.

$\eta/\text{mV}$	50	100	150	200	250
$I/\text{mA}$	8.8	25.0	58.0	131	298

**Method** The anodic process is the oxidation  $\text{Fe}^{2+}(\text{aq}) \rightarrow \text{Fe}^{3+}(\text{aq}) + e^-$ . To analyse the data, we make a Tafel plot (of  $\ln j$  against  $\eta$ ) using the anodic form (eqn 21F.5b). The intercept at  $\eta=0$  is  $\ln j_0$  and the slope is  $(1-\alpha)f$ .

**Answer** Draw up the following table:

$\eta/\text{mV}$	50	100	150	200	250
$j/(\text{mA cm}^{-2})$	4.4	12.5	29.0	65.5	149
$\ln(j/(\text{mA cm}^{-2}))$	1.48	2.53	3.37	4.18	5.00

The points are plotted in Fig. 21F.10. The high overpotential region gives a straight line of intercept 0.88 and slope 0.0165. From the former it follows that  $\ln(j_0/(\text{mA cm}^{-2})) = 0.88$ , so  $j_0 = 2.4 \text{ mA cm}^{-2}$ . From the latter,

$$(1-\alpha)f = \underbrace{0.0165}_{\text{Slope}} \underbrace{\frac{1}{\text{mV}^{-1}}}_{\text{Units of } \ln j / \eta}$$

so

$$\alpha = 1 - \frac{\overbrace{0.0165 \text{ mV}^{-1}}^{16.5 \text{ V}^{-1}}}{\underbrace{f}_{38.9 \text{ V}^{-1}}} = 1 - 0.42 \dots = 0.58$$

Note that the Tafel plot is nonlinear for  $\eta < 100 \text{ mV}$ ; in this region  $\alpha f \eta = 2.3$  and the approximation that  $\alpha f \eta \gg 1$  fails.

**Self-test 21F.2** Repeat the analysis using the following cathodic current data:

$\eta/\text{mV}$	-50	-100	-150	-200	-250	-300
$I/\text{mA}$	0.3	1.5	6.4	27.6	118.6	510

Answer:  $\alpha = 0.75$ ,  $j_0 = 0.041 \text{ mA cm}^{-2}$

Figure 21F.10 A Tafel plot is used to measure the exchange current density (given by the extrapolated intercept at  $\eta=0$ ) and the transfer coefficient (from the slope). The data are from Example 21F.1.

## 21F.3 Voltammetry

One of the assumptions in the derivation of the Butler–Volmer equation is the negligible conversion of the electroactive species at low current densities, resulting in uniformity of concentration near the electrode. This assumption fails at high current densities because the consumption of electroactive species close to the electrode results in a concentration gradient. The diffusion of the species towards the electrode from the bulk is slow and may become rate determining; a larger overpotential is then needed to produce a given current. This effect is called **concentration polarization**. Concentration polarization is important in the interpretation of **voltammetry**, the study of the current through an electrode as a function of the applied potential difference.

The kind of output from **linear-sweep voltammetry** is illustrated in Fig. 21F.11. Initially, the absolute value of the potential

Figure 21F.11 (a) The change of potential with time and (b) the resulting current/potential curve in a voltammetry experiment. The peak value of the current density is proportional to the concentration of electroactive species (for instance,  $[\text{Ox}]$ ) in solution.

is low, and the current is due to the migration of ions in the solution. However, as the potential approaches the reduction potential of the reducible solute, the current grows. Soon after the potential exceeds the reduction potential the current rises and reaches a maximum value. This maximum current is proportional to the molar concentration of the species, so that concentration can be determined from the peak height after subtraction of an extrapolated baseline.

In **cyclic voltammetry** the potential is applied with a triangular waveform (linearly up, then linearly down) and the current is monitored. A typical cyclic voltammogram is shown in Fig. 21F.12. The shape of the curve is initially like that of a linear-sweep experiment, but after reversal of the sweep there is a rapid change in current on account of the high concentration of oxidizable species close to the electrode that was generated on the reductive sweep. When the potential is close to the value required to oxidize the reduced species, there is a substantial current until all the oxidation is complete, and the current returns to zero. Cyclic voltammetry data are obtained at scan rates of about  $50 \text{ mV s}^{-1}$ , so a scan over a range of  $2 \text{ V}$  takes about  $80 \text{ s}$ .

When the reduction reaction at the electrode can be reversed, as in the case of the  $[\text{Fe}(\text{CN})_6]^{3-}/[\text{Fe}(\text{CN})_6]^{4-}$  couple, the cyclic voltammogram is broadly symmetric about the standard potential of the couple (as in Fig. 21F.12). The scan is initiated with  $[\text{Fe}(\text{CN})_6]^{3-}$  present in solution, and as the potential approaches  $E^\ominus$  for the couple, the  $[\text{Fe}(\text{CN})_6]^{3-}$  near the electrode is reduced and current begins to flow. As the potential continues to change, the current begins to decline again because all the  $[\text{Fe}(\text{CN})_6]^{3-}$  near the electrode has been reduced and the current reaches its limiting value. The potential is now returned linearly to its initial value, and the reverse series of events occurs with the  $[\text{Fe}(\text{CN})_6]^{4-}$  produced during the forward scan now undergoing oxidation. The peak of current lies on the other side of  $E^\ominus$ , so the species present and its standard potential can be identified, as indicated in the illustration, by noting the locations of the two peaks.

**Figure 21F.12** (a) The change of potential with time and (b) the resulting current/potential curve in a cyclic voltammetry experiment.

The overall shape of the curve gives details of the kinetics of the electrode process and the change in shape as the rate of change of potential is altered gives information on the rates of the processes involved. For example, the matching peak on the return phase of the potential sweep may be missing, which indicates that the oxidation (or reduction) is irreversible. The appearance of the curve may also depend on the timescale of the sweep, for if the sweep is too fast some processes might not have time to occur. This style of analysis is illustrated in the following example.

### Example 21F.2 Analysing a cyclic voltammetry experiment

The electroreduction of *p*-bromonitrobenzene in liquid ammonia is believed to occur by the following mechanism:

Suggest the likely form of the cyclic voltammogram expected on the basis of this mechanism.

**Method** Decide which steps are likely to be reversible on the timescale of the potential sweep: such processes will give symmetrical voltammograms. Irreversible processes will give unsymmetrical shapes as reduction (or oxidation) might not occur. However, at fast sweep rates, an intermediate might not have time to react, and a reversible shape will be observed.

**Answer** At slow sweep rates, the second reaction has time to occur, and a curve typical of a two-electron reduction will be

**Figure 21F.13** (a) When a non-reversible step in a reaction mechanism has time to occur, the cyclic voltammogram may not show the reverse oxidation or reduction peak. (b) However, if the rate of sweep is increased, the return step may be caused to occur before the irreversible step has had time to intervene, and a typical 'reversible' voltammogram is obtained.

observed, but there will be no oxidation peak on the second half of the cycle because the product,  $C_6H_5NO_2$ , cannot be oxidized (Fig. 21F.13a). At fast sweep rates, the second reaction does not have time to take place before oxidation of the  $BrC_6H_4NO_2^-$  intermediate starts to occur during the reverse scan, so the voltammogram will be typical of a reversible one-electron reduction (Fig. 21F.13b).

**Self-test 21F.3** Suggest an interpretation of the cyclic voltammogram shown in Fig. 21F.14. The electroactive material is  $ClC_6H_4CN$  in acid solution; after reduction to  $ClC_6H_4CN^-$  the radical anion may form  $C_6H_5CN$  irreversibly.

**Figure 21F.14** The cyclic voltammogram referred to in *Self-test 21F.3*.

Answer:  $ClC_6H_4CN + e^- \rightleftharpoons ClC_6H_4CN^-$ ,  $ClC_6H_4CN^- + H^+ + e^- \rightarrow C_6H_5CN + Cl^-$ ,  $C_6H_5CN + e^- \rightleftharpoons C_6H_5CN^-$

## 21F.4 Electrolysis

To induce current to flow through an electrolytic cell and bring about a nonspontaneous cell reaction, the applied potential difference must exceed the zero-current potential by at least the **cell overpotential**, the sum of the overpotentials at the two electrodes and the ohmic drop ( $IR_s$ , where  $R_s$  is the internal resistance of the cell) due to the current through the electrolyte. The additional potential needed to achieve a detectable rate of reaction may need to be large when the exchange current density at the electrodes is small. For similar reasons, a working galvanic cell generates a smaller potential than under zero-current conditions. In this section we see how to cope with both aspects of the overpotential.

The relative rates of gas evolution or metal deposition during electrolysis can be estimated from the Butler–Volmer equation and tables of exchange current densities. From eqn 21F.6a and assuming equal transfer coefficients, we write the ratio of the cathodic currents as

$$\frac{j'}{j} = \frac{j'_0}{j_0} e^{(\eta - \eta')\alpha f} \quad (21F.7)$$

where  $j'$  is the current density for electrodeposition and  $j$  is that for gas evolution, and  $j'_0$  and  $j_0$  are the corresponding exchange current densities. This equation shows that metal deposition is favoured by a large exchange current density and relatively high gas evolution overpotential (so  $\eta - \eta'$  is positive and large). Note that  $\eta < 0$  for a cathodic process, so  $-\eta' > 0$ . The exchange current density depends strongly on the nature of the electrode surface, and changes in the course of the electrodeposition of one metal on another. A very crude criterion is that significant evolution or deposition occurs only if the overpotential exceeds about 0.6 V.

A glance at Table 21F.1 shows the wide range of exchange current densities for a metal/hydrogen electrode. The most sluggish exchange currents occur for lead and mercury:  $1 \text{ pA cm}^{-2}$  corresponds to a monolayer of atoms being replaced in about 5 years. For such systems, a high overpotential is needed to induce significant hydrogen evolution. In contrast, the value for platinum ( $1 \text{ mA cm}^{-2}$ ) corresponds to a monolayer being replaced in 0.1 s, so significant gas evolution occurs for a much lower overpotential.

The exchange current density also depends on the crystal face exposed. For the deposition of copper on copper, the (100) face has  $j_0 = 1 \text{ mA cm}^{-2}$ , so for the same overpotential the (100) face grows at 2.5 times the rate of the (111) face, for which  $j_0 = 0.4 \text{ mA cm}^{-2}$ .

## 21F.5 Working galvanic cells

In working galvanic cells (those not balanced against an external potential), the overpotential leads to a smaller potential than under zero-current conditions. Furthermore, we expect the cell potential to decrease as current is generated because it is then no longer working reversibly and can therefore do less than maximum work.

We shall consider the cell  $M|M^+(aq)||M^+(aq)|M'$  and ignore all the complications arising from liquid junctions. The potential of the cell is  $E' = \Delta\phi_R - \Delta\phi_L$ . Because the cell potential differences differ from their zero-current values by overpotentials, we can write  $\Delta\phi_X = E_X + \eta_X$  where X is L or R for the left or right electrode, respectively. The cell potential is therefore

$$E' = E + \eta_R - \eta_L \quad (21F.8a)$$

To avoid confusion about signs ( $\eta_R$  is negative,  $\eta_L$  is positive) and to emphasize that a working cell has a lower potential than a zero-current cell, we shall write this expression as

$$E' = E - |\eta_R| - |\eta_L| \quad (21F.8b)$$

with  $E$  the cell potential. We should also subtract the ohmic potential difference  $IR_s$ , where  $R_s$  is the cell's internal resistance:

$$E' = E - |\eta_R| - |\eta_L| - IR_s \quad (21F.8c)$$

The ohmic term is a contribution to the cell's irreversibility—it is a thermal dissipation term—so the sign of  $IR_s$  is always such as to reduce the potential in the direction of zero.

The overpotentials in eqn 21F.8 can be calculated from the Butler–Volmer equation for a given current,  $I$ , being drawn. We shall simplify the equations by supposing that the areas,  $A$ , of the electrodes are the same, that only one electron is transferred in the rate-determining steps at the electrodes, that the transfer coefficients are both  $\frac{1}{2}$ , and that the high-overpotential limit of the Butler–Volmer equation may be used. Then from eqns 21F.6a and 21F.8c we find

$$E' = E - IR_s - \frac{4RT}{F} \ln \left( \frac{I}{Aj} \right) \quad \bar{j} = (j_{0L} j_{0R})^{1/2} \quad (21F.9)$$

where  $j_{0L}$  and  $j_{0R}$  are the exchange current densities for the two electrodes.

#### Brief illustration 21F.2 The working potential

Suppose that a cell consists of two electrodes each of area  $10 \text{ cm}^2$  with exchange current densities  $5 \mu\text{A cm}^{-2}$  and has internal resistance  $10 \Omega$ . At  $298 \text{ K}$   $RT/F = 25.7 \text{ mV}$ . The zero-current cell potential is  $1.5 \text{ V}$ . If the cell is producing a current of  $10 \text{ mA}$ , its working potential will be

$$\begin{aligned} E' &= 1.5 \text{ V} - \overbrace{(10 \text{ mA}) \times (10 \Omega)}^{0.10 \text{ V}} \\ &\quad - 4(25.7 \text{ mV}) \ln \left( \overbrace{\frac{10 \text{ mA}}{(10 \text{ cm}^2) \times (5 \mu\text{A cm}^{-2})}}^{0.54 \text{ V} \dots} \right) \\ &= 0.9 \text{ V} \end{aligned}$$

We have used  $1 \text{ A } \Omega = 1 \text{ V}$ . Note that we have ignored various other factors that reduce the cell potential, such as the inability of reactants to diffuse rapidly enough to the electrodes.

**Self-test 21F.4** What is the effective resistance at  $25^\circ\text{C}$  of an electrode interface when the overpotential is small? Evaluate it for a  $\text{Pt, H}_2|\text{H}^+$  electrode with a surface area of  $1.0 \text{ cm}^2$ .

Answer:  $33 \Omega$

Electric storage cells operate as galvanic cells while they are producing electricity but as electrolytic cells while they are being charged by an external supply. The lead–acid battery is an old device, but one well suited to the job of starting cars (and the only one available). During charging the cathode reaction is the reduction of  $\text{Pb}^{2+}$  and its deposition as lead on the lead electrode. Deposition occurs instead of the reduction of the acid to hydrogen because the latter has a low exchange current density on lead. The anode reaction during charging is the oxidation of  $\text{Pb(II)}$  to  $\text{Pb(IV)}$ , which is deposited as the oxide  $\text{PbO}_2$ . On discharge, the two reactions run in reverse. Because they have such high exchange current densities the discharge can occur rapidly, which is why the lead battery can produce large currents on demand.

## Checklist of concepts

- 1. An **electrical double layer** consists of sheets of opposite charge at the surface of the electrode and next to it in the solution.
- 2. Models of the double layer include the **Helmholtz layer model** and the **Gouy-Chapman model**.
- 3. The **Galvani potential difference** is the potential difference between the bulk of the metal electrode and the bulk of the solution.
- 4. The current density at an electrode is expressed by the **Butler–Volmer equation**.
- 5. A **Tafel plot** is the plot of the logarithm of the current density against the overpotential (see below).
- 6. **Voltammetry** is the study of the current through an electrode as a function of the applied potential difference.
- 7. To induce current to flow through an electrolytic cell and bring about a nonspontaneous cell reaction, the applied potential difference must exceed the cell potential by at least the **cell overpotential**.
- 8. In working galvanic cells the overpotential leads to a smaller potential than under zero-current conditions and the cell potential decreases as current is generated.

## Checklist of equations

Property	Equation	Comment	Equation number
Butler-Volmer equation	$j = j_0 \{e^{(1-\alpha)f\eta} - e^{-\alpha f\eta}\}$		21F.1
Tafel plots	$\ln j = \ln j_0 + (1 - \alpha)f\eta$	Anodic current density	21F.5b
	$\ln j = \ln j_0 - \alpha f\eta$	Cathodic current density	21F.6b
Potential of a working galvanic cell	$E' = E - IR_s - (4RT/F) \ln(I/A\bar{j})$	$\bar{j} = (j_{0L}j_{0R})^{1/2}$	21F.9

# CHAPTER 21 Reaction dynamics

## TOPIC 21A Collision theory

### Discussion questions

**21A.1** Discuss how the collision theory of gases builds on the kinetic-molecular theory.

**21A.2** How might collision theory change for real gases?

**21A.3** Describe the essential features of the harpoon mechanism.

**21A.4** Discuss the significance of the steric  $P$ -factor in the RRK model.

### Exercises

**21A.1(a)** Calculate the collision frequency,  $z$ , and the collision density,  $Z$ , in ammonia,  $R = 190$  pm, at  $30^\circ\text{C}$  and  $120$  kPa. What is the percentage increase when the temperature is raised by  $10$  K at constant volume?

**21A.1(b)** Calculate the collision frequency,  $z$ , and the collision density,  $Z$ , in carbon monoxide,  $R = 180$  pm at  $30^\circ\text{C}$  and  $120$  kPa. What is the percentage increase when the temperature is raised by  $10$  K at constant volume?

**21A.2(a)** Collision theory depends on knowing the fraction of molecular collisions having at least the kinetic energy  $E_a$  along the line of flight. What is this fraction when (i)  $E_a = 20$  kJ mol $^{-1}$ , (ii)  $E_a = 100$  kJ mol $^{-1}$  at (1)  $350$  K and (2)  $900$  K?

**21A.2(b)** Collision theory depends on knowing the fraction of molecular collisions having at least the kinetic energy  $E_a$  along the line of flight. What is this fraction when (i)  $E_a = 15$  kJ mol $^{-1}$ , (ii)  $E_a = 150$  kJ mol $^{-1}$  at (1)  $300$  K and (2)  $800$  K?

**21A.3(a)** Calculate the percentage increase in the fractions in Exercise 21A.2(a) when the temperature is raised by  $10$  K.

**21A.3(b)** Calculate the percentage increase in the fractions in Exercise 21A.2(b) when the temperature is raised by  $10$  K.

**21A.4(a)** Use the collision theory of gas-phase reactions to calculate the theoretical value of the second-order rate constant for the reaction  $\text{H}_2(\text{g}) + \text{I}_2(\text{g}) \rightarrow 2 \text{HI}(\text{g})$  at  $650$  K, assuming that it is elementary and bimolecular. The collision cross section is  $0.36$  nm $^2$ , the reduced mass is  $3.32 \times 10^{-27}$  kg, and the activation energy is  $171$  kJ mol $^{-1}$ . (Assume a steric factor of 1.)

**21A.4(b)** Use the collision theory of gas-phase reactions to calculate the theoretical value of the second-order rate constant for the reaction

$\text{D}_2(\text{g}) + \text{Br}_2(\text{g}) \rightarrow 2 \text{HBr}(\text{g})$  at  $450$  K, assuming that it is elementary and bimolecular. Take the collision cross section as  $0.30$  nm $^2$ , the reduced mass as  $3.930m_0$ , and the activation energy as  $200$  kJ mol $^{-1}$ . (Assume a steric factor of 1.)

**21A.5(a)** For the gaseous reaction  $\text{A} + \text{B} \rightarrow \text{P}$ , the reactive cross-section obtained from the experimental value of the pre-exponential factor is  $9.2 \times 10^{-22}$  m $^2$ . The collision cross-sections of A and B estimated from the transport properties are  $0.95$  and  $0.65$  nm $^2$  respectively. Calculate the  $P$ -factor for the reaction.

**21A.5(b)** For the gaseous reaction  $\text{A} + \text{B} \rightarrow \text{P}$ , the reactive cross-section obtained from the experimental value of the pre-exponential factor is  $8.7 \times 10^{-22}$  m $^2$ . The collision cross-sections of A and B estimated from the transport properties are  $0.88$  and  $0.40$  nm $^2$ , respectively. Calculate the  $P$ -factor for the reaction.

**21A.6(a)** Consider the unimolecular decomposition of a nonlinear molecule containing five atoms according to RRK theory. If  $P = 3.0 \times 10^{-5}$ , what is the value of  $E^*/E$ ?

**21A.6(b)** Consider the unimolecular decomposition of a linear molecule containing four atoms according to RRK theory. If  $P = 0.025$ , what is the value of  $E^*/E$ ?

**21A.7(a)** Suppose that an energy of  $250$  kJ mol $^{-1}$  is available in a collision but  $200$  kJ mol $^{-1}$  is needed to break a particular bond in a molecule with  $s = 10$ . Use the RRK model to calculate the steric  $P$ -factor.

**21A.7(b)** Suppose that an energy of  $500$  kJ mol $^{-1}$  is available in a collision but  $300$  kJ mol $^{-1}$  is needed to break a particular bond in a molecule with  $s = 12$ . Use the RRK model to calculate the steric  $P$ -factor.

### Problems

**21A.1** In the dimerization of methyl radicals at  $25^\circ\text{C}$ , the experimental pre-exponential factor is  $2.4 \times 10^{10}$  dm $^3$  mol $^{-1}$  s $^{-1}$ . What are (a) the reactive cross-section, (b) the  $P$ -factor for the reaction if the C–H bond length is  $154$  pm?

**21A.2** Nitrogen dioxide reacts bimolecularly in the gas phase:  $\text{NO}_2 + \text{NO}_2 \rightarrow \text{NO} + \text{NO} + \text{O}_2$ . The temperature dependence of the second-order rate constant for the rate law  $d[\text{P}]/dt = k_r[\text{NO}_2]^2$  is given in the following table. What are the  $P$ -factor and the reactive cross-section for the reaction?

$T/\text{K}$	600	700	800	1000
$k_r/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1})$	$4.6 \times 10^2$	$9.7 \times 10^3$	$1.3 \times 10^5$	$3.1 \times 10^6$

Take  $\sigma = 0.60$  nm $^2$ .

**21A.3** The diameter of the methyl radical is about  $308$  pm. What is the maximum rate constant in the expression  $d[\text{C}_2\text{H}_6]/dt = k_r[\text{CH}_3]^2$  for second-order recombination of radicals at room temperature? 10 per cent of a sample

of ethane of volume  $1.0$  dm $^3$  at  $298$  K and  $100$  kPa is dissociated into methyl radicals. What is the minimum time for 90 per cent recombination?

**21A.4** The total cross-sections for reactions between alkali metal atoms and halogen molecules are given in the following table (R.D. Levine and R.B. Bernstein, *Molecular reaction dynamics*, Clarendon Press, Oxford, 72 (1974)). Assess the data in terms of the harpoon mechanism.

$\sigma^*/\text{nm}^2$	$\text{Cl}_2$	$\text{Br}_2$	$\text{I}_2$
Na	1.24	1.16	0.97
K	1.54	1.51	1.27
Rb	1.90	1.97	1.67
Cs	1.96	2.04	1.95

Electron affinities are approximately  $1.3$  eV ( $\text{Cl}_2$ ),  $1.2$  eV ( $\text{Br}_2$ ), and  $1.7$  eV ( $\text{I}_2$ ), and ionization energies are  $5.1$  eV (Na),  $4.3$  eV (K),  $4.2$  eV (Rb), and  $3.9$  eV (Cs).

**21A.5<sup>†</sup>** One of the most historically significant studies of chemical reaction rates was that by M. Bodenstein (*Z. physik. Chem.* **29**, 295 (1899)) of the gas-phase reaction  $2 \text{HI}(\text{g}) \rightarrow \text{H}_2(\text{g}) + \text{I}_2(\text{g})$  and its reverse, with rate constants  $k_r$  and  $k'_r$ , respectively. The measured rate constants as a function of temperature are

$T/\text{K}$	647	666	683	700	716	781
$k_r/(22.4 \text{ dm}^3 \text{ mol}^{-1} \text{ min}^{-1})$	0.230	0.588	1.37	3.10	6.70	105.9
$k'_r/(22.4 \text{ dm}^3 \text{ mol}^{-1} \text{ min}^{-1})$	0.0140	0.0379	0.0659	0.172	0.375	3.58

Demonstrate that these data are consistent with the collision theory of bimolecular gas-phase reactions.

**21A.6<sup>†</sup>** R. Atkinson (*J. Phys. Chem. Ref. Data* **26**, 215 (1997)) has reviewed a large set of rate constants relevant to the atmospheric chemistry of volatile

organic compounds. The recommended rate constant for the bimolecular association of  $\text{O}_2$  with an alkyl radical R at 298 K is  $4.7 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  for  $\text{R} = \text{C}_2\text{H}_5$  and  $8.4 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  for  $\text{R} = \text{cyclohexyl}$ . Assuming no energy barrier, compute the steric factor,  $P$ , for each reaction. *Hint:* Obtain collision diameters from collision cross-sections of similar molecules in the *Resource section*.

**21A.7** According to the RRK model (see *Justification 21A.1*)

$$P = \frac{n!(n-n^*+s-1)!}{(n-n^*)!(n+s-1)!}$$

Use Stirling's approximation of the form  $\ln x! \approx x \ln x - x$  to deduce that  $P \approx (n-n^*/n)^{s-1}$  when  $s-1 \ll n-n^*$ . *Hint:* replace terms of the form  $n-n^*+s-1$  by  $n-n^*$  inside logarithms but retain  $n-n^*+s-1$  when it is a factor of a logarithm.

## TOPIC 21B Diffusion-controlled reactions

### Discussion questions

**21B.1** Distinguish between a diffusion-controlled reaction and an activation-controlled reaction. Do both have activation energies?

**21B.2** Describe the role of the encounter pair in the cage effect.

### Exercises

**21B.1(a)** A typical diffusion coefficient for small molecules in aqueous solution at 25 °C is  $6 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . If the critical reaction distance is 0.5 nm, what value is expected for the second-order rate constant for a diffusion-controlled reaction?

**21B.1(b)** Suppose that the typical diffusion coefficient for a reactant in aqueous solution at 25 °C is  $5.2 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ . If the critical reaction distance is 0.4 nm, what value is expected for the second-order rate constant for the diffusion-controlled reaction?

**21B.2(a)** Calculate the magnitude of the diffusion-controlled rate constant at 298 K for a species in (i) water, (ii) pentane. The viscosities are  $1.00 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ , and  $2.2 \times 10^{-4} \text{ kg m}^{-1} \text{ s}^{-1}$ , respectively.

**21B.2(b)** Calculate the magnitude of the diffusion-controlled rate constant at 298 K for a species in (i) decylbenzene, (ii) concentrated sulfuric acid. The viscosities are 3.36 cP and 27 cP, respectively.

**21B.3(a)** Calculate the magnitude of the diffusion-controlled rate constant at 320 K for the recombination of two atoms in water, for which  $\eta = 0.89 \text{ cP}$ . Assuming the concentration of the reacting species is  $1.5 \text{ mmol dm}^{-3}$  initially,

how long does it take for the concentration of the atoms to fall to half that value? Assume the reaction is elementary.

**21B.3(b)** Calculate the magnitude of the diffusion-controlled rate constant at 320 K for the recombination of two atoms in benzene, for which  $\eta = 0.601 \text{ cP}$ . Assuming the concentration of the reacting species is  $2.0 \text{ mmol dm}^{-3}$  initially, how long does it take for the concentration of the atoms to fall to half that value? Assume the reaction is elementary.

**21B.4(a)** Two neutral species, A and B, with diameters 655 pm and 1820 pm, respectively, undergo the diffusion-controlled reaction  $\text{A} + \text{B} \rightarrow \text{P}$  in a solvent of viscosity  $2.93 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$  at 40 °C. Calculate the initial rate  $d[\text{P}]/dt$  if the initial concentrations of A and B are  $0.170 \text{ mol dm}^{-3}$  and  $0.350 \text{ mol dm}^{-3}$ , respectively.

**21B.4(b)** Two neutral species, A and B, with diameters 421 pm and 945 pm, respectively, undergo the diffusion-controlled reaction  $\text{A} + \text{B} \rightarrow \text{P}$  in a solvent of viscosity 1.35 cP at 20 °C. Calculate the initial rate  $d[\text{P}]/dt$  if the initial concentrations of A and B are  $0.155 \text{ mol dm}^{-3}$  and  $0.195 \text{ mol dm}^{-3}$ , respectively.

### Problems

**21B.1** Confirm that eqn 21B.8 is a solution of eqn 21B.7, where  $[\text{J}]$  is a solution of the same equation but with  $k_r = 0$  and for the same initial conditions.

**21B.2** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book to explore the effect of varying the value of the rate constant  $k_r$  on the spatial variation of  $[\text{J}]^*$  (see eqn 21B.8 with  $[\text{J}]$  given in eqn 21B.9) for a constant value of the diffusion constant  $D$ .

**21B.3** Confirm that if the initial condition is  $[\text{J}] = 0$  at  $t = 0$  everywhere, and the boundary condition is  $[\text{J}] = [\text{J}]_0$  at  $t > 0$  at all points on a surface, then

<sup>†</sup> These problems were supplied by Charles Trapp and Carmen Giunta.

the solutions  $[\text{J}]^*$  in the presence of a first-order reaction that removed J are related to those in the absence of reaction,  $[\text{J}]$ , by

$$[\text{J}]^* = k_r \int_0^t [\text{J}] e^{-k_r t} dt + [\text{J}] e^{-k_r t}$$

Base your answer on eqn 21B.5.

**21B.4<sup>\*</sup>** The compound  $\alpha$ -tocopherol, a form of vitamin E, is a powerful antioxidant that may help to maintain the integrity of biological membranes. R.H. Bisby and A.W. Parker (*J. Amer. Chem. Soc.* **117**, 5664 (1995)) studied

the reaction of photochemically excited duroquinone with the antioxidant in ethanol. Once the duroquinone was photochemically excited, a bimolecular reaction took place at a rate described as diffusion limited. (a) Estimate the

rate constant for a diffusion-limited reaction in ethanol. (b) The reported rate constant was  $2.77 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ; estimate the critical reaction distance if the sum of diffusion constants is  $1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ .

## TOPIC 21C Transition-state theory

### Discussion questions

**21C.1** Describe in outline the formulation of the Eyring equation.

**21C.2** How is femtosecond spectroscopy used to examine the structures of activated complexes?

**21C.3** Explain the physical origin of the kinetic salt effect. What might be the effect of the relative permittivity of the medium?

**21C.4** How do kinetic isotope effects provide insight into the mechanism of a reaction?

### Exercises

**21C.1(a)** The reaction of propylxanthate ion in acetic acid buffer solutions has the mechanism  $A^- + H^+ \rightarrow P$ . Near  $30^\circ\text{C}$  the rate constant is given by the empirical expression  $k_r = (2.05 \times 10^{13}) e^{-(8681 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Evaluate the energy and entropy of activation at  $30^\circ\text{C}$ .

**21C.1(b)** The reaction  $A^- + H^+ \rightarrow P$  has a rate constant given by the empirical expression  $k_r = (6.92 \times 10^{12}) e^{-(5925 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Evaluate the energy and entropy of activation at  $25^\circ\text{C}$ .

**21C.2(a)** When the reaction in Exercise 21C.1(a) occurs in a dioxane/water mixture which is 30 per cent dioxane by mass, the rate constant fits  $k_r = (7.78 \times 10^{14}) e^{-(9134 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  near  $30^\circ\text{C}$ . Calculate  $\Delta^\ddagger G$  for the reaction at  $30^\circ\text{C}$ .

**21C.2(b)** A rate constant is found to fit the expression  $k_r = (4.98 \times 10^{13}) e^{-(4972 \text{ K})/T} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  near  $25^\circ\text{C}$ . Calculate  $\Delta^\ddagger G$  for the reaction at  $25^\circ\text{C}$ .

**21C.3(a)** The gas phase association reaction between  $F_2$  and  $IF_5$  is first order in each of the reactants. The energy of activation for the reaction is  $58.6 \text{ kJ mol}^{-1}$ . At  $65^\circ\text{C}$  the rate constant is  $7.84 \times 10^{-3} \text{ kPa}^{-1} \text{ s}^{-1}$ . Calculate the entropy of activation at  $65^\circ\text{C}$ .

**21C.3(b)** A gas-phase recombination reaction is first order in each of the reactants. The energy of activation for the reaction is  $39.7 \text{ kJ mol}^{-1}$ . At  $65^\circ\text{C}$  the rate constant is  $0.35 \text{ m}^3 \text{ s}^{-1}$ . Calculate the entropy of activation at  $65^\circ\text{C}$ .

**21C.4(a)** Calculate the entropy of activation for a collision between two structureless particles at  $300 \text{ K}$ , taking  $M = 65 \text{ g mol}^{-1}$  and  $\sigma = 0.35 \text{ nm}^2$ .

**21C.4(b)** Calculate the entropy of activation for a collision between two structureless particles at  $450 \text{ K}$ , taking  $M = 92 \text{ g mol}^{-1}$  and  $\sigma = 0.45 \text{ nm}^2$ .

**21C.5(a)** The pre-exponential factor for the gas-phase decomposition of ozone at low pressures is  $4.6 \times 10^{12} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and its activation energy is  $10.0 \text{ kJ mol}^{-1}$ . What are (i) the entropy of activation, (ii) the enthalpy of activation, (iii) the Gibbs energy of activation at  $298 \text{ K}$ ?

**21C.5(b)** The pre-exponential factor for a gas-phase decomposition of a gas at low pressures is  $2.3 \times 10^{13} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and its activation energy is  $30.0 \text{ kJ mol}^{-1}$ . What are (i) the entropy of activation, (ii) the enthalpy of activation, (iii) the Gibbs energy of activation at  $298 \text{ K}$ ?

**21C.6(a)** The rate constant of the reaction  $H_2O_2(aq) + I^-(aq) + H^+(aq) \rightarrow H_2O(l) + HIO(aq)$  is sensitive to the ionic strength of the aqueous solution in which the reaction occurs. At  $25^\circ\text{C}$ ,  $k_r = 12.2 \text{ dm}^6 \text{ mol}^{-2} \text{ min}^{-1}$  at an ionic strength of  $0.0525$ . Use the Debye–Hückel limiting law to estimate the rate constant at zero ionic strength.

**21C.6(b)** At  $25^\circ\text{C}$ ,  $k_r = 1.55 \text{ dm}^6 \text{ mol}^{-2} \text{ min}^{-1}$  at an ionic strength of  $0.0241$  for a reaction in which the rate-determining step involves the encounter of two singly charged cations. Use the Debye–Hückel limiting law to estimate the rate constant at zero ionic strength.

### Problems

**21C.1** The rates of thermolysis of a variety of *cis*- and *trans*-azoalkanes have been measured over a range of temperatures in order to settle a controversy concerning the mechanism of the reaction. In ethanol an unstable *cis*-azoalkane decomposed at a rate that was followed by observing the  $N_2$  evolution, and this led to the rate constants given in the following table (P.S. Engel and D.J. Bishop, *J. Amer. Chem. Soc.* **97**, 6754 (1975)). Calculate the enthalpy, entropy, energy, and Gibbs energy of activation at  $-20^\circ\text{C}$ .

$\theta/^\circ\text{C}$	-24.82	-20.73	-17.02	-13.00	-8.95
$10^4 \times k_r/\text{s}^{-1}$	1.22	2.31	4.39	8.50	14.3

**21C.2** In an experimental study of a bimolecular reaction in aqueous solution, the second-order rate constant was measured at  $25^\circ\text{C}$  and at a variety of ionic strengths and the results are tabulated in the following table. It is known that a singly charged ion is involved in the rate-determining step. What is the charge on the other ion involved?

$I/(\text{mol kg}^{-1})$	0.0025	0.0037	0.0045	0.0065	0.0085
$k_r/(\text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$	1.05	1.12	1.16	1.18	1.26

**21C.3** Derive the expression for  $k_r$  given in *Example* 21C.1 by introducing the equations for the thermal wavelengths.

**21C.4** The rate constant of the reaction  $I^-(aq) + H_2O_2(aq) \rightarrow H_2O(l) + IO^-(aq)$  varies slowly with ionic strength, even though the Debye–Hückel limiting law predicts no effect. Use the following data from  $25^\circ\text{C}$  to find the dependence of  $\log k_r$  on the ionic strength:

$I/(\text{mol kg}^{-1})$	0.0207	0.0525	0.0925	0.1575
$k_r/(\text{dm}^3 \text{ mol}^{-1} \text{ min}^{-1})$	0.663	0.670	0.679	0.694

Evaluate the limiting value of  $k_r$  at zero ionic strength. What does the result suggest for the dependence of  $\log \gamma$  on ionic strength for a neutral molecule in an electrolyte solution?

**21C.5\*** For the gas phase reaction  $A + A \rightarrow A_2$ , the experimental rate constant,  $k_p$ , has been fitted to the Arrhenius equation with the pre-exponential factor  $A = 4.07 \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at 300 K and an activation energy of  $65.43 \text{ kJ mol}^{-1}$ . Calculate  $\Delta^\ddagger S$ ,  $\Delta^\ddagger H$ ,  $\Delta^\ddagger U$ , and  $\Delta^\ddagger G$  for the reaction.

**21C.6** Use the Debye–Hückel limiting law to show that changes in ionic strength can affect the rate of reaction catalysed by  $\text{H}^+$  from the deprotonation of a weak acid. Consider the mechanism:  $\text{H}^+ + \text{B} \rightarrow \text{P}$ , where  $\text{H}^+$  comes from the deprotonation of the weak acid, HA. The weak acid has a fixed concentration. First show that  $\log [\text{H}^+]$ , derived from the ionization of HA, depends on the activity coefficients of ions and thus depends on the ionic strength. Then find the relationship between  $\log(\text{rate})$  and  $\log [\text{H}^+]$  to show that the rate also depends on the ionic strength.

**21C.7\*** Show that bimolecular reactions between nonlinear molecules are much slower than between atoms even when the activation energies of both reactions are equal. Use transition-state theory and make the following assumptions. (1) All vibrational partition functions are close to unity; (2) all rotational partition functions are approximately  $1 \times 10^{1.5}$ , which is a reasonable order of magnitude number; (3) the translational partition function for each species is  $1 \times 10^{26}$ .

**21C.8** This exercise gives some familiarity with the difficulties involved in predicting the structure of activated complexes. It also demonstrates the importance of femtosecond spectroscopy to our understanding of chemical dynamics because direct experimental observation of the activated complex removes much of the ambiguity of theoretical predictions. Consider the attack of H on  $\text{D}_2$ , which is one step in the  $\text{H}_2 + \text{D}_2$  reaction. (a) Suppose that the H approaches  $\text{D}_2$  from the side and forms a complex in the form of an isosceles triangle. Take the H–D distance as 30 per cent greater than in  $\text{H}_2$  (74 pm) and the D–D distance as 20 per cent greater than in  $\text{H}_2$ . Let the critical coordinate be the antisymmetric stretching vibration in which one H–D bond stretches as the other shortens. Let all the vibrations be at about  $1000 \text{ cm}^{-1}$ . Estimate  $k_r$  for this reaction at 400 K using the experimental activation energy of about  $35 \text{ kJ mol}^{-1}$ . (b) Now change the model of the activated complex in part (a) and make it linear. Use the same estimated molecular bond lengths and vibrational frequencies to calculate  $k_r$  for this choice of model. (c) Clearly,

there is much scope for modifying the parameters of the models of the activated complex. Use mathematical software or write and run a program that allows you to vary the structure of the complex and the parameters in a plausible way, and look for a model (or more than one model) that gives a value of  $k_r$  close to the experimental value,  $4 \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ .

**21C.9\*** M. Cyfert et al. (*Int. J. Chem. Kinet.* **28**, 103 (1996)) examined the oxidation of tris(1,10-phenanthroline)iron(II) by periodate in aqueous solution, a reaction which shows autocatalytic behaviour. To assess the kinetic salt effect, they measured rate constants at a variety of concentrations of  $\text{Na}_2\text{SO}_4$  far in excess of reactant concentrations and reported the following data:

$[\text{Na}_2\text{SO}_4]/(\text{mol kg}^{-1})$	0.2	0.15	0.1	0.05	0.025	0.0125	0.005
$k_r/(\text{dm}^{3/2} \text{ mol}^{-1/2} \text{ s}^{-1})$	0.462	0.430	0.390	0.321	0.283	0.252	0.224

What can be inferred about the charge of the activated complex of the rate-determining step?

**21C.10** The study of conditions that optimize the association of proteins in solution guides the design of protocols for formation of large crystals that are amenable to analysis by X-ray diffraction techniques. It is important to characterize protein dimerization because the process is considered to be the rate-determining step in the growth of crystals of many proteins. Consider the variation with ionic strength of the rate constant of dimerization in aqueous solution of a cationic protein P:

$I/(\text{mol kg}^{-1})$	0.0100	0.0150	0.0200	0.0250	0.0300	0.0350
$k_r/k_r'$	8.10	13.30	20.50	27.80	38.10	52.00

What can be deduced about the charge of P?

**21C.11** Predict the order of magnitude of the primary isotope effect on the relative rates of displacement of (a)  $^1\text{H}$  and  $^3\text{H}$  in a C–H bond, (b)  $^{16}\text{O}$  and  $^{18}\text{O}$  in a C–O bond. Will raising the temperature enhance the difference? Take  $k_f(\text{C–H}) = 450 \text{ N m}^{-1}$ ,  $k_f(\text{C–O}) = 1750 \text{ N m}^{-1}$ .

## TOPIC 21D The dynamics of molecular collisions

### Discussion questions

**21D.1** Describe how the following techniques are used in the study of chemical dynamics: infrared chemiluminescence, laser-induced fluorescence, multiphoton ionization, resonant multiphoton ionization, and reaction product imaging.

**21D.2** Discuss the relationship between the saddle-point energy and the activation energy of a reaction.

**21D.3** A method for directing the outcome of a chemical reaction consists of using molecular beams to control the relative orientations of reactants during

a collision. Consider the reaction  $\text{Rb} + \text{CH}_3\text{I} \rightarrow \text{RbI} + \text{CH}_3$ . How should  $\text{CH}_3\text{I}$  molecules and Rb atoms be oriented to maximize the production of RbI?

**21D.4** Consider a reaction with an attractive potential energy surface. Discuss how the initial distribution of reactant energy affects how efficiently the reaction proceeds. Repeat for a repulsive potential energy surface.

**21D.5** Describe how molecular beams are used to investigate intermolecular potentials.

### Exercises

**21D.1(a)** The interaction between two diatomic molecules is described by an attractive potential energy surface. What distribution of vibrational and translational energies among reactants and products is most likely to lead to a successful reaction?

**21D.1(b)** The interaction between two diatomic molecules has a repulsive potential energy surface. What distribution of vibrational and translational energies among reactants and products is most likely to lead to a successful reaction?

**21D.2(a)** If the cumulative reaction probability were independent of energy, what is the temperature dependence of the rate constant predicted by the numerator of eqn 21D.6?

**21D.2(b)** If the cumulative reaction probability equalled 1 for energies less than a barrier height  $V$  and vanished for higher energies, what is the temperature dependence of the rate constant predicted by the numerator of eqn 21D.6?

## Problems

**21D.1** Show that the intensities of a molecular beam before and after passing through a chamber of length  $L$  containing inert scattering atoms are related by  $I = I_0 e^{-N\sigma L}$ , where  $\sigma$  is the collision cross-section and  $N$  the number density of scattering atoms.

**21D.2** In a molecular beam experiment to measure collision cross-sections it was found that the intensity of a CsCl beam was reduced to 60 per cent of its intensity on passage through  $\text{CH}_2\text{F}_2$  at  $10 \mu\text{Torr}$ , but that when the target was Ar at the same pressure the intensity was reduced only by 10 per cent. What are the relative cross-sections of the two types of collision? Why is one much larger than the other?

**21D.3** Consider the collision between a hard-sphere molecule of radius  $R_1$  and mass  $m$ , and an infinitely massive impenetrable sphere of radius  $R_2$ . Plot

the scattering angle  $\theta$  as a function of the impact parameter  $b$ . Carry out the calculation using simple geometrical considerations.

**21D.4** The dependence of the scattering characteristics of atoms on the energy of the collision can be modelled as follows. We suppose that the two colliding atoms behave as impenetrable spheres, as in Problem 21D.3, but that the effective radius of the heavy atoms depends on the speed  $v$  of the light atom. Suppose its effective radius depends on  $v$  as  $R_2 e^{-v/v^*}$ , where  $v^*$  is a constant. Take  $R_1 = \frac{1}{2} R_2$  for simplicity and an impact parameter  $b = \frac{1}{2} R_2$ , and plot the scattering angle as a function of (a) speed, (b) kinetic energy of approach.

## TOPIC 21E Electron transfer in homogeneous systems

### Discussion questions

**21E.1** Discuss how the following factors determine the rate of electron transfer in homogeneous systems: the distance between electron donor and acceptor, the standard Gibbs energy of the process, and the reorganization energy of the redox active species and the surrounding medium.

**21E.2** What role does tunnelling play in electron transfer?

**21E.3** Explain why the rate constant decreases as the reaction becomes more exergonic in the inverted region.

### Exercises

**21E.1(a)** For a pair of electron donor and acceptor at 298 K,  $H_{\text{et}}(d) = 0.04 \text{ cm}^{-1}$ ,  $\Delta_r G^\ominus = -0.185 \text{ eV}$  and  $k_{\text{et}} = 37.5 \text{ s}^{-1}$ . Estimate the value of the reorganization energy.

**21E.1(b)** For a pair of electron donor and acceptor at 298 K,  $k_{\text{et}} = 2.02 \times 10^5 \text{ s}^{-1}$  for  $\Delta_r G^\ominus = -0.665 \text{ eV}$ . The standard reaction Gibbs energy changes to  $\Delta_r G^\ominus = -0.975 \text{ eV}$  when a substituent is added to the electron acceptor and the rate constant for electron transfer changes to  $k_{\text{et}} = 3.33 \times 10^6 \text{ s}^{-1}$ . Assuming that

the distance between donor and acceptor is the same in both experiments, estimate the values of  $H_{\text{et}}(d)$  and  $\Delta E_{\text{R}}$ .

**21E.2(a)** For a pair of electron donor and acceptor,  $k_{\text{et}} = 2.02 \times 10^5 \text{ s}^{-1}$  when  $d = 1.11 \text{ nm}$  and  $k_{\text{et}} = 4.51 \times 10^4 \text{ s}^{-1}$  when  $r = 1.23 \text{ nm}$ . Assuming that  $\Delta_r G^\ominus$  and  $\Delta E_{\text{R}}$  are the same in both experiments, estimate the value of  $\beta$ .

**21E.2(b)** Refer to Exercise 21E.2(a). Estimate the value of  $k_{\text{et}}$  when  $d = 1.59 \text{ nm}$ .

## Problems

**21E.1** Consider the reaction  $\text{D} + \text{A} \rightarrow \text{D}^+ + \text{A}^-$ . The rate constant  $k_r$  may be determined experimentally or may be predicted by the *Marcus cross-relation*  $k_r = (k_{\text{DD}} k_{\text{AA}} K)^{1/2} f$ , where  $k_{\text{DD}}$  and  $k_{\text{AA}}$  are the experimental rate constants for the electron self-exchange processes  $^* \text{D} + \text{D} \rightarrow ^* \text{D}^+ + \text{D}$  and  $^* \text{A} + \text{A} \rightarrow ^* \text{A}^+ + \text{A}$ , respectively, and  $f$  is a function of  $K = [\text{D}^+][\text{A}^-]/[\text{D}][\text{A}]$ ,  $k_{\text{DD}}$ ,  $k_{\text{AA}}$ , and the collision frequencies. Derive the approximate form of the Marcus cross-relation by following these steps. (a) Use eqn 21E.7 to write expressions for  $\Delta^\ddagger G$ ,  $\Delta^\ddagger G_{\text{DD}}$ , and  $\Delta^\ddagger G_{\text{AA}}$ , keeping in mind that  $\Delta_r G^\ominus = 0$  for the electron self-exchange reactions. (b) Assume that the reorganization energy  $\Delta E_{\text{R,DA}}$  for the reaction  $\text{D} + \text{A} \rightarrow \text{D}^+ + \text{A}^-$  is the average of the reorganization energies  $\Delta E_{\text{R,DD}}$  and  $\Delta E_{\text{R,AA}}$  of the electron self-exchange reactions. Then show that in the limit of small magnitude of  $\Delta_r G^\ominus$ , or  $|\Delta_r G^\ominus| \ll \Delta E_{\text{R,DA}}$ ,  $\Delta^\ddagger G = \frac{1}{2} (\Delta^\ddagger G_{\text{DD}} + \Delta^\ddagger G_{\text{AA}} + \Delta_r G^\ominus)$ , where  $\Delta_r G^\ominus$  is the standard Gibbs energy for the reaction  $\text{D} + \text{A} \rightarrow \text{D}^+ + \text{A}^-$ . (c) Use an equation of the form of eqn 21E.4 to write expressions for  $k_{\text{DD}}$  and  $k_{\text{AA}}$ . (d) Use eqn 21E.4 and the result above to write an expression for  $k_r$ . (e) Complete the derivation by using the results from part (c), the relation  $K = e^{-\Delta_r G^\ominus/RT}$ , and assuming that all  $\kappa v^\ddagger$  terms, which may be interpreted as collision frequencies, are identical.

**21E.2** Consider the reaction  $\text{D} + \text{A} \rightarrow \text{D}^+ + \text{A}^-$ . The rate constant  $k_r$  may be determined experimentally or may be predicted by the Marcus cross-relation

(see Problem 21E.1). It is common to make the assumption that  $f \approx 1$ . Use the approximate form of the Marcus relation to estimate the rate constant for the reaction  $\text{Ru}(\text{bpy})_3^{3+} + \text{Fe}(\text{H}_2\text{O})_6^{2+} \rightarrow \text{Ru}(\text{bpy})_3^{2+} + \text{Fe}(\text{H}_2\text{O})_6^{3+}$ , where bpy stands for 4,4'-bipyridine. The following data will be useful:

**21E.3** A useful strategy for the study of electron transfer in proteins consists of attaching an electroactive species to the protein's surface and then measuring  $k_{\text{et}}$  between the attached species and an electroactive protein cofactor. J.W. Winkler and H.B. Gray (*Chem. Rev.* **92**, 369 (1992)) summarize data for cytochrome *c* modified by replacement of the haem iron by a zinc ion, resulting in a zinc-porphyrin (ZnP) group in the interior of the protein, and by attachment of a ruthenium ion complex to a surface histidine amino acid. The edge-to-edge distance between the electroactive species was thus fixed at 1.23 nm. A variety of ruthenium ion complexes with different

standard potentials was used. For each ruthenium-modified protein, either the  $\text{Ru}^{2+} \rightarrow \text{ZnP}^+$  or the  $\text{ZnP}^+ \rightarrow \text{Ru}^{3+}$ , in which the electron donor is an electronically excited state of the zinc-porphyrin group formed by laser excitation, was monitored. This arrangement leads to different standard reaction Gibbs energies because the redox couples  $\text{ZnP}^+/\text{ZnP}$  and  $\text{ZnP}^+/\text{ZnP}^+$  have different standard potentials, with the electronically excited porphyrin being a more powerful reductant. Use the following data to estimate the reorganization energy for this system:

$\Delta_r G^\ominus/\text{eV}$	0.665	0.705	0.745	0.975	1.015	1.055
$k_{\text{et}}/(10^6 \text{ s}^{-1})$	0.657	1.52	1.12	8.99	5.76	10.1

**21E.4** The photosynthetic reaction centre of the purple photosynthetic bacterium *Rhodospseudomonas viridis* contains a number of bound co-factors that participate in electron transfer reactions. The following table shows data compiled by Moser et al. (*Nature* 355, 796 (1992)) on the rate constants for electron transfer between different co-factors and their edge-to-edge distances:

Reaction	$\text{BChl}^- \rightarrow \text{BPh}$	$\text{BPh}^- \rightarrow \text{BChl}_2^+$	$\text{BPh}^- \rightarrow \text{Q}_A$	$\text{cyt } c_{559} \rightarrow \text{BChl}_2$
$d/\text{nm}$	0.48	0.95	0.96	1.23
$k_{\text{et}}/\text{s}^{-1}$	$1.58 \times 10^{12}$	$3.98 \times 10^9$	$1.00 \times 10^9$	$1.58 \times 10^8$

Reaction	$\text{Q}_A^- \rightarrow \text{Q}_B$	$\text{Q}_A^- \rightarrow \text{BChl}_2^+$
$d/\text{nm}$	1.35	2.24
$k_{\text{et}}/\text{s}^{-1}$	$3.98 \times 10^7$	63.1

(BChl, bacteriochlorophyll;  $\text{BChl}_2$ , bacteriochlorophyll dimer, functionally distinct from BChl; BPh, bacteriopheophytin;  $\text{Q}_A$  and  $\text{Q}_B$ , quinone molecules bound to two distinct sites;  $\text{cyt } c_{559}$ , a cytochrome bound to the reaction centre complex). Are these data in agreement with the behaviour predicted by eqn 21E.9? If so, evaluate the value of  $\beta$ .

**21E.5** The rate constant for electron transfer between a cytochrome *c* and the bacteriochlorophyll dimer of the reaction centre of the purple bacterium *Rhodobacter sphaeroides* (Problem 21E.4) decreases with decreasing temperature in the range 300 K to 130 K. Below 130 K, the rate constant becomes independent of temperature. Account for these results.

## TOPIC 21F Processes at electrodes

### Discussion questions

**21F.1** Describe the various models of the electrode–electrolyte interface.

**21F.2** In what sense is electron transfer at an electrode an activated process?

**21F.3** Discuss the technique of cyclic voltammetry and account for the characteristic shape of a cyclic voltammogram, such as those shown in Figs. 21F.13 and 21F.14.

### Exercises

**21F.1(a)** The transfer coefficient of a certain electrode in contact with  $\text{M}^{3+}$  and  $\text{M}^{4+}$  in aqueous solution at 25 °C is 0.39. The current density is found to be  $55.0 \text{ mA cm}^{-2}$  when the overpotential is 125 mV. What is the overpotential required for a current density of  $75 \text{ mA cm}^{-2}$ ?

**21F.1(b)** The transfer coefficient of a certain electrode in contact with  $\text{M}^{2+}$  and  $\text{M}^{3+}$  in aqueous solution at 25 °C is 0.42. The current density is found to be  $17.0 \text{ mA cm}^{-2}$  when the overpotential is 105 mV. What is the overpotential required for a current density of  $72 \text{ mA cm}^{-2}$ ?

**21F.2(a)** Determine the exchange current density from the information given in Exercise 21F.1(a).

**21F.2(b)** Determine the exchange current density from the information given in Exercise 21F.1(b).

**21F.3(a)** To a first approximation, significant evolution or deposition occurs in electrolysis only if the overpotential exceeds about 0.6 V. To illustrate this criterion determine the effect that increasing the overpotential from 0.40 V to 0.60 V has on the current density in the electrolysis of 1.0 M NaOH(aq), which is  $1.0 \text{ mA cm}^{-2}$  at 0.4 V and 25 °C. Take  $\alpha = 0.5$ .

**21F.3(b)** Determine the effect that increasing the overpotential from 0.50 V to 0.60 V has on the current density in the electrolysis of 1.0 M NaOH(aq), which is  $1.22 \text{ mA cm}^{-2}$  at 0.50 V and 25 °C. Take  $\alpha = 0.50$ .

**21F.4(a)** Use the data in Table 21F.1 for the exchange current density and transfer coefficient for the reaction  $2 \text{ H}^+ + 2 \text{ e}^- \rightarrow \text{H}_2$  on nickel at 25 °C to determine what current density would be needed to obtain an overpotential of 0.20 V as calculated from (i) the Butler–Volmer equation, and (ii) the Tafel equation. Is the validity of the Tafel approximation affected at higher overpotentials (of 0.4 V and more)?

**21F.4(b)** Use the data in Table 21F.1 for the exchange current density and transfer coefficient for the reaction  $\text{Fe}^{3+} + \text{e}^- \rightarrow \text{Fe}^{2+}$  on platinum at 25 °C to determine what current density would be needed to obtain an overpotential of 0.30 V as calculated from (i) the Butler–Volmer equation, and (ii) the Tafel equation. Is the validity of the Tafel approximation affected at higher overpotentials (of 0.4 V and more)?

**21F.5(a)** A typical exchange current density, that for  $\text{H}^+$  discharge at platinum, is  $0.79 \text{ mA cm}^{-2}$  at 25 °C. What is the current density at an electrode when its overpotential is (i) 10 mV, (ii) 100 mV, (iii)  $-5.0 \text{ V}$ ? Take  $\alpha = 0.5$ .

**21F.5(b)** The exchange current density for a Pt| $\text{Fe}^{3+}, \text{Fe}^{2+}$  electrode is  $2.5 \text{ mA cm}^{-2}$ . The standard potential of the electrode is +0.77 V. Calculate the current flowing through an electrode of surface area  $1.0 \text{ cm}^2$  as a function of the potential of the electrode. Take unit activity for both ions.

**21F.6(a)** How many electrons or protons are transported through the double layer in each second when the Pt,  $\text{H}_2|\text{H}^+$ , Pt| $\text{Fe}^{3+}, \text{Fe}^{2+}$ , and Pb,  $\text{H}_2|\text{H}^+$  electrodes are at equilibrium at 25 °C? Take the area as  $1.0 \text{ cm}^2$  in each case. Estimate the number of times each second a single atom on the surface takes part in an electron transfer event, assuming an electrode atom occupies about  $(280 \text{ pm})^2$  of the surface.

**21F.6(b)** How many electrons or protons are transported through the double layer in each second when the Cu,  $\text{H}_2|\text{H}^+$  and Pt| $\text{Ce}^{4+}, \text{Ce}^{3+}$  electrodes are at equilibrium at 25 °C? Take the area as  $1.0 \text{ cm}^2$  in each case. Estimate the number of times each second a single atom on the surface takes part in an electron transfer event, assuming an electrode atom occupies about  $(260 \text{ pm})^2$  of the surface.

**21F.7(a)** What is the effective resistance at 25 °C of an electrode interface when the overpotential is small? Evaluate it for 1.0 cm<sup>2</sup> (i) Pt,H<sub>2</sub>|H<sup>+</sup>, (ii) Hg,H<sub>2</sub>|H<sup>+</sup> electrodes.

**21F.7(b)** Evaluate the effective resistance at 25 °C of an electrode interface for 1.0 cm<sup>2</sup> (i) Pb,H<sub>2</sub>|H<sup>+</sup>, (ii) Pt|Fe<sup>2+</sup>,Fe<sup>3+</sup> electrodes.

## Problems

**21F.1** In an experiment on the Pt|H<sub>2</sub>|H<sup>+</sup> electrode in dilute H<sub>2</sub>SO<sub>4</sub> the following current densities were observed at 25 °C. Evaluate  $\alpha$  and  $j_0$  for the electrode.

$\eta/\text{mV}$	50	100	150	200	250
$j/(\text{mA cm}^{-2})$	2.66	8.91	29.9	100	335

How would the current density at this electrode depend on the overpotential of the same set of magnitudes but of opposite sign?

**21F.2** The standard potentials of lead and tin are -126 mV and -136 mV, respectively, at 25 °C, and the overpotential for their deposition are close to zero. What should their relative activities be in order to ensure simultaneous deposition from a mixture?

**21F.3\*** The rate of deposition of iron,  $\nu$ , on the surface of an iron electrode from an aqueous solution of Fe<sup>2+</sup> has been studied as a function of potential,  $E$ , relative to the standard hydrogen electrode, by J. Kanya (*J. Electroanal. Chem.* **84**, 83 (1977)). The values in the table below are based on the data obtained with an electrode of surface area 9.1 cm<sup>2</sup> in contact with a solution of concentration 1.70  $\mu\text{mol dm}^{-3}$  in Fe<sup>2+</sup>. (a) Assuming unit activity coefficients, calculate the zero current potential of the Fe<sup>2+</sup>/Fe cathode and the overpotential at each value of the working potential. (b) Calculate the cathodic current density,  $j_c$ , from the rate of deposition of Fe<sup>2+</sup> for each value of  $E$ . (c) Examine the extent to which the data fit the Tafel equation and calculate the exchange current density.

$\nu/(\text{pmol s}^{-1})$	1.47	2.18	3.11	7.26
$-E/\text{mV}$	702	727	752	812

**21F.4\*** V.V. Losev and A.P. Pchel'nikov (*Soviet Electrochem.* **6**, 34 (1970)) obtained the following current-voltage data for an indium anode relative to a standard hydrogen electrode at 293 K:

$-E/\text{V}$	0.388	0.365	0.350	0.335
$j/(\text{A m}^{-2})$	0	0.590	1.438	3.507

Use these data to calculate the transfer coefficient and the exchange current density. What is the cathodic current density when the potential is 0.365 V?

**21F.5\*** An early study of the hydrogen overpotential is that of H. Bowden and T. Rideal (*Proc. Roy. Soc.* **A120**, 59 (1928)), who measured the overpotential for H<sub>2</sub> evolution with a mercury electrode in dilute aqueous solutions of H<sub>2</sub>SO<sub>4</sub> at 25 °C. Determine the exchange current density and transfer coefficient,  $\alpha$ , from their data:

**21F.8(a)** The exchange current density for H<sup>+</sup> discharge at zinc is about 50 pA cm<sup>-2</sup>. Can zinc be deposited from a unit activity aqueous solution of a zinc salt?

**21F.8(b)** The standard potential of the Zn<sup>2+</sup>|Zn electrode is -0.76 V at 25 °C. The exchange current density for H<sup>+</sup> discharge at platinum is 0.79 mA cm<sup>-2</sup>. Can zinc be plated on to platinum at that temperature? (Take unit activities.)

$j/(\text{mA m}^{-2})$	2.9	6.3	28	100	250	630	1650	3300
$\eta/\text{V}$	0.60	0.65	0.73	0.79	0.84	0.89	0.93	0.96

Explain any deviations from the result expected from the Tafel equation.

**21F.6** If  $\alpha = \frac{1}{2}$ , an electrode interface is unable to rectify alternating current because the current density curve is symmetrical about  $\eta = 0$ . When  $\alpha \neq \frac{1}{2}$ , the magnitude of the current density depends on the sign of the overpotential, and so some degree of 'faradaic rectification' may be obtained. Suppose that the overpotential varies as  $\eta = \eta_0 \cos \omega t$ . Derive an expression for the mean flow of current (averaged over a cycle) for general  $\alpha$ , and confirm that the mean current is zero when  $\alpha = \frac{1}{2}$ . In each case work in the limit of small  $\eta_0$  but to second order in  $\eta_0 F/RT$ . Calculate the mean direct current at 25 °C for a 1.0 cm<sup>2</sup> hydrogen-platinum electrode with  $\alpha = 0.38$  when the overpotential varies between  $\pm 10$  mV at 50 Hz.

**21F.7** Now suppose that the overpotential is in the high overpotential region at all times even though it is oscillating. What waveform will the current across the interface show if it varies linearly and periodically (as a sawtooth waveform) between  $\eta_-$  and  $\eta_+$  around  $\eta_0$ ? Take  $\alpha = \frac{1}{2}$ .

**21F.8** Figure 21.1 shows four different examples of voltammograms. Identify the processes occurring in each system. In each case the vertical axis is the current and the horizontal axis is the (negative) electrode potential.

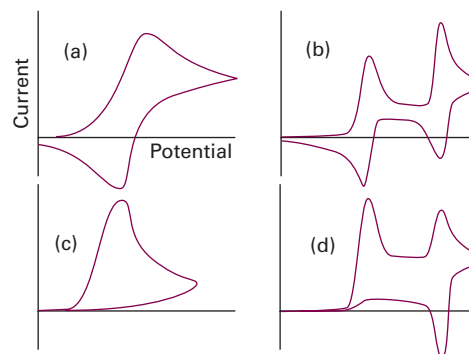

Figure 21.1 The voltammograms used in Problem 21F.8.

## Integrated activities

**21.1** Estimate the orders of magnitude of the partition functions involved in a rate expression. State the order of magnitude of  $q_m^T/N_A$ ,  $q^R$ ,  $q^V$ ,  $q^E$  for typical molecules. Check that in the collision of two structureless molecules the order of magnitude of the pre-exponential factor is of the same order as that predicted by collision theory. Go on to estimate the  $P$ -factor for a reaction in which  $A + B \rightarrow P$ , and  $A$  and  $B$  are nonlinear triatomic molecules.

**21.2** Discuss the factors that govern the rates of photo-induced electron transfer according to Marcus theory and that govern the rates of resonance

energy transfer according to Förster theory (Topic 20G). Can you find similarities between the two theories?

**21.3** Calculate the thermodynamic limit to the zero-current potential of fuel cells operating on (a) hydrogen and oxygen, (b) methane and air, and (c) propane and air. Use the Gibbs energy information in the *Resource section*, and take the species to be in their standard states at 25 °C.

# CHAPTER 22

## Processes on solid surfaces

Processes at solid surfaces govern the viability of industry constructively, as in catalysis, and the permanence of its products destructively, as in corrosion. Chemical reactions at solid surfaces may differ sharply from reactions in the bulk, for reaction pathways of much lower activation energy may be provided by the surface, and hence result in catalysis. This chapter extends the material introduced in Chapters 20 and 21 by showing how to deal with processes on solid surfaces.

### 22A An introduction to solid surfaces

We begin by exploring the structure of solid surfaces. This Topic also describes a number of experimental techniques commonly used in surface science.

### 22B Adsorption and desorption

Although we began with a discussion of clean surfaces, for chemists the important aspects of a surface are the attachment of substances to it and the reactions that take place there. In this Topic we discuss the extent to which a solid surface is covered and the variation of the extent of coverage with pressure and temperature.

### 22C Heterogeneous catalysis

This Topic discusses chemical reactions on solid surfaces. We focus on how surfaces affect the rate and course of chemical change by acting as the site of catalysis.

### What is the impact of this material?

Almost the whole of modern chemical industry depends on the development, selection, and application of catalysts, with heterogeneous catalysts being particularly important. All we can hope to do in *Impact* I22.1 is to give a brief indication of some of the problems involved. Other than the ones we consider, these problems include the danger of the catalyst being poisoned by by-products or impurities, and economic considerations relating to cost and lifetime.

To read more about the impact of this material, scan the QR code, or go to [bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-22-1.html](https://bcs.whfreeman.com/webpub/chemistry/pchem10e/impact/pchem-22-1.html)

### ► Why do you need to know this material?

To understand the thermodynamics and kinetics of chemical reactions occurring on solid surfaces, which underlie much of catalysis and therefore the chemical industry, you need to understand surface structure, composition, and growth.

### ► What is the key idea?

Structural features, including defects, play important roles in physical and chemical processes occurring on solid surfaces.

### ► What do you need to know already?

You need to be aware of the structure of solids (Topic 18A), but not in detail. This Topic draws on results from the kinetic theory of gases (Topic 1B).

A great deal of chemistry occurs at solid surfaces. Heterogeneous catalysis (Topic 22C) is just one example, with the surface providing reactive sites where reactants can attach, be torn apart, and react with other reactants. Even as simple an act as dissolving is intrinsically a surface phenomenon, with the solid gradually escaping into the solvent from sites on the surface. Surface deposition, in which atoms are laid down on a surface

to create layers, is crucial to the semiconductor industry, as it is the way in which integrated circuits are created. Electrodes are essentially surfaces at which electron transfer occurs, and their efficiency depends crucially on an understanding of the events there (Topic 21F).

## 22A.1 Surface growth

**Adsorption** is the attachment of particles to a solid surface; **desorption** is the reverse process. The substance that adsorbs is the **adsorbate** and the material to which it adsorbs is the **adsorbent** or **substrate**.

A simple picture of a perfect crystal surface is as a tray of oranges in a grocery store (Fig. 22A.1). A gas molecule that collides with the surface can be imagined as a ping-pong ball bouncing erratically over the oranges. The molecule loses energy as it bounces, but it is likely to escape from the surface before it has lost enough kinetic energy to be trapped. The same is true, to some extent, of an ionic crystal in contact with a solution. There is little energy advantage for an ion in solution to discard some of its solvating molecules and stick at an exposed position on the surface.

The picture changes when the surface has defects, for then there are ridges of incomplete layers of atoms or ions. A common type of surface defect is a **step** between two otherwise flat layers of atoms called **terraces** (Fig. 22A.2). A step defect might itself have defects, for it might have kinks. When an atom settles on a terrace it bounces across it under the influence of the intermolecular potential, and might come to a step or a corner formed by a kink. Instead of interacting with a single terrace

**Figure 22A.1** A schematic diagram of the flat surface of a solid. This primitive model is largely supported by scanning tunnelling microscope images.

Figure 22A.2 Some of the kinds of defects that may occur on otherwise perfect terraces. Defects play an important role in surface growth and catalysis.

Figure 22A.3 The slower-growing faces of a crystal dominate its final external appearance. Three successive stages of the growth are shown.

atom, the molecule now interacts with several, and the interaction may be strong enough to trap it. Likewise, when ions deposit from solution, the loss of the solvation interaction is offset by a strong Coulombic interaction between the arriving ions and several ions at the surface defect.

The rapidity of growth depends on the crystal plane concerned, and the slowest growing faces dominate the appearance of the crystal. This feature is explained in Fig. 22A.3, where we see that, although the horizontal face grows forward most rapidly, it grows itself out of existence, and the slower-growing faces survive.

Under normal conditions, a surface exposed to a gas is constantly bombarded with molecules and a freshly prepared surface is covered very quickly. Just how quickly can be estimated using the kinetic model of gases and the following expression for the collision flux (eqn 19A.6):

$$Z_w = \frac{p}{(2\pi mkT)^{1/2}} \quad \text{Collision flux} \quad (22A.1)$$

#### Brief illustration 22A.1 The collision flux

If we write  $m = M/N_A$ , where  $M$  is the molar mass of the gas, eqn 22A.1 becomes

$$Z_w = \frac{Z_0}{(TM)^{1/2}} p$$

After inserting numerical values for the constants and selecting units for the variables, the practical form of this expression is:

$$Z_w = \frac{Z_0(p/\text{Pa})}{\{(T/\text{K})(M/(\text{g mol}^{-1}))\}^{1/2}} \quad \text{with } Z_0 = 2.63 \times 10^{24} \text{ m}^{-2} \text{ s}^{-1}$$

For air, with  $M \approx 29 \text{ g mol}^{-1}$ , at  $p = 1 \text{ atm} = 1.01325 \times 10^5 \text{ Pa}$  and  $T = 298 \text{ K}$ , we obtain  $Z_w = 2.9 \times 10^{27} \text{ m}^{-2} \text{ s}^{-1}$ . Because  $1 \text{ m}^2$  of metal surface consists of about  $10^{19}$  atoms, each atom is struck about  $10^8$  times each second. Even if only a few collisions leave a molecule adsorbed to the surface, the time for which a freshly prepared surface remains clean is very short.

**Self-test 22A.1** Calculate the collision flux with a surface of a vessel containing propane at  $25^\circ\text{C}$  when the pressure is  $100 \text{ Pa}$ .

Answer:  $Z_w = 2.30 \times 10^{20} \text{ cm}^{-2} \text{ s}^{-1}$

## 22A.2 Physisorption and chemisorption

Molecules and atoms can attach to surfaces in two ways. In **physisorption** (a contraction of 'physical adsorption'), there is a van der Waals interaction (for example, a dispersion or a dipolar interaction, Topic 16B) between the adsorbate and the substrate; van der Waals interactions have a long range but are weak, and the energy released when a particle is physisorbed is of the same order of magnitude as the enthalpy of condensation. Such small energies can be absorbed as vibrations of the lattice and dissipated as thermal motion, and a molecule bouncing across the surface will gradually lose its energy and finally adsorb to it in the process called **accommodation**.

The enthalpy of physisorption can be measured by monitoring the rise in temperature of a sample of known heat capacity, and typical values are in the region of  $-20 \text{ kJ mol}^{-1}$  (Table 22A.1). This small enthalpy change is insufficient to lead to bond breaking, so a physisorbed molecule retains its identity, although it might be distorted by the presence of the surface.

In **chemisorption** (a contraction of 'chemical adsorption'), the molecules (or atoms) stick to the surface by forming a chemical (usually covalent) bond, and tend to find sites that maximize their coordination number with the substrate. The

Table 22A.1\* Maximum observed standard enthalpies of physisorption,  $\Delta_{\text{ad}}H^\ominus / (\text{kJ mol}^{-1})$ , at  $298 \text{ K}$

Adsorbate	$\Delta_{\text{ad}}H^\ominus / (\text{kJ mol}^{-1})$
$\text{CH}_4$	-21
$\text{H}_2$	-84
$\text{H}_2\text{O}$	-59
$\text{N}_2$	-21

\* More values are given in the Resource section.

**Table 22A.2\*** Standard enthalpies of chemisorption,  $\Delta_{\text{ad}}H^{\ominus}$  (kJ mol<sup>-1</sup>), at 298 K

Adsorbate	Adsorbent (substrate)		
	Cr	Fe	Ni
C <sub>2</sub> H <sub>4</sub>	-427	-285	-243
CO		-192	
H <sub>2</sub>	-188	-134	
NH <sub>3</sub>		-188	-155

\* More values are given in the *Resource section*.

enthalpy of chemisorption is very much greater than that for physisorption, and typical values are in the region of  $-200$  kJ mol<sup>-1</sup> (Table 22A.2). The distance between the surface and the closest adsorbate atom is also typically shorter for chemisorption than for physisorption. A chemisorbed molecule may be torn apart at the demand of the unsatisfied valencies of the surface atoms, and the existence of molecular fragments on the surface as a result of chemisorption is one reason why solid surfaces catalyse reactions (Topic 22C).

Except in special cases, chemisorption must be exothermic. A spontaneous process requires  $\Delta G < 0$  at constant pressure and temperature. Because the translational freedom of the adsorbate is reduced when it is adsorbed,  $\Delta S$  is negative. Therefore, in order for  $\Delta G = \Delta H - T\Delta S$  to be negative,  $\Delta H$  must be negative (that is, the process must be exothermic). Exceptions may occur if the adsorbate dissociates and has high translational mobility on the surface. For example, H<sub>2</sub> adsorbs endothermically on glass because there is a large increase of translational entropy accompanying the dissociation of the molecules into atoms that move quite freely over the surface. In this case, the entropy change in the process  $\text{H}_2(\text{g}) \rightarrow 2 \text{H}(\text{glass})$  is sufficiently positive to overcome the small positive enthalpy change.

The enthalpy of adsorption depends on the extent of surface coverage, mainly because the adsorbate particles interact with each other. If the particles repel each other (as for CO on palladium) the adsorption becomes less exothermic (the enthalpy of adsorption less negative) as coverage increases. Moreover, studies show that such species settle on the surface in a disordered way until packing requirements demand order. If the adsorbate particles attract one another (as for O<sub>2</sub> on tungsten), then they tend to cluster together in islands, and growth occurs at the borders. These adsorbates also show order-disorder transitions when they are heated enough for thermal motion to overcome the particle-particle interactions, but not so much that they are desorbed.

Whether a result of physisorption or chemisorption, the extent of surface coverage is normally expressed as the **fractional coverage**,  $\theta$ .

$$\theta = \frac{\text{number of adsorption sites occupied}}{\text{number of adsorption sites available}}$$

*Definition* Fractional coverage (22A.2)

The fractional coverage is often expressed in terms of the volume of adsorbate adsorbed by  $\theta = V/V_{\infty}$ , where  $V_{\infty}$  is the volume of adsorbate corresponding to complete monolayer coverage. In each case, the volumes in the definition of  $\theta$  are those of the free gas measured under the same conditions of temperature and pressure, not the volume the adsorbed gas occupies when attached to the surface.

#### Brief illustration 22A.2 Fractional coverage

For the adsorption of CO on charcoal at 273 K,  $V_{\infty} = 111 \text{ cm}^3$ , a value corrected to 1 atm. When the partial pressure of CO is 80.0 kPa, the value of  $V$  (also corrected to 1 atm) is  $41.6 \text{ cm}^3$ , so it follows that  $\theta = (41.6 \text{ cm}^3)/(111 \text{ cm}^3) = 0.375$ .

**Self-test 22A.2** It is commonly observed that  $\theta$  increases sharply with the partial pressure of adsorbate at low pressures, but becomes increasingly less dependent on partial pressure at high pressures. Explain this behaviour.

Answer: See Topic 22B

## 22A.3 Experimental techniques

A vast array of experimental techniques are used to study the composition and structure of solid surfaces at the atomic level. Many of the arrangements allow for direct visualization of changes in the surface as adsorption and chemical reactions take place there.

Experimental procedures must begin with a clean surface. The obvious way to retain cleanliness of a surface is to reduce the pressure and reduce the number of impacts on the surface. When the pressure is reduced to 0.1 mPa (as in a simple vacuum system) the collision flux falls to about  $10^{18} \text{ m}^{-2} \text{ s}^{-1}$ , corresponding to one hit per surface atom in each 0.1 s. Even that is too frequent in most experiments, and in **ultrahigh vacuum** (UHV) techniques pressures as low as 0.1  $\mu\text{Pa}$  (when  $Z_{\text{W}} = 10^{15} \text{ m}^{-2} \text{ s}^{-1}$ ) are reached on a routine basis and as low as 1 nPa (when  $Z_{\text{W}} = 10^{13} \text{ m}^{-2} \text{ s}^{-1}$ ) are reached with special care. These collision fluxes correspond to each surface atom being hit once every  $10^5$  to  $10^6$  s, or about once a day.

### (a) Microscopy

The basic approach of illuminating a small area of a sample and collecting light with a microscope has been used for many years to image small specimens. However, the resolution of a microscope, the minimum distance between two objects that leads to two distinct images, is on the order of the wavelength of the light being used. Therefore, conventional microscopes employing visible light have resolutions in the micrometre range and are blind to features on a scale of nanometres.

One technique that is often used to image nanometre-sized objects is **electron microscopy**, in which a beam of electrons with a well-defined de Broglie wavelength (Topic 7A) replaces the lamp found in traditional light microscopes. Instead of glass or quartz lenses, magnetic fields are used to focus the beam. In **transmission electron microscopy (TEM)**, the electron beam passes through the specimen and the image is collected on a screen. In **scanning electron microscopy (SEM)**, electrons scattered back from a small irradiated area of the sample are detected and the electrical signal is sent to a video screen. An image of the surface is then obtained by scanning the electron beam across the sample.

As in traditional light microscopy, the wavelength of and the ability to focus the incident beam—in this case a beam of electrons focused by magnetic fields—govern the resolution. It is now possible to achieve atomic resolution with TEM instruments. Resolution on the order of a few nanometres is possible with SEM instruments.

**Scanning probe microscopy (SPM)** is a collection of techniques that can be used to make visible and manipulate objects as small as atoms on surfaces. One version is **scanning tunnelling microscopy (STM)**, in which a platinum–rhodium or tungsten needle is scanned across the surface of a conducting solid. When the tip of the needle is brought very close to the surface, electrons tunnel across the intervening space (Fig. 22A.4). In the ‘constant-current mode’ of operation, the stylus moves up and down according to the form of the surface, and the topography of the surface, including any adsorbates, can be mapped on an atomic scale. The vertical motion of the stylus is achieved by fixing it to a piezoelectric cylinder, which contracts or expands according to the potential difference it experiences. In the ‘constant- $z$  mode’, the vertical position of the stylus is held constant and the current is monitored. Because the tunnelling probability is very sensitive to the size of the gap, the microscope can detect tiny, atom-scale variations in the height of the surface.

Figure 22A.5 shows an example of the kind of image obtained with a surface, in this case of gallium arsenide that has been modified by addition of caesium atoms. Each ‘bump’ on

**Figure 22A.4** A scanning tunnelling microscope makes use of the current of electrons that tunnel between the surface and the tip. That current is very sensitive to the distance of the tip above the surface.

**Figure 22A.5** An STM image of caesium atoms on a gallium arsenide surface.

the surface corresponds to an atom. In a further variation of the STM technique, the tip may be used to nudge single atoms around on the surface, making possible the fabrication of complex and yet very tiny nanometre-sized materials and devices.

Diffusion characteristics of an adsorbate can be examined by using STM to follow the change in surface characteristics. An adsorbed atom makes a random walk across the surface, and the diffusion coefficient,  $D$ , can be inferred from the mean distance,  $d$ , travelled in an interval  $\tau$  by using the two-dimensional random walk expression  $d = (D\tau)^{1/2}$ . The value of  $D$  for different crystal planes at different temperatures can be determined directly in this way, and the activation energy for migration over each plane obtained from the Arrhenius-like expression

$$D = D_0 e^{-E_{a,\text{diff}}/RT} \quad \text{Temperature dependence of the diffusion coefficient} \quad (22A.3)$$

where  $E_{a,\text{diff}}$  is the activation energy for diffusion and  $D_0$  is the diffusion coefficient in the limit of infinite temperature.

### Brief illustration 22A.3 Diffusion coefficients

Typical values for W atoms on tungsten have  $E_{a,\text{diff}}$  in the range 57–87 kJ mol<sup>-1</sup> and  $D_0 \approx 3.8 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ . It follows from eqn 22A.3 that at 800 K the diffusion coefficient varies approximately from

$$D = (3.8 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}) \times e^{-5.7 \times 10^{-2} \text{ J mol}^{-1} / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1} \times 800 \text{ K})} \\ = 7.2 \times 10^{-15} \text{ m}^2 \text{ s}^{-1}$$

to

$$D = (3.8 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}) \times e^{-8.7 \times 10^{-2} \text{ J mol}^{-1} / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1} \times 800 \text{ K})} \\ = 7.9 \times 10^{-17} \text{ m}^2 \text{ s}^{-1}$$

**Self-test 22A.3** For CO on tungsten, the activation energy falls from 144 kJ mol<sup>-1</sup> at low surface coverage to 88 kJ mol<sup>-1</sup> when the coverage is high. Calculate the ratio  $D_{\text{high}}/D_{\text{low}}$  of diffusion coefficients at 800 K.

Answer:  $4.5 \times 10^3$

**Figure 22A.6** In atomic force microscopy, a laser beam is used to monitor the tiny changes in position of a probe as it is attracted to or repelled by atoms on a surface.

In **atomic force microscopy** (AFM), a sharpened tip attached to a cantilever is scanned across the surface. The force exerted by the surface and any molecules attached to it pushes or pulls on the tip and deflects the cantilever (Fig. 22A.6). The deflection is monitored by using a laser beam. Because no current needs to pass between the sample and the probe, the technique can be applied to non-conducting surfaces and to liquid samples.

Two modes of operation of AFM are common. In ‘contact mode’, or ‘constant-force mode’, the force between the tip and surface is held constant and the tip makes contact with the surface. This mode of operation can damage fragile samples on the surface. In ‘non-contact’, or ‘tapping mode’, the tip bounces up and down with a specified frequency and never quite touches the surface. The amplitude of the tip’s oscillation changes when it passes over a species adsorbed on the surface.

### (b) Ionization techniques

The chemical composition of a surface can be determined by a variety of ionization techniques. The same techniques can be used to detect any remaining contamination after cleaning and to detect layers of material adsorbed later in the experiment.

One technique is **photoemission spectroscopy**, a derivative of the photoelectric effect (Topic 7A), in which X-rays (for XPS) or hard (short wavelength) ultraviolet (for UPS) ionizing radiation is used, giving rise to ejected electrons from adsorbed species. The kinetic energies of the electrons ejected from their orbitals are measured and the pattern of energies is a fingerprint of the material present (Fig. 22A.7). UPS, which examines electrons ejected from valence shells, is also used to establish the bonding characteristics and the details of valence shell electronic structures of substances on the surface. Its usefulness is its ability to reveal which orbitals of the adsorbate are involved in the bond to the substrate.

**Figure 22A.7** The X-ray photoelectron emission spectrum of a sample of gold contaminated with a surface layer of mercury. (M.W. Roberts and C.S. McKee, *Chemistry of the metal–gas interface*, Oxford (1978).)

#### Brief illustration 22A.4 A UPS spectrum

The principal difference between the photoemission results on free benzene and benzene adsorbed on palladium is in the energies of the  $\pi$  electrons. This difference is interpreted as meaning that the  $C_6H_6$  molecules lie parallel to the surface and are attached to it by their  $\pi$  orbitals.

**Self-test 22A.4** When adsorbed to palladium, pyridine ( $C_6H_5N$ ) stands almost perpendicular to the surface. Suggest a mode of attachment of the molecule to palladium atoms on the surface.

Answer: Data are consistent with a  $\sigma$  bond formed by the nitrogen lone pair.

A very important technique, which is widely used in the microelectronics industry, is **Auger electron spectroscopy** (AES). The **Auger effect** (pronounced oh-zhey) is the emission of a second electron after high energy radiation has expelled another. The first electron to depart leaves a hole in a low-lying orbital, and an upper electron falls into it. The energy this transition releases may result either in the generation of radiation, which is called **X-ray fluorescence** (Fig. 22A.8a) or in the ejection of another electron (Fig. 22A.8b). The latter is the ‘secondary electron’ of the Auger effect. The energies of the secondary electrons are characteristic of the material present, so the Auger effect effectively takes a fingerprint of the sample. In practice, the Auger spectrum is normally obtained by irradiating the sample with an electron beam of energy in the range 1–5 keV rather than electromagnetic radiation. In **scanning Auger electron microscopy** (SAM), the finely focused electron beam is scanned over the surface and a map of composition is compiled; the resolution can reach below about 50 nm.

### (c) Diffraction techniques

A useful technique for determining the arrangement of the atoms close to the surface is **low energy electron diffraction**

**Figure 22A.8** When an electron is expelled from a solid (a) an electron of higher energy may fall into the vacated orbital and emit an X-ray photon to produce X-ray fluorescence. Alternatively (b) the electron falling into the orbital may give up its energy to another electron, which is ejected in the Auger effect.

(LEED). This technique is like X-ray diffraction (Topic 18A) but uses the wave character of electrons, and the sample is now the surface of a solid. The use of low energy electrons (with energies in the range 10–200 eV, corresponding to wavelengths in the range 100–400 pm) ensures that the diffraction is caused only by atoms on and close to the surface. The experimental arrangement is shown in Fig. 22A.9, and typical LEED patterns, obtained by photographing the fluorescent screen through the viewing port, are shown in Fig. 22A.10.

Observations using LEED show that the surface of a crystal rarely has exactly the same form as a slice through the bulk because surface and bulk atoms experience different forces. **Reconstruction** refers to processes by which atoms on the surface achieve their equilibrium structures. As a general rule, it is found that metal surfaces are simply truncations of the bulk lattice, but the distance between the top layer of atoms and the one below is contracted by around 5 per cent. Semiconductors generally have surfaces reconstructed to a depth of several layers. Reconstruction occurs in ionic solids. For example, in

**Figure 22A.9** A schematic diagram of the apparatus used for a LEED experiment. The electrons diffracted by the surface layers are detected by the fluorescence they cause on the phosphor screen.

**Figure 22A.10** LEED photographs of (a) a clean platinum surface and (b) after its exposure to propyne,  $\text{CH}_3\text{C}\equiv\text{CH}$ . (Photographs provided by Professor G.A. Somorjai.)

**Figure 22A.11** The structure of a surface close to the point of attachment of  $\text{CH}_3\text{C}-$  to the (110) surface of rhodium at 300 K and the changes in positions of the metal atoms that accompany chemisorption.

lithium fluoride the  $\text{Li}^+$  and  $\text{F}^-$  ions close to the surface apparently lie on slightly different planes. An actual example of the detail that can now be obtained from refined LEED techniques is shown in Fig. 22A.11 for  $\text{CH}_3\text{C}-$  adsorbed on a (111) plane of rhodium.

#### Example 22A.1 Interpreting a LEED pattern

The LEED pattern from a clean (110) face of palladium is shown in (a) below. The reconstructed surface gives a LEED pattern shown as (b). What can be inferred about the structure of the reconstructed surface?

**Method** Recall from Bragg's law (Topic 18A),  $\lambda = 2d \sin \theta$ , that for a given wavelength, the greater the separation  $d$  of the layers, the smaller is the scattering angle (so that  $2d \sin \theta$

remains constant). It follows that, in terms of the LEED pattern, the farther apart the atoms responsible for the pattern, the closer the spots appear in the pattern. Twice the separation between the atoms corresponds to half the separation between the spots, and vice versa. Therefore, inspect the two patterns and identify how the new pattern relates to the old.

**Answer** The horizontal separation between spots is unchanged, which indicates that the atoms remain in the same position in that dimension when reconstruction occurs. However, the vertical spacing is halved, which suggests that the atoms are twice as far apart in that direction as they are in the unreconstructed surface.

**Self-test 22A.5** Sketch the LEED pattern for a surface that differs from that shown in (a) above by tripling the vertical separation.

The presence of terraces, steps, and kinks in a surface shows up in LEED patterns, and their surface density (the number of defects in a region divided by the area of the region) can be estimated. The importance of this type of measurement will emerge later. Three examples of how steps and kinks affect the pattern are shown in Fig. 22A.12. The samples used were obtained by cleaving a crystal at different angles to a plane of atoms. Only terraces are produced when the cut is parallel to

**Figure 22A.12** LEED patterns may be used to assess the defect density of a surface. The photographs correspond to a platinum surface with (a) low defect density, (b) regular steps separated by about six atoms, and (c) regular steps with kinks. (Photographs provided by Professor G.A. Samorjai.)

the plane, and the density of steps increases as the angle of the cut increases. The observation of additional structure in the LEED patterns, rather than blurring, shows that the steps are arrayed regularly.

#### (d) Determination of the extent and rates of adsorption and desorption

A common technique for measuring rates of processes on surfaces is to monitor the rates of flow of gas into and out of the system: the difference is the rate of gas uptake by the sample. Integration of this rate then gives the fractional coverage at any stage.

- **Gravimetry**, in which the sample is weighed on a microbalance during the experiment, is used to determine the extent and kinetics of adsorption and desorption.

The technique commonly uses a **quartz crystal microbalance** (QCM), in which the mass of a sample adsorbed on the surface of a quartz crystal is related to changes in the characteristic vibrational frequency of the crystal. In this way, masses as small as a few nanograms can be measured reliably.

- **Second harmonic generation** (SHG), the conversion of an intense, pulsed laser beam to radiation with twice its initial frequency is very important for the study of all types of surfaces, including thin films and liquid–gas interfaces.

For example, adsorption of gas molecules on to a surface alters the intensity of the SHG signal, allowing for determination of the rates of surface processes and the fractional coverage. Because pulsed lasers are the excitation sources, time-resolved measurements of the kinetics and dynamics of surface processes are possible on timescales as short as femtoseconds.

- **Surface plasmon resonance** (SPR), the absorption of energy from an incident beam of electromagnetic radiation by surface ‘plasmons’, is a very sensitive technique now used routinely in the study of adsorption and desorption.

To understand the technique we need to examine the terms ‘surface plasmon’ and ‘resonance’ in its name.

The mobile delocalized valence electrons of metals form a **plasma**, a dense gas of charged particles. Bombardment of this plasma by light or an electron beam can cause transient changes in the distribution of electrons, with some regions becoming slightly denser than others. Coulomb repulsion in the regions of high density causes electrons to move away from each other, so lowering their density. The resulting oscillations in electron density, the **plasmons**, can be excited both in the bulk and on the surface of a metal. A surface plasmon propagates away from the surface, but the amplitude of the wave, also called an

**Figure 22A.13** The experimental arrangement for the observation of surface plasmon resonance, as explained in the text.

**evanescent wave**, decreases sharply with distance from the surface. The ‘resonance’ in the name refers to the absorption that can be observed with appropriate choice of the wavelength and angle of incidence of the excitation beam.

It is common practice to use a monochromatic beam and to vary the angle of incidence (the  $\phi$  in Fig. 22A.13). The beam passes through a prism that strikes one side of a thin film of gold or silver. Because the evanescent wave interacts with material a short distance away from the surface, the angle at which resonant absorption occurs depends on the refractive index of the medium on the opposite side of the metallic film. Thus, changing the identity and quantity of material on the surface changes the resonance angle.

The SPR technique can be used in the study of the binding of molecules to a surface or binding of ligands to a biopolymer attached to the surface; this interaction mimics the biological recognition processes that occur in cells. Examples of complexes amenable to analysis include antibody–antigen and protein–DNA interactions. The most important advantage of SPR is its sensitivity: it is possible to measure the deposition of nanograms of material on to a surface. The main disadvantage of the technique is its requirement for immobilization of at least one of the components of the system under study.

## Checklist of concepts

- 1. **Adsorption** is the attachment of molecules to a surface; the substance that adsorbs is the adsorbate and the underlying material is the adsorbent or substrate. The reverse of adsorption is desorption.
- 2. Surface defects play an important role in surface growth and catalysis.
- 3. **Reconstruction** refers to processes by which atoms on the surface achieve their equilibrium structures.
- 4. Techniques for studying surfaces include **scanning electron microscopy (SEM)**, **transmission electron microscopy (TEM)**, **scanning probe microscopy (SPM)**, **photoemission spectroscopy**, **Auger electron spectroscopy (AES)**, **low energy electron diffraction (LEED)**, **gravimetry**, **second harmonic generation (SHG)**, and **surface plasmon resonance (SPR)**.

### ► Why do you need to know this material?

To understand how surfaces can affect the rates of chemical reactions, you need to know how to assess the extent of surface coverage and the factors that determine the rates at which molecules attach to and detach from solid surfaces.

### ► What is the key idea?

The extent of surface coverage can be expressed in terms of isotherms derived on the basis of dynamic equilibria between adsorbed and free material.

### ► What do you need to know already?

This Topic extends the discussion of adsorption in Topic 22A. You need to be familiar with the basic ideas of chemical kinetics (Topics 20A–20C), the Arrhenius equation (Topic 20D), and the expression of reaction mechanisms as rate laws (Topic 20E).

Here we consider the extent to which a solid surface is covered and the variation of the extent of coverage with pressure and temperature. For simplicity, we consider only gas/solid systems. We use this material in Topic 22C to discuss how surfaces affect the rate and course of chemical change by acting as the site of catalysis.

## 22B.1 Adsorption isotherms

In adsorption (Topic 22A) the free gas and the adsorbed gas are in dynamic equilibrium, and the fractional coverage,  $\theta$ , of the surface (eqn 22A.2) depends on the pressure of the overlying gas. The variation of  $\theta$  with pressure at a chosen temperature is called the **adsorption isotherm**.

Many of the techniques discussed in Topic 22A can be used to measure  $\theta$ . Another is **flash desorption**, in which the sample is suddenly heated (electrically) and the resulting rise of pressure is interpreted in terms of the amount of adsorbate originally on the sample.

### (a) The Langmuir isotherm

The simplest physically plausible isotherm is based on three assumptions:

- Adsorption cannot proceed beyond monolayer coverage.
- All sites are equivalent.
- The ability of a molecule to adsorb at a given site is independent of the occupation of neighbouring sites (that is, there are no interactions between adsorbed molecules).

The dynamic equilibrium is

with rate constants  $k_a$  for adsorption and  $k_d$  for desorption. The rate of change of the surface coverage,  $d\theta/dt$ , due to adsorption is proportional to the partial pressure  $p$  of A and the number of vacant sites  $N(1 - \theta)$ , where  $N$  is the total number of sites:

$$\frac{d\theta}{dt} = k_a p N (1 - \theta) \quad \text{Rate of adsorption} \quad (22B.1a)$$

The rate of change of  $\theta$  due to desorption is proportional to the number of adsorbed species,  $N\theta$ :

$$\frac{d\theta}{dt} = -k_d N\theta \quad \text{Rate of desorption} \quad (22B.1b)$$

At equilibrium there is no net change (that is, the sum of these two rates is zero), and solving  $k_a p N(1-\theta) - k_d N\theta = 0$  for  $\theta$  gives the **Langmuir isotherm**:

$$\theta = \frac{\alpha p}{1 + \alpha p} \quad \alpha = \frac{k_a}{k_d} \quad \text{Langmuir isotherm} \quad (22B.2)$$

The dimensions of  $\alpha$  are 1/pressure.

### Example 22B.1 Using the Langmuir isotherm

The data given below are for the adsorption of CO on charcoal at 273 K. Confirm that they fit the Langmuir isotherm, and find the constant  $\alpha$  and the volume corresponding to complete coverage. In each case  $V$  has been corrected to 1 atm (101.325 kPa).

$p/\text{kPa}$	13.3	26.7	40.0	53.3	66.7	80.0	93.3
$V/\text{cm}^3$	10.2	18.6	25.5	31.5	36.9	41.6	46.1

**Method** From eqn 22B.2,  $\alpha p\theta + \theta = \alpha p$ . With  $\theta = V/V_\infty$  (eqn 22A.2), where  $V_\infty$  is the volume corresponding to complete coverage, this expression can be rearranged into

$$\frac{p}{V} = \frac{p}{V_\infty} + \frac{1}{\alpha V_\infty}$$

Hence, a plot of  $p/V$  against  $p$  should give a straight line of slope  $1/V_\infty$  and intercept  $1/\alpha V_\infty$ .

**Answer** The data for the plot are as follows:

$p/\text{kPa}$	13.3	26.7	40.0	53.3	66.7	80.0	93.3
$(p/\text{kPa})/(V/\text{cm}^3)$	1.30	1.44	1.57	1.69	1.81	1.92	2.02

**Figure 22B.1** The plot of the data in Example 22B.1. As illustrated here, the Langmuir isotherm predicts that a straight line should be obtained when  $p/V$  is plotted against  $p$ .

The points are plotted in Fig. 22B.1. The (least squares) slope is 0.009 00, so  $V_\infty = 111 \text{ cm}^3$ . The intercept at  $p=0$  is 1.20, so

$$\alpha = \frac{1}{(111 \text{ cm}^3) \times (1.20 \text{ kPa cm}^3)} = 7.51 \times 10^{-3} \text{ kPa}^{-1}$$

**Self-test 22B.1** Repeat the calculation for the following data:

$p/\text{kPa}$	13.3	26.7	40.0	53.3	66.7	80.0	93.3
$V/\text{cm}^3$	10.3	19.3	27.3	34.1	40.0	45.5	48.0

Answer:  $128 \text{ cm}^3$ ,  $6.69 \times 10^{-3} \text{ kPa}^{-1}$

For adsorption with dissociation, when  $A_2$  adsorbs as 2 A, the rate of adsorption is proportional to the pressure and to the probability that both fragments A will find sites. The latter is now proportional to the *square* of the number of vacant sites:

$$\frac{d\theta}{dt} = k_a p \{N(1-\theta)\}^2 \quad (22B.3a)$$

The rate of desorption is proportional to the frequency of encounters of the fragments on the surface, and is therefore second order in the number of fragments present:

$$\frac{d\theta}{dt} = -k_d (N\theta)^2 \quad (22B.3b)$$

The condition for no net change leads to the isotherm

$$\theta = \frac{(\alpha p)^{1/2}}{1 + (\alpha p)^{1/2}} \quad \text{Langmuir isotherm for adsorption with dissociation} \quad (22B.4)$$

The surface coverage now depends more weakly on pressure than for non-dissociative adsorption.

The shapes of the Langmuir isotherms with and without dissociation are shown in Figs. 22B.2 and 22B.3. The fractional

**Figure 22B.2** The Langmuir isotherm for dissociative adsorption,  $A_2(g) \rightarrow 2 A(\text{surface})$ , for different values of  $\alpha$ .

Figure 22B.3 The Langmuir isotherm for non-dissociative adsorption for different values of  $\alpha$ .

coverage increases with increasing pressure, and approaches 1 only at very high pressure, when the gas is forced on to every available site of the surface.

### (b) The isosteric enthalpy of adsorption

The Langmuir isotherm depends on the value of  $\alpha = k_a/k_d$ , which depends on the temperature. As we show in the following *Justification*, the temperature dependence of  $\alpha$  can be used to determine the **isosteric enthalpy of adsorption**,  $\Delta_{\text{ad}}H^\ominus$ , the standard enthalpy of adsorption at a fixed surface coverage, by using the relation

$$\left( \frac{\partial \ln(\alpha p^\ominus)}{\partial T} \right)_\theta = \frac{\Delta_{\text{ad}}H^\ominus}{RT^2} \quad \text{isosteric enthalpy of adsorption} \quad (22\text{B.5})$$

#### Justification 22B.1 The isosteric enthalpy of adsorption

It follows from the treatment in Topic 20C that the quantity  $\alpha p^\ominus = (k_a/k_d) \times p^\ominus$  is an equilibrium constant for the process  $A(\text{g}) + M(\text{surface}) \rightleftharpoons AM(\text{surface})$ , and can therefore be expressed in terms of the standard Gibbs energy of adsorption,  $\Delta_{\text{ad}}G^\ominus$  through eqn 6A.14 ( $\Delta G^\ominus = -RT \ln K$ ) as

$$\ln(\alpha p^\ominus) = -\frac{\Delta_{\text{ad}}G^\ominus}{RT}$$

We can then infer from the Gibbs–Helmholtz equation (eqn 6B.2,  $d(\Delta G/T)/dT = -\Delta H/RT^2$ ) that

$$\frac{d \ln(\alpha p^\ominus)}{dT} = \frac{\Delta_{\text{ad}}H^\ominus}{RT^2}$$

There is the possibility that the enthalpy of adsorption depends on the fractional coverage, so this expression is confined to constant  $\theta$ , which implies the partial derivative form in eqn 22B.5.

#### Example 22B.2 Measuring the isosteric enthalpy of adsorption

The data below show the pressures of CO needed for the volume of adsorption (corrected to 1 atm and 0°C) to be 10.0 cm<sup>3</sup> using the same sample as in *Example 22B.1*. In this case, there is no dissociation. Calculate the adsorption enthalpy at this surface coverage.

$T/\text{K}$	200	210	220	230	240	250
$p/\text{kPa}$	4.00	4.95	6.03	7.20	8.47	9.85

**Method** The Langmuir isotherm for adsorption without dissociation (eqn 22B.2), can be rearranged to  $\alpha p = \theta/(1 - \theta)$ , a constant when  $\theta$  is constant. We need to guard against problems with units as we manipulate expressions, and in this case it will prove useful to write  $\alpha p = \text{constant}$  as  $(\alpha p^\ominus) \times (p/p^\ominus) = \text{constant}$ . It then follows that

$$\ln\{(\alpha p^\ominus)(p/p^\ominus)\} = \ln(\alpha p^\ominus) + \ln(p/p^\ominus) = \text{constant}$$

and from eqn 22B.5 that

$$\left( \frac{\partial \ln(p/p^\ominus)}{\partial T} \right)_\theta = - \left( \frac{\partial \ln(\alpha p^\ominus)}{\partial T} \right)_\theta = - \frac{\Delta_{\text{ad}}H^\ominus}{RT^2}$$

With  $d(1/T)/dT = -1/T^2$ , and therefore  $dT = -T^2 d(1/T)$ , this expression becomes

$$\left( \frac{\partial \ln(p/p^\ominus)}{\partial(1/T)} \right)_\theta = \frac{\Delta_{\text{ad}}H^\ominus}{R}$$

Therefore, a plot of  $\ln(p/p^\ominus)$  against  $1/T$  should be a straight line of slope  $\Delta_{\text{ad}}H^\ominus/R$ .

Figure 22B.4 The isosteric enthalpy of adsorption can be obtained from the slope of the plot of  $\ln(p/p^\ominus)$  against  $1/T$ , where  $p$  is the pressure needed to achieve the specified surface coverage. The data used are from *Example 22B.2*.

**Answer** With  $p^\ominus = 1 \text{ bar} = 10^2 \text{ kPa}$ , we draw up the following table:

$T/\text{K}$	200	210	220	230	240	250
$10^3/(T/\text{K})$	5.00	4.76	4.55	4.35	4.17	4.00
$(p/p^\ominus) \times 10^2$	4.00	4.95	6.03	7.20	8.47	9.85
$\ln(p/p^\ominus)$	-3.22	-3.01	-2.81	-2.63	-2.47	-2.32

The points are plotted in Fig. 22B.4. The slope (of the least squares fitted line) is  $-0.904$ , so

$$\Delta_{\text{ad}}H^\ominus = -(0.904 \times 10^3 \text{ K}) \times R = -7.52 \text{ kJ mol}^{-1}$$

**Self-test 22B.2** Repeat the calculation using the following data:

$T/\text{K}$	200	210	220	230	240	250
$p/\text{kPa}$	4.32	5.59	7.07	8.80	10.67	12.80

Answer:  $-9.0 \text{ kJ mol}^{-1}$

Two assumptions of the Langmuir isotherm are the independence and equivalence of the adsorption sites. Deviations from the isotherm can often be traced to the failure of these assumptions. For example, the enthalpy of adsorption often becomes less negative as  $\theta$  increases, which suggests that the energetically most favourable sites are occupied first. Also, substrate-substrate interactions on the surface can be important. A number of isotherms have been developed to deal with cases where deviations from the Langmuir isotherm are important.

### (c) The BET isotherm

If the initial adsorbed layer can act as a substrate for further (for example, physical) adsorption, then, instead of the isotherm levelling off to some saturated value at high pressures, it can be expected to rise indefinitely. The most widely used isotherm dealing with multilayer adsorption was derived by Stephen Brunauer, Paul Emmett, and Edward Teller and is called the **BET isotherm**:

$$\frac{V}{V_{\text{mon}}} = \frac{cz}{(1-z)\{1-(1-c)z\}} \quad \text{with} \quad z = \frac{p}{p^*} \quad \text{BET isotherm} \quad (22\text{B.6})$$

In this expression, which is obtained in the following *Justification*,  $p^*$  is the vapour pressure above a layer of adsorbate that is more than one molecule thick and which resembles a pure bulk liquid,  $V_{\text{mon}}$  is the volume corresponding to monolayer coverage, and  $c$  is a constant which is large when the enthalpy of desorption from a monolayer is large compared with the enthalpy of vaporization of the liquid adsorbate:

$$c = e^{(\Delta_{\text{des}}H^\ominus - \Delta_{\text{vap}}H^\ominus)/RT} \quad (22\text{B.7})$$

**Figure 22B.5** Plots of the BET isotherm for different values of  $c$ . The value of  $V/V_{\text{mon}}$  rises indefinitely because the adsorbate may condense on the covered substrate surface.

Figure 22B.5 illustrates the shapes of BET isotherms. They rise indefinitely as the pressure is increased because there is no limit to the amount of material that may condense when multilayer coverage is possible. A BET isotherm is not accurate at all pressures, but it is widely used in industry to determine the surface areas of solids.

### Justification 22B.2 The BET isotherm

We suppose that at equilibrium a fraction  $\theta_0$  of the surface sites are unoccupied, a fraction  $\theta_1$  is covered by a monolayer, a fraction  $\theta_2$  is covered by a bilayer, and so on. The number of adsorbed molecules is therefore

$$N = N_{\text{sites}}(\theta_1 + 2\theta_2 + 3\theta_3 + \dots)$$

where  $N_{\text{sites}}$  is the total number of sites. We now follow the derivation that led to the Langmuir isotherm (eqn 22B.2) but allow for different rates of desorption from the substrate and the various layers:

First layer:	Rate of adsorption = $Nk_{a,0}p\theta_0$ Rate of desorption = $Nk_{d,0}\theta_1$ At equilibrium, $k_{a,0}p\theta_0 = k_{d,0}\theta_1$
Second layer:	Rate of adsorption = $Nk_{a,1}p\theta_1$ Rate of desorption = $Nk_{d,1}\theta_2$ At equilibrium, $k_{a,1}p\theta_1 = k_{d,1}\theta_2$
Third layer:	Rate of adsorption = $Nk_{a,2}p\theta_2$ Rate of desorption = $Nk_{d,2}\theta_3$ At equilibrium, $k_{a,2}p\theta_2 = k_{d,2}\theta_3$

and so on. We now suppose that once a monolayer has been formed, all the rate constants involving adsorption and

desorption from the physisorbed layers are the same, and write these equations as

$$\begin{aligned}k_{a,0}p\theta_0 &= k_{d,0}\theta_1, \text{ so} \\ \theta_1 &= (k_{a,0}/k_{d,0})p\theta_0 = \alpha_0 p\theta_0 \\ k_{a,1}p\theta_1 &= k_{d,1}\theta_2, \text{ so} \\ \theta_2 &= (k_{a,1}/k_{d,1})p\theta_1 = (k_{a,0}/k_{d,0})(k_{a,1}/k_{d,1})p^2\theta_0 = \alpha_0\alpha_1 p^2\theta_0 \\ k_{a,1}p\theta_2 &= k_{d,1}\theta_3, \text{ so} \\ \theta_3 &= (k_{a,1}/k_{d,1})p\theta_2 = (k_{a,0}/k_{d,0})(k_{a,1}/k_{d,1})^2 p^3\theta_0 = \alpha_0\alpha_1^2 p^3\theta_0\end{aligned}$$

and so on, with  $\alpha_0 = k_{a,0}/k_{d,0}$  and  $\alpha_1 = k_{a,1}/k_{d,1}$  the ratios of rate constants for adsorption to the substrate and an overlayer, respectively. Now, because  $\theta_0 + \theta_1 + \theta_2 + \dots = 1$ , it follows that

$$\begin{aligned}\theta_0 + \alpha_0 p\theta_0 + \alpha_0\alpha_1 p^2\theta_0 + \alpha_0\alpha_1^2 p^3\theta_0 + \dots \\ = \theta_0 + \alpha_0 p\theta_0 \{1 + \alpha_1 p + \alpha_1^2 p^2 + \dots\} \\ \stackrel{1+x+x^2+\dots=1/(1-x)}{=} \left\{1 + \frac{\alpha_0 p}{1 - \alpha_1 p}\right\} \theta_0 = \left\{\frac{1 - \alpha_1 p + \alpha_0 p}{1 - \alpha_1 p}\right\} \theta_0\end{aligned}$$

Then, because this expression is equal to 1,

$$\theta_0 = \frac{1 - \alpha_1 p}{1 - (\alpha_1 - \alpha_0)p}$$

In a similar way, we can write the number of adsorbed species as

$$\begin{aligned}N &= N_{\text{sites}}\alpha_0 p\theta_0 + 2N_{\text{sites}}\alpha_0\alpha_1 p^2\theta_0 + \dots \\ &= N_{\text{sites}}\alpha_0 p\theta_0 (1 + 2\alpha_1 p + 3\alpha_1^2 p^2 + \dots) \\ &\stackrel{1+2x+3x^2+\dots=1/(1-x)^2}{=} \frac{N_{\text{sites}}\alpha_0 p\theta_0}{(1 - \alpha_1 p)^2}\end{aligned}$$

By combining the last two expressions, we obtain

$$N = \frac{N_{\text{sites}}\alpha_0 p}{(1 - \alpha_1 p)^2} \times \frac{1 - \alpha_1 p}{1 - (\alpha_1 - \alpha_0)p} = \frac{N_{\text{sites}}\alpha_0 p}{(1 - \alpha_1 p)\{1 - (\alpha_1 - \alpha_0)p\}}$$

The ratio  $N/N_{\text{sites}}$  is equal to the ratio  $V/V_{\text{mon}}$ , where  $V$  is the total volume adsorbed and  $V_{\text{mon}}$  the volume adsorbed had there been complete monolayer coverage. The equilibrium of the adsorption and desorption from the overlayers is equivalent to the vaporization  $A(l) \rightleftharpoons A(g)$  of the pure adsorbate, with matching forward and reverse rates:  $k_d = k_a p^*$ , where  $p^*$  is the vapour pressure of the liquid adsorbate. Therefore,  $\alpha_1 = k_{a,1}/k_{d,1} = 1/p^*$ . Then, with  $z = p/p^*$  and  $c = \alpha_0/\alpha_1$ , the last equation becomes

$$\frac{V}{V_{\text{mon}}} = \frac{\alpha_0 p}{(1 - p/p^*)\{1 - (1 - \alpha_0/\alpha_1)p/p^*\}} = \frac{cz}{(1 - z)\{1 - (1 - c)z\}}$$

as in eqn 22B.6.

As in *Justification* 22B.1,  $\alpha_0$  and  $\alpha_1$  are related to the Gibbs energy changes accompanying adsorption to the substrate and condensation on the adsorbed layers,  $\Delta_{\text{ad}}G^\ominus$  and  $\Delta_{\text{con}}G^\ominus$ , which in turn can be related to the Gibbs energies for the

opposite processes, desorption from the substrate and vaporization from the overlayer, by  $\Delta_{\text{des}}G^\ominus = -\Delta_{\text{ad}}G^\ominus$  and  $\Delta_{\text{vap}}G^\ominus = -\Delta_{\text{con}}G^\ominus$ . Therefore, from  $\ln(\alpha p^\ominus) = -\Delta G^\ominus/RT$  in each case,

$$\alpha_0 p^\ominus = e^{-\Delta_{\text{ad}}G^\ominus/RT} = e^{\Delta_{\text{des}}G^\ominus/RT} \text{ and } \alpha_1 p^\ominus = e^{-\Delta_{\text{con}}G^\ominus/RT} = e^{\Delta_{\text{vap}}G^\ominus/RT}$$

The ratio  $c$  then becomes (after cancelling the  $p^\ominus$  and writing  $\Delta G^\ominus = \Delta H^\ominus - T\Delta S^\ominus$  in each case)

$$c = \frac{\alpha_0}{\alpha_1} = \frac{e^{\Delta_{\text{des}}G^\ominus/RT}}{e^{\Delta_{\text{vap}}G^\ominus/RT}} = \frac{e^{\Delta_{\text{des}}H^\ominus/RT} e^{-\Delta_{\text{des}}S^\ominus/R}}{e^{\Delta_{\text{vap}}H^\ominus/RT} e^{-\Delta_{\text{vap}}S^\ominus/R}}$$

If the entropies of desorption and vaporization are assumed to be the same because they correspond to very similar processes in terms of the escape of the condensed adsorbate to the gas phase, this ratio becomes

$$c = \frac{e^{\Delta_{\text{des}}H^\ominus/RT}}{e^{\Delta_{\text{vap}}H^\ominus/RT}} = e^{(\Delta_{\text{des}}H^\ominus - \Delta_{\text{vap}}H^\ominus)/RT}$$

as in eqn 21B.7.

### Example 22B.3 Using the BET isotherm

The data below relate to the adsorption of  $N_2$  on rutile ( $\text{TiO}_2$ ) at 75 K. Confirm that they fit a BET isotherm in the range of pressures reported, and determine  $V_{\text{mon}}$  and  $c$ .

$p/\text{kPa}$	0.160	1.87	6.11	11.67	17.02	21.92	27.29
$V/\text{mm}^3$	601	720	822	935	1046	1146	1254

At 75 K,  $p^* = 76.0$  kPa. The volumes have been corrected to 1.00 atm and 273 K and refer to 1.00 g of substrate.

**Method** Equation 22B.6 can be reorganized into

$$\frac{z}{(1-z)V} = \frac{1}{cV_{\text{mon}}} + \frac{(c-1)z}{cV_{\text{mon}}}$$

It follows that  $(c-1)/cV_{\text{mon}}$  can be obtained from the slope of a plot of the expression on the left against  $z$ , and  $cV_{\text{mon}}$  can be found from the intercept at  $z=0$ . The results can then be combined to give  $c$  and  $V_{\text{mon}}$ .

**Answer** We draw up the following table:

$p/\text{kPa}$	0.160	1.87	6.11	11.67	17.02	21.92	27.29
$10^3 z$	2.11	24.6	80.4	154	224	288	359
$10^4 z/(1-z)$ ( $V/\text{mm}^3$ )	0.035	0.350	1.06	1.95	2.76	3.53	4.47

These points are plotted in Fig. 22B.6. The least squares best line has an intercept at 0.0398, so

$$\frac{1}{cV_{\text{mon}}} = 3.98 \times 10^{-6} \text{ mm}^{-3}$$

**Figure 22B.6** The BET isotherm can be tested, and the parameters determined, by plotting  $z/(1-z)V$  against  $z=p/p^*$ . The data are from *Example 22B.3*.

The slope of the line is  $1.23 \times 10^{-2}$ , so

$$\frac{c-1}{cV_{\text{mon}}} = (1.23 \times 10^{-2}) \times 10^3 \times 10^{-4} \text{ mm}^{-3} = 1.23 \times 10^{-3} \text{ mm}^{-3}$$

The solutions of these equations are  $c = 310$  and  $V_{\text{mon}} = 811 \text{ mm}^3$ . At 1.00 atm and 273 K,  $811 \text{ mm}^3$  corresponds to  $3.6 \times 10^{-5} \text{ mol}$ , or  $2.2 \times 10^{19}$  atoms. Because each atom occupies an area of about  $0.16 \text{ nm}^2$ , the surface area of the sample is about  $3.5 \text{ m}^2$ .

**Self-test 22B.3** Repeat the calculation for the following data:

$p/\text{kPa}$	0.160	1.87	6.11	11.67	17.02	21.92	27.29
$V/\text{cm}^3$	235	559	649	719	790	860	950

Answer: 370,  $615 \text{ cm}^3$

When  $c \gg 1$ , the BET isotherm takes the simpler form

$$\frac{V}{V_{\text{mon}}} = \frac{1}{1-z} \quad \text{BET isotherm when } c \gg 1 \quad (22B.8)$$

This expression is applicable to unreactive gases on polar surfaces, for which  $c \approx 10^2$  because  $\Delta_{\text{des}}H^\ominus$  is then significantly greater than  $\Delta_{\text{vap}}H^\ominus$  (eqn 22B.7). The BET isotherm fits experimental observations moderately well over restricted pressure ranges, but it errs by underestimating the extent of adsorption at low pressures and by overestimating it at high pressures.

#### (d) The Temkin and Freundlich isotherms

An assumption of the Langmuir isotherm is the independence and equivalence of the adsorption sites. Deviations from the isotherm can often be traced to the failure of these assumptions. For example, the enthalpy of adsorption often becomes less negative as  $\theta$  increases, which suggests that the energetically most favourable sites are occupied first. Various attempts

have been made to take these variations into account. The **Temkin isotherm**,

$$\theta = c_1 \ln(c_2 p) \quad \text{Temkin isotherm} \quad (22B.9)$$

where  $c_1$  and  $c_2$  are constants, corresponds to supposing that the adsorption enthalpy changes linearly with pressure. The **Freundlich isotherm**

$$\theta = c_1 p^{1/c_2} \quad \text{Freundlich isotherm} \quad (22B.10)$$

corresponds to a logarithmic change. This isotherm attempts to incorporate the role of substrate–substrate interactions on the surface.

Different isotherms agree with experiment more or less well over restricted ranges of pressure, but they remain largely empirical. Empirical, however, does not mean useless for, if the parameters of a reasonably reliable isotherm are known, reasonably reliable results can be obtained for the extent of surface coverage under various conditions. This kind of information is essential for any discussion of heterogeneous catalysis (Topic 22C).

## 22B.2 The rates of adsorption and desorption

We have noted that adsorption and desorption are activated processes, in the sense that they have an activation energy and follow Arrhenius behaviour. Now we are ready to look more closely at the origin of the activation energy in these processes, with a special focus on chemisorption.

### (a) The precursor state

Figure 22B.7 shows how the potential energy of a molecule varies with its distance from the substrate surface. As the molecule approaches the surface its energy falls as it becomes physisorbed into the **precursor state** for chemisorption (see Topic 22A). Dissociation into fragments often takes place as a molecule moves into its chemisorbed state, and after an initial increase of energy as the bonds stretch there is a sharp decrease as the adsorbate–substrate bonds reach their full strength. Even if the molecule does not fragment, there is likely to be an initial increase of potential energy as the molecule approaches the surface and the bonds adjust.

In most cases, therefore, we can expect there to be a potential energy barrier separating the precursor and chemisorbed states. This barrier, though, might be low, and might not rise above the energy of a distant, stationary particle (as in Fig. 22B.7a). In this case, chemisorption is not an activated process and can be expected to be rapid. Many gas adsorptions on clean metals appear to be non-activated. In some cases, however, the

**Figure 22B.7** The potential energy profiles for the dissociative chemisorption of an  $A_2$  molecule. In each case,  $P$  is the enthalpy of (non-dissociative) physisorption and  $C$  that for chemisorption (at  $T=0$ ). The relative locations of the curves determine whether the chemisorption is (a) not activated or (b) activated.

barrier rises above the zero axis (as in Fig. 22B.7b); such chemisorptions are activated and slower than the non-activated kind. An example is  $H_2$  on copper, which has an activation energy in the region of  $20\text{--}40\text{ kJ mol}^{-1}$ .

One point that emerges from this discussion is that rates are not good criteria for distinguishing between physisorption and chemisorption. Chemisorption can be fast if the activation energy is small or zero, but it may be slow if the activation energy is large. Physisorption is usually fast, but it can appear to be slow if adsorption is taking place on a porous medium.

#### Brief illustration 22B.1 The rate of activated adsorption

Consider two adsorption experiments for hydrogen on different faces of a copper crystal. In one, Face 1, the activation energy is  $28\text{ kJ mol}^{-1}$  and on the other, Face 2, the activation energy is  $33\text{ kJ mol}^{-1}$ . The ratio of the rates of chemisorption on equal areas of the two faces at  $250\text{ K}$  is

$$\frac{\text{Rate}(1)}{\text{Rate}(2)} = \frac{Ae^{-E_{a,\text{ads}}(1)/RT}}{Ae^{-E_{a,\text{ads}}(2)/RT}} = e^{-(E_{a,\text{ads}}(1)-E_{a,\text{ads}}(2))/RT} \\ = e^{5 \times 10^3 \text{ J mol}^{-1} / (8.3145 \text{ J K}^{-1} \text{ mol}^{-1}) \times (250 \text{ K})} = 11$$

We have assumed that the  $A$  factor is the same for each face.

**Self-test 22B.4** What are the relative rates when the temperature is increased to  $300\text{ K}$ ?

Answer: 7

### (b) Adsorption and desorption at the molecular level

The rate at which a surface is covered by adsorbate depends on the ability of the substrate to dissipate the energy of the incoming particle as thermal motion as it crashes on to the surface. If

the energy is not dissipated quickly, the particle migrates over the surface until a vibration expels it into the overlying gas or it reaches an edge. The proportion of collisions with the surface that successfully lead to adsorption is called the **sticking probability**,  $s$ :

$$s = \frac{\text{rate of adsorption of particles by the surface}}{\text{rate of collision of particles with the surface}}$$

Definition Sticking probability (22B.11)

The denominator can be calculated from the kinetic model (from  $Z_{\text{W}}$ , Topic 22A), and the numerator can be measured by observing the rate of change of pressure.

Values of  $s$  vary widely. For example, at room temperature  $\text{CO}$  has  $s$  in the range  $0.1\text{--}1.0$  for several d-metal surfaces, but for  $\text{N}_2$  on rhenium  $s < 10^{-2}$ , indicating that more than a hundred collisions are needed before one molecule sticks successfully. Beam studies on specific crystal planes show a pronounced specificity: for  $\text{N}_2$  on tungsten,  $s$  ranges from  $0.74$  on the (320) faces down to less than  $0.01$  on the (110) faces at room temperature. The sticking probability decreases as the surface coverage increases (Fig. 22B.8). A simple assumption is that  $s$  is proportional to  $1 - \theta$ , the fraction uncovered, and it is common to write

$$s = (1 - \theta)s_0$$

Commonly used form of the sticking probability

(22B.12)

where  $s_0$  is the sticking probability on a perfectly clean surface. The results in the illustration do not fit this expression because they show that  $s$  remains close to  $s_0$  until the coverage has risen to about  $6 \times 10^{13}$  molecules  $\text{cm}^{-2}$ , and then falls steeply. The explanation is probably that the colliding molecule does not enter the chemisorbed state at once, but moves over the surface until it encounters an empty site.

**Figure 22B.8** The sticking probability of  $\text{N}_2$  on various faces of a tungsten crystal and its dependence on surface coverage. Note the very low sticking probability for the (110) and (111) faces. (Data provided by Professor D.A. King.)

Desorption is always activated because the particles have to be lifted from the foot of a potential well. A physisorbed particle vibrates in its shallow potential well, and might shake itself off the surface after a short time. If the temperature dependence of the first-order rate of departure follows Arrhenius behaviour, then  $k_d = Ae^{-E_{a,des}/RT}$ , with  $E_{a,des}$  the activation energy for desorption. Therefore, the half-life for remaining on the surface has a temperature dependence

$$t_{1/2} = \frac{\ln 2}{k_d} = \tau_0 e^{E_{a,des}/RT} \quad \tau_0 = \frac{\ln 2}{A} \quad \text{Residence half-life} \quad (22B.13)$$

Note the positive sign in the exponent: the greater the activation energy for desorption, the larger the residence half-life.

#### Brief illustration 22B.2 Residence half-lives

If we suppose that  $1/\tau_0$  is approximately the same as the vibrational frequency of the weak particle–surface bond (about  $10^{12}$  Hz) and  $E_d \approx 25$  kJ mol<sup>-1</sup>, then residence half-lives of around 10 ns are predicted at room temperature. Lifetimes close to 1 s are obtained only by lowering the temperature to about 100 K. For chemisorption, with  $E_d = 100$  kJ mol<sup>-1</sup> and guessing that  $\tau_0 = 10^{-14}$  s (because the adsorbate–substrate bond is quite stiff), we expect a residence half-life of about  $3 \times 10^3$  s (about an hour) at room temperature, decreasing to 1 s at about 350 K.

**Self-test 22B.5** For how long on average would an atom remain on a surface at 800 K if its desorption activation energy is 200 kJ mol<sup>-1</sup>? Take  $\tau_0 = 0.10$  ps.

Answer:  $t_{1/2} = 1.3$  s

The desorption activation energy can be measured in several ways. However, we must be guarded in its interpretation because it often depends on the fractional coverage, and so might change as desorption proceeds. Moreover, the transfer of concepts such as ‘reaction order’ and ‘rate constant’ from bulk studies to surfaces is hazardous, and there are few examples of strictly first-order or second-order desorption kinetics (just as there are few integral-order reactions in the gas phase too).

If we disregard these complications, one way of measuring the desorption activation energy is to monitor the rate of increase in pressure when the sample is maintained at a series of temperatures, and to attempt to make an Arrhenius plot. A more sophisticated technique is **temperature programmed desorption** (TPD) or **thermal desorption spectroscopy** (TDS). The basic observation is a surge in desorption rate (as monitored by a mass spectrometer) when the temperature is raised linearly to the temperature at which desorption occurs rapidly, but once the desorption has occurred there is no more adsorbate to escape from the surface, so the desorption flux falls again

**Figure 22B.9** The TPD spectrum of H<sub>2</sub> on the (100) face of tungsten. The three peaks indicate the presence of three sites with different adsorption enthalpies and therefore different desorption activation energies (P.W. Tamm and L.D. Schmidt, *J. Chem. Phys.* **51**, 5352 (1969)).

as the temperature continues to rise. The TPD spectrum, the plot of desorption flux against temperature, therefore shows a peak, the location of which depends on the desorption activation energy. There are three maxima in the example shown in Fig. 22B.9, indicating the presence of three sites with different activation energies.

In many cases only a single activation energy (and a single peak in the TPD spectrum) is observed. When several peaks are observed they might correspond to adsorption on different crystal planes or to multilayer adsorption. For instance, Cd atoms on tungsten show two activation energies, one of 18 kJ mol<sup>-1</sup> and the other of 90 kJ mol<sup>-1</sup>. The explanation is that the more tightly bound Cd atoms are attached directly to the substrate, and the less strongly bound are in a layer (or layers) above the primary overlayer. Another example of a system showing two desorption activation energies is CO on tungsten, the values being 120 kJ mol<sup>-1</sup> and 300 kJ mol<sup>-1</sup>. The explanation is believed to be the existence of two types of metal–adsorbate binding site, one involving a simple M–CO bond, the other adsorption with dissociation into individually adsorbed C and O atoms.

#### (c) Mobility on surfaces

A further aspect of the strength of the interactions between adsorbate and substrate is the mobility of the adsorbate. Mobility is often a vital feature of a catalyst’s activity, because a catalyst might be impotent if the reactant molecules adsorb so strongly that they cannot migrate.

The activation energy for diffusion over a surface need not be the same as for desorption because the particles may be able to move through valleys between potential peaks without leaving the surface completely. In general, the activation energy for migration is about 10–20 per cent of the energy of the surface–adsorbate bond, but the actual value depends on the extent of

coverage. The defect structure of the sample (which depends on the temperature) may also play a dominant role because the adsorbed molecules might find it easier to skip across a terrace than to roll along the foot of a step, and these molecules

might become trapped in vacancies in an otherwise flat terrace. Diffusion may also be easier across one crystal face than another, and so the surface mobility depends on which lattice planes are exposed.

## Checklist of concepts

- 1. An **adsorption isotherm** is the variation of the surface coverage  $\theta$  with pressure at a chosen temperature.
- 2. **Flash desorption** is a technique in which the sample is suddenly heated (electrically) and the resulting rise of pressure is interpreted in terms of the amount of adsorbate originally on the substrate.
- 3. Examples of adsorption isotherms include the **Langmuir**, **BET**, **Temkin**, and **Freundlich** isotherms.
- 4. The **sticking probability** is the proportion of collisions with the surface that successfully lead to adsorption.
- 5. Desorption is an activated process; the desorption activation energy is measured by **temperature-programmed desorption** or **thermal desorption spectroscopy**.
- 6. The mobility of adsorbates on a surface is dominated by diffusion.

## Checklist of equations

Property	Equation	Comment	Equation number
Langmuir isotherm:		Independent and equivalent sites, monolayer coverage	
(a) without dissociation	$\theta = \alpha p / (1 + \alpha p)$		22B.2
(b) with dissociation	$\theta = (\alpha p)^{1/2} / \{1 + (\alpha p)^{1/2}\}$		22B.4
Isosteric enthalpy of adsorption	$(\partial \ln(\alpha p^\ominus) / \partial T)_\theta = \Delta_{\text{ad}} H^\ominus / RT^2$		22B.5
BET isotherm	$V/V_{\text{mon}} = cz / (1-z) \{1 - (1-c)z\}$ , $z = p/p^*$ , $c = e^{(\Delta_{\text{des}} H^\ominus - \Delta_{\text{vap}} H^\ominus) / RT}$	Multilayer adsorption	22B.6–7
Temkin isotherm	$\theta = c_1 \ln(c_2 p)$	Enthalpy of adsorption varies with $\theta$	22B.9
Freundlich isotherm	$\theta = c_1 p^{1/c_2}$	Substrate–substrate interactions	22B.10
Sticking probability	$s = (1 - \theta)s_0$	Approximate form	22B.12

### ► Why do we need to know this material?

Catalysis is at the heart of the chemical industry, and an understanding of the concepts is essential for developing new catalysts.

### ► What is the key idea?

In heterogeneous catalysis, the pathway for lowering the activation energy of a reaction commonly involves chemisorption of one or more reactants.

### ► What do we need to know already?

Catalysis is introduced in Topic 20H. This Topic builds on the discussion of reaction mechanisms (Topic 20E), the Arrhenius equation (Topic 20D), and adsorption isotherms (Topic 22B).

A **heterogeneous catalyst** is a catalyst in a different phase from the reaction mixture. For example, the hydrogenation of ethene to ethane, a gas-phase reaction, is accelerated in the presence of a solid catalyst such as palladium, platinum, or nickel. The metal provides a surface to which the reactants bind; this binding facilitates encounters between reactants and increases the rate of the reaction. This Topic is an exploration of catalytic activity on surfaces, building on the concepts developed in Topic 22B.

## 22C.1 Mechanisms of heterogeneous catalysis

Many catalysts depend on **co-adsorption**, the adsorption of two or more species. One consequence of the presence of a second species may be the modification of the electronic structure at the surface of a metal. For instance, partial coverage of d-metal surfaces by alkali metals has a pronounced effect on the electron distribution at the surface and reduces the work function of the metal (the energy needed to remove an electron; see Topic 7A). Such modifiers can act as promoters (to enhance the action of catalysts) or as poisons (to inhibit catalytic action).

Figure 22C.1 shows the potential energy curve for a reaction influenced by the action of a heterogeneous catalyst. Differences between Fig. 22C.1 and 20H.1 arise from the fact that heterogeneous catalysis normally depends on at least one reactant being adsorbed (usually chemisorbed) and modified to an **active phase** in which it readily undergoes reaction, and desorption of products. Modification of the reactant often takes the form of a fragmentation of the reactant molecules. In practice, the active phase is dispersed as very small particles of linear dimension less than 2 nm on a porous oxide support. **Shape-selective catalysts**, such as the zeolites, which have a pore size that can distinguish shapes and sizes at a molecular scale, have high internal specific surface areas, in the range of  $100\text{--}500\text{ m}^2\text{ g}^{-1}$ .

Mechanisms of reactions catalysed by surfaces can be treated quantitatively by using the techniques of Topic 20E (on the

**Figure 22C.1** The reaction profile for catalysed and uncatalysed reactions. The catalysed reaction path includes activation energies for adsorption and desorption as well as an overall lower activation energy for the process.

development of rate laws based on proposed reaction mechanisms) and the adsorption isotherms developed in Topic 22B. Here we explore some simple mechanisms that can give significant insight into surface-catalysed reactions.

### (a) Unimolecular reactions

The rate law of a surface-catalysed unimolecular reaction, such as the decomposition of a substance on a surface, can be written in terms of an adsorption isotherm if the rate is supposed to be proportional to the extent of surface coverage. For example, if the fractional coverage  $\theta$  is given by the Langmuir isotherm (eqn 22B.2,  $\theta = \alpha p / (1 + \alpha p)$ ), we would write

$$v = k_r \theta = \frac{k_r \alpha p}{1 + \alpha p} \quad (22C.1)$$

where  $p$  is the pressure of the adsorbing substance.

#### Brief illustration 22C.1 Surface-catalysed unimolecular decomposition

Consider the decomposition of phosphine ( $\text{PH}_3$ ) on tungsten, which is first order at low pressures. We can use eqn 22C.1 to account for this observation. When the pressure is so low that  $\alpha p \ll 1$ , we can neglect  $\alpha p$  in the denominator of eqn 22C.1 and obtain  $v = k_r \alpha p$ . The decomposition is predicted to be first order, as observed experimentally.

**Self-test 22C.1** Write a rate law for the decomposition of  $\text{PH}_3$  on tungsten at high pressures

Answer:  $v = k_r$ ; the reaction is zeroth order at high pressures

### (b) The Langmuir–Hinshelwood mechanism

In the **Langmuir–Hinshelwood mechanism** (LH mechanism) of surface-catalysed reactions, the reaction takes place by encounters between molecular fragments and atoms adsorbed on the surface. We therefore expect the rate law to be second order in the extent of surface coverage:

Insertion of the appropriate isotherms for A and B then gives the reaction rate in terms of the partial pressures of the reactants.

#### Example 22C.1 Writing a rate law based on the Langmuir–Hinshelwood mechanism

Consider a reaction  $\text{A} + \text{B} \rightarrow \text{P}$  in which A and B follow Langmuir isotherms and adsorb without dissociation. Devise a rate law that is consistent with the Langmuir–Hinshelwood mechanism.

**Method** Begin by following the procedures outlined in Topic 22B for the derivation of the Langmuir isotherm to write expressions for  $\theta_A$  and  $\theta_B$ , the fractional coverages of A and B, respectively. However, note that, unlike the simple situation in Topic 22B, two species compete for the same sites on the surface. Then, use eqn 22C.2 to express the rate law.

**Answer** Because two species compete for sites on the surface, the number of vacant sites is equal to  $N(1 - \theta_A - \theta_B)$ , where  $N$  is the total number of sites. It follows from eqns 22B.1a and 22B.1b that the rates of adsorption and desorption are given by

$$\begin{array}{ll} \text{Rate of adsorption of A} & \text{Rate of desorption of A} \\ = k_{a,A} p_A N(1 - \theta_A - \theta_B) & = k_{d,A} N \theta_A \\ \text{Rate of adsorption of B} & \text{Rate of desorption of B} \\ = k_{a,B} p_B N(1 - \theta_A - \theta_B) & = k_{d,B} N \theta_B \end{array}$$

At equilibrium, the rates of adsorption and desorption for each species are equal, and, with  $\alpha_A = k_{a,A}/k_{d,A}$  and  $\alpha_B = k_{a,B}/k_{d,B}$ , it follows that

$$\begin{array}{l} \alpha_A p_A (1 - \theta_A - \theta_B) = \theta_A \\ \alpha_B p_B (1 - \theta_A - \theta_B) = \theta_B \end{array}$$

The solutions of this pair of simultaneous equations (see *Self-test 22C.2*) are

$$\theta_A = \frac{\alpha_A p_A}{1 + \alpha_A p_A + \alpha_B p_B} \quad \theta_B = \frac{\alpha_B p_B}{1 + \alpha_A p_A + \alpha_B p_B}$$

It follows from eqn 22C.2 that the rate law is

$$v = \frac{k_r \alpha_A \alpha_B p_A p_B}{(1 + \alpha_A p_A + \alpha_B p_B)^2}$$

The parameters  $\alpha$  in the isotherms and the rate constant  $k_r$  are all temperature-dependent, so the overall temperature dependence of the rate may be strongly non-Arrhenius (in the sense that the reaction rate is unlikely to be proportional to  $e^{-E_a/RT}$ ). The LH mechanism is dominant for the catalytic oxidation of CO to  $\text{CO}_2$ .

**Self-test 22C.2** Provide the missing steps in the derivation of the expression for  $v$ .

### (c) The Eley–Rideal mechanism

In the **Eley–Rideal mechanism** (ER mechanism) of a surface-catalysed reaction, a gas-phase molecule collides with another molecule already adsorbed on the surface. The rate of formation of product is expected to be proportional to the partial pressure,  $p_B$ , of the non-adsorbed gas B and the extent of surface coverage,  $\theta_A$ , of the adsorbed gas A. It follows that the rate law should be

The rate constant,  $k_r$ , might be much larger than for the uncatalysed gas-phase reaction because the reaction on the surface has a low activation energy and the adsorption itself is often not activated.

If we know the adsorption isotherm for A, we can express the rate law in terms of its partial pressure,  $p_A$ . For example, the adsorption of A follows a Langmuir isotherm in the pressure range of interest, then the rate law would be

$$v = \frac{k_r \alpha p_A p_B}{1 + \alpha p_A} \quad (22C.4)$$

### Brief illustration 22C.2 The Eley–Rideal mechanism

According to eqn 22C.4, when the partial pressure of A is high (in the sense  $\alpha p_A \gg 1$ ) there is almost complete surface coverage, and the rate is equal to  $k_r p_B$ . Now the rate-determining step is the collision of B with the adsorbed fragments. When the pressure of A is low ( $\alpha p_A \ll 1$ ), perhaps because of its reaction, the rate is equal to  $k_r \alpha p_A p_B$ ; now the extent of surface coverage is important in the determination of the rate.

**Self-test 22C.3** Rewrite eqn 22C.4 for cases where A is a diatomic molecule that adsorbs as atoms.

$$\text{Answer: } v = k_r p_B (\alpha p_A)^{1/2} / (1 + (\alpha p_A)^{1/2})$$

Almost all thermal surface-catalysed reactions are thought to take place by the LH mechanism but a number of reactions with an ER mechanism have also been identified from molecular beam investigations. For example, the reaction between  $\text{H(g)}$  and  $\text{D(ad)}$  to form  $\text{HD(g)}$  is thought to be by an ER mechanism involving the direct collision and pick-up of the adsorbed D atom by the incident H atom. However, the two mechanisms should really be thought of as ideal limits with all reactions lying somewhere between the two and showing features of each one.

## 22C.2 Catalytic activity at surfaces

It has become possible to investigate how the catalytic activity of a surface depends on its structure as well as its composition. For instance, the cleavage of C–H and H–H bonds appears to depend on the presence of steps and kinks, and a terrace often has only minimal catalytic activity.

The reaction  $\text{H}_2 + \text{D}_2 \rightarrow 2\text{HD}$  has been studied in detail. For this reaction, terrace sites are inactive but one molecule in ten reacts when it strikes a step. Although the step itself might be the important feature, it may be that the presence of the step merely exposes a more reactive crystal face (the step face itself). Likewise, the dehydrogenation of hexane to hexene

**Figure 22C.2** A volcano curve of catalytic activity arises because although the reactants must adsorb reasonably strongly, they must not adsorb so strongly that they are immobilized. The lower curve refers to the first series of d-block metals, the upper curve to the second and third series of d-block metals. The group numbers relate to the periodic table inside the back cover.

depends strongly on the kink density, and it appears that kinks are needed to cleave C–C bonds. These observations suggest a reason why even small amounts of impurities may poison a catalyst: they are likely to attach to step and kink sites, and so impair the activity of the catalyst entirely. A constructive outcome is that the extent of dehydrogenation may be controlled relative to other types of reactions by seeking impurities that adsorb at kinks and act as specific poisons.

The activity of a catalyst depends on the strength of chemisorption as indicated by the ‘volcano’ curve in Fig. 22C.2 (which is so-called on account of its general shape). To be active, the catalyst should be extensively covered by adsorbate, which is the case if chemisorption is strong. On the other hand, if the strength of the substrate–adsorbate bond becomes too great, the activity declines either because the other reactant molecules cannot react with the adsorbate or because the adsorbate molecules are immobilized on the surface. This pattern of behaviour suggests that the activity of a catalyst should initially increase with strength of adsorption (as measured, for instance, by the enthalpy of adsorption) and then decline, and that the most active catalysts should be those lying near the summit of the volcano. Most active metals are those that lie close to the middle of the d block. Many metals are suitable for adsorbing gases, and some trends are summarized in Table 22C.1.

### Brief illustration 22C.3 Trends in chemisorption abilities

We see from Table 22C.1 that for a number of metals the general order of adsorption strengths decreases along the series  $\text{O}_2$ ,  $\text{C}_2\text{H}_2$ ,  $\text{C}_2\text{H}_4$ ,  $\text{CO}$ ,  $\text{H}_2$ ,  $\text{CO}_2$ ,  $\text{N}_2$ . Some of these molecules

adsorb dissociatively (for example,  $H_2$ ). Elements from the d block, such as iron, titanium, and chromium, show a strong activity towards all these gases, but manganese and copper are unable to adsorb  $N_2$  and  $CO_2$ . Metals towards the left of the periodic table (for example, magnesium) can adsorb (and, in fact, react with) only the most active gas ( $O_2$ ).

**Self-test 22C.4** Why is iron a good catalyst for the formation of ammonia from  $N_2(g)$  and  $H_2(g)$ ?

Answer: See Fig. 22C.2 and Table 22C.1

**Table 22C.1** Chemisorption abilities\*

	$O_2$	$C_2H_2$	$C_2H_4$	CO	$H_2$	$CO_2$	$N_2$

## Checklist of concepts

- 1. A **catalyst** is a substance that accelerates a reaction but undergoes no net chemical change.
- 2. A **heterogeneous catalyst** is a catalyst in a different phase from the reaction mixture.
- 3. In the **Langmuir–Hinshelwood mechanism** of surface-catalysed reactions, the reaction takes place by encounters between molecular fragments and atoms adsorbed on the surface.
- 4. In the **Eley–Rideal mechanism** of a surface-catalysed reaction, a gas-phase molecule collides with another molecule already adsorbed on the surface.
- 5. The activity of a catalyst depends on the strength of chemisorption.

## Checklist of equations

Property	Equation	Comment	Equation number
Langmuir–Hinshelwood mechanism	$v = k_r \theta_A \theta_B$	Competitive adsorption	22C.2
Eley–Rideal mechanism	$v = k_r p_B \theta_A$	Adsorption of A	22C.3

## CHAPTER 22 Processes on solid surfaces

### TOPIC 22A An introduction to solid surfaces

#### Discussion questions

**22A.1** (a) What topographical features are found on clean surfaces?  
 (b) Describe how steps and terraces can be formed by dislocations.

**22A.2** Drawing from knowledge you have acquired through the text, describe the advantages and limitations of each of the microscopy, diffraction, and ionizations techniques designated by the acronyms AFM, LEED, SAM, SEM, STM, and TEM.

#### Exercises

**22A.1(a)** Calculate the frequency of molecular collisions per square centimetre of surface in a vessel containing (i) hydrogen, (ii) propane at 25 °C when the pressure is 0.10  $\mu$ Torr.

**22A.1(b)** Calculate the frequency of molecular collisions per square centimetre of surface in a vessel containing (i) nitrogen, (ii) methane at 25 °C when the pressure is 10.0 Pa. Repeat the calculations for a pressure of 0.150  $\mu$ Torr.

**22A.2(a)** What pressure of argon gas is required to produce a collision rate of  $4.5 \times 10^{20} \text{ s}^{-1}$  at 425 K on a circular patch of surface of diameter 1.5 mm?

**22A.2(b)** What pressure of nitrogen gas is required to produce a collision rate of  $5.00 \times 10^{19} \text{ s}^{-1}$  at 525 K on a circular patch of surface of diameter 2.0 mm?

#### Problems

**22A.1** The movement of atoms and ions on a surface depends on their ability to leave one position and stick to another, and therefore on the energy changes that occur. As an illustration, consider a two-dimensional square lattice of singly charged positive and negative ions separated by 200 pm, and consider a cation on the upper terrace of this array. Calculate, by direct summation, its Coulombic interaction when it is in an empty lattice point directly above an anion. Now consider a high step in the same lattice, and let the cation move into the corner formed by the step and the terrace. Calculate the Coulombic energy for this position, and decide on the likely settling point for the cation.

**22A.2** In a study of the catalytic properties of a titanium surface it was necessary to maintain the surface free from contamination. Calculate the collision frequency per square centimetre of surface made by  $\text{O}_2$  molecules at (a) 100 kPa, (b) 1.00 Pa and 300 K. Estimate the number of collisions made with a single surface atom in each second. The conclusions underline the importance of working at very low pressures (much lower than 1 Pa, in fact)

in order to study the properties of uncontaminated surfaces. Take the nearest neighbour distance as 291 pm.

**22A.3** Nickel is face-centred cubic with a unit cell of side 352 pm. What is the number of atoms per square centimetre exposed on a surface formed by (a) (100), (b) (110), (c) (111) planes? Calculate the frequency of molecular collisions with a single atom in a vessel containing (i) hydrogen, (ii) propane at 25 °C when the pressure is 100 Pa and 0.10  $\mu$ Torr.

**22A.4** The LEED pattern from a clean unreconstructed (110) face of a metal is shown below. Sketch the LEED pattern for a surface that was reconstructed by tripling the horizontal separation between the atoms.

### TOPIC 22B Adsorption and desorption

#### Discussion questions

**22B.1** Distinguish between the following adsorption isotherms: Langmuir, BET, Temkin, and Freundlich. Indicate when and why each is likely to be appropriate.

**22B.2** What approximations underlie the formulation of the Langmuir and BET isotherms?

#### Exercises

**22B.1(a)** The volume of oxygen gas at 0 °C and 104 kPa adsorbed on the surface of 1.00 g of a sample of silica at 0 °C was 0.286 cm<sup>3</sup> at 145.4 Torr and 1.443 cm<sup>3</sup> at 760 Torr. What is the value of  $V_{\text{mon}}$ ?

**22B.1(b)** The volume of gas at 20 °C and 1.00 bar adsorbed on the surface of 1.50 g of a sample of silica at 0 °C was 1.52 cm<sup>3</sup> at 56.4 kPa and 2.77 cm<sup>3</sup> at 108 kPa. What is the value of  $V_{\text{mon}}$ ?

**22B.2(a)** The enthalpy of adsorption of CO on a surface is found to be  $-120 \text{ kJ mol}^{-1}$ . Estimate the mean lifetime of a CO molecule on the surface at 400 K.

**22B.2(b)** The enthalpy of adsorption of ammonia on a nickel surface is found to be  $-155 \text{ kJ mol}^{-1}$ . Estimate the mean lifetime of an  $\text{NH}_3$  molecule on the surface at 500 K.

**22B.3(a)** A certain solid sample adsorbs 0.44 mg of CO when the pressure of the gas is 26.0 kPa and the temperature is 300 K. The mass of gas adsorbed when the pressure is 3.0 kPa and the temperature is 300 K is 0.19 mg. The Langmuir isotherm is known to describe the adsorption. Find the fractional coverage of the surface at the two pressures.

**22B.3(b)** A certain solid sample adsorbs 0.63 mg of CO when the pressure of the gas is 36.0 kPa and the temperature is 300 K. The mass of gas adsorbed when the pressure is 4.0 kPa and the temperature is 300 K is 0.21 mg. The Langmuir isotherm is known to describe the adsorption. Find the fractional coverage of the surface at the two pressures.

**22B.4(a)** The adsorption of a gas is described by the Langmuir isotherm with  $\alpha = 0.75 \text{ kPa}^{-1}$  at 25 °C. Calculate the pressure at which the fractional surface coverage is (i) 0.15, (ii) 0.95.

**22B.4(b)** The adsorption of a gas is described by the Langmuir isotherm with  $\alpha = 0.548 \text{ kPa}^{-1}$  at 25 °C. Calculate the pressure at which the fractional surface coverage is (i) 0.20, (ii) 0.75.

**22B.5(a)** A solid in contact with a gas at 12 kPa and 25 °C adsorbs 2.5 mg of the gas and obeys the Langmuir isotherm. The enthalpy change when 1.00 mmol of the adsorbed gas is desorbed is +10.2 J. What is the equilibrium pressure for the adsorption of 2.5 mg of gas at 40 °C?

**22B.5(b)** A solid in contact with a gas at 8.86 kPa and 25 °C adsorbs 4.67 mg of the gas and obeys the Langmuir isotherm. The enthalpy change when 1.00 mmol of the adsorbed gas is desorbed is +12.2 J. What is the equilibrium pressure for the adsorption of the same mass of gas at 45 °C?

**22B.6(a)** Nitrogen gas adsorbed on charcoal to the extent of  $0.921 \text{ cm}^3 \text{ g}^{-1}$  at 490 kPa and 190 K, but at 250 K the same amount of adsorption was achieved only when the pressure was increased to 3.2 MPa. What is the enthalpy of adsorption of nitrogen on charcoal?

**22B.6(b)** Nitrogen gas adsorbed on a surface to the extent of  $1.242 \text{ cm}^3 \text{ g}^{-1}$  at 350 kPa and 180 K, but at 240 K the same amount of adsorption was achieved only when the pressure was increased to 1.02 MPa. What is the enthalpy of adsorption of nitrogen on the surface?

## Problems

**22B.1** Use mathematical software, a spreadsheet, or the *Living graphs* on the web site of this book to perform the following calculations: (a) Use eqn 22B.2 to generate a family of curves showing the dependence of  $1/\theta$  on  $1/p$  for several values of  $\alpha$ . (b) Use eqn 22B.4 to generate a family of curves showing the dependence of  $1/\theta$  on  $1/p$  for several values of  $\alpha$ . On the basis of your results from parts (a) and (b), discuss how plots of  $1/\theta$  against  $1/p$  can be used to distinguish between adsorption with and without dissociation. (c) Use eqn 22B.6 to generate a family of curves showing the dependence of  $zV_{\text{mon}}/(1-z)V$  on  $z$  for different values of  $c$ .

**22B.2** The following data are for the chemisorption of hydrogen on copper powder at 25 °C. Confirm that they fit the Langmuir isotherm at low coverages. Then find the value of  $\alpha$  for the adsorption equilibrium and the adsorption volume corresponding to complete coverage.

$p/\text{Pa}$	25	129	253	540	1000	1593
$V/\text{cm}^3$	0.042	0.163	0.221	0.321	0.411	0.471

**22B.3** The data for the adsorption of ammonia on barium fluoride are reported in the following tables. Confirm that they fit a BET isotherm and find values of  $c$  and  $V_{\text{mon}}$ .

(a)  $\theta = 0^\circ\text{C}$ ,  $p^* = 429.6 \text{ kPa}$ :

$p/\text{kPa}$	14.0	37.6	65.6	79.2	82.7	100.7	106.4
$V/\text{cm}^3$	11.1	13.5	14.9	16.0	15.5	17.3	16.5

**22B.7(a)** In an experiment on the adsorption of oxygen on tungsten it was found that the same volume of oxygen was desorbed in 27 min at 1856 K and 2.0 min at 1978 K. What is the activation energy of desorption? How long would it take for the same amount to desorb at (i) 298 K, (ii) 3000 K?

**22B.7(b)** In an experiment on the adsorption of ethene on iron it was found that the same volume of the gas was desorbed in 1856 s at 873 K and 8.44 s at 1012 K. What is the activation energy of desorption? How long would it take for the same amount of ethene to desorb at (i) 298 K, (ii) 1500 K?

**22B.8(a)** The average time for which an oxygen atom remains adsorbed to a tungsten surface is 0.36 s at 2548 K and 3.49 s at 2362 K. What is the activation energy for chemisorption?

**22B.8(b)** The average time for which a hydrogen atom remains adsorbed on a manganese surface is 35 per cent shorter at 1000 K than at 600 K. What is the activation energy for chemisorption?

**22B.9(a)** For how long on average would an H atom remain on a surface at 400 K if its desorption activation energy is (i)  $15 \text{ kJ mol}^{-1}$ , (ii)  $150 \text{ kJ mol}^{-1}$ ? Take  $\tau_0 = 0.10 \text{ ps}$ . For how long on average would the same atoms remain at 1000 K?

**22B.9(b)** For how long on average would an atom remain on a surface at 298 K if its desorption activation energy is (i)  $20 \text{ kJ mol}^{-1}$ , (ii)  $200 \text{ kJ mol}^{-1}$ ? Take  $\tau_0 = 0.12 \text{ ps}$ . For how long on average would the same atoms remain at 800 K?

**22B.10(a)** Hydrogen iodide is very strongly adsorbed on gold but only slightly adsorbed on platinum. Assume the adsorption follows the Langmuir isotherm and predict the order of the HI decomposition reaction on each of the two metal surfaces.

**22B.10(b)** Suppose it is known that ozone adsorbs on a particular surface in accord with a Langmuir isotherm. How could you use the pressure dependence of the fractional coverage to distinguish between adsorption (i) without dissociation, (ii) with dissociation into  $\text{O} + \text{O}_2$ , (iii) with dissociation into  $\text{O} + \text{O} + \text{O}$ ?

(b)  $\theta = 18.6^\circ\text{C}$ ,  $p^* = 819.7 \text{ kPa}$ :

$p/\text{kPa}$	5.3	8.4	14.4	29.2	62.1	74.0	80.1	102.0
$V/\text{cm}^3$	9.2	9.8	10.3	11.3	12.9	13.1	13.4	14.1

**22B.4** The following data have been obtained for the adsorption of  $\text{H}_2$  on the surface of 1.00 g of copper at 0 °C. The volume of  $\text{H}_2$  below is the volume that the gas would occupy at STP (0 °C and 1 atm).

$p/\text{atm}$	0.050	0.100	0.150	0.200	0.250
$V/\text{cm}^3$	23.8	13.3	8.70	6.80	5.71

Determine the volume of  $\text{H}_2$  necessary to form a monolayer and estimate the surface area of the copper sample. The density of liquid hydrogen is  $0.708 \text{ g cm}^{-3}$ .

**22B.5\*** M.-G. Olivier and R. Jadot (*J. Chem. Eng. Data* 42, 230 (1997)) studied the adsorption of butane on silica gel. They report the following amounts of absorption (in moles per kilogram of silica gel) at 303 K:

$p/\text{kPa}$	31.00	38.22	53.03	76.38	101.97
$n/(\text{mol kg}^{-1})$	1.00	1.17	1.54	2.04	2.49
$p/\text{kPa}$	130.47	165.06	182.41	205.75	219.91
$n/(\text{mol kg}^{-1})$	2.90	3.22	3.30	3.35	3.36

Fit these data to a Langmuir isotherm, and determine the value of  $n$  that corresponds to complete coverage and the constant  $K$ .

\* These problems were supplied by Charles Trapp and Carmen Giunta.

**22B.6** The designers of a new industrial plant wanted to use a catalyst code-named CR-1 in a step involving the fluorination of butadiene. As a first step in the investigation they determined the form of the adsorption isotherm. The volume of butadiene adsorbed per gram of CR-1 at 15 °C varied with pressure as given below. Is the Langmuir isotherm suitable at this pressure?

$p/\text{kPa}$	13.3	26.7	40.0	53.3	66.7	80.0
$V/\text{cm}^3$	17.9	33.0	47.0	60.8	75.3	91.3

Investigate whether the BET isotherm gives a better description of the adsorption of butadiene on CR-1. At 15 °C,  $p^*$  (butadiene) = 200 kPa. Find  $V_{\text{mon}}$  and  $c$ .

**22B.7** C. Huang and W.P. Cheng (*J. Colloid Interface Sci.* **188**, 270 (1997)) examined the adsorption of the hexacyanoferrate(III) ion,  $[\text{Fe}(\text{CN})_6]^{3-}$ , on  $\gamma\text{-Al}_2\text{O}_3$  from aqueous solution. They modelled the adsorption with a modified Langmuir isotherm, obtaining the following values of  $\alpha$  at pH = 6.5:

$T/\text{K}$	283	298	308	318
$10^{-11}\alpha$	2.642	2.078	1.286	1.085

Determine the isosteric enthalpy of adsorption,  $\Delta_{\text{ads}}H^\ominus$ , at this pH. The researchers also reported  $\Delta_{\text{ads}}S^\ominus = +146 \text{ J mol}^{-1} \text{ K}^{-1}$  under these conditions. Determine  $\Delta_{\text{ads}}G^\ominus$ .

**22B.8** In a study relevant to automobile catalytic converters, C.E. Wartnaby et al. (*J. Phys. Chem.* **100**, 12483 (1996)) measured the enthalpy of adsorption of CO, NO, and O<sub>2</sub> on initially clean platinum (110) surfaces. They report  $\Delta_{\text{ads}}H^\ominus$  for NO to be  $-160 \text{ kJ mol}^{-1}$ . How much more strongly adsorbed is NO at 500 °C than at 400 °C?

**22B.9** The removal or recovery of volatile organic compounds (VOCs) from exhaust gas streams is an important process in environmental engineering. Activated carbon has long been used as an adsorbent in this process, but the presence of moisture in the stream reduces its effectiveness. M.-S. Chou and J.-H. Chiou (*J. Environ. Engng. ASCE* **123**, 437(1997)) have studied the effect of moisture content on the adsorption capacities of granular activated carbon (GAC) for normal hexane and cyclohexane in air streams. From their data for dry streams containing cyclohexane, shown in the following table, they conclude that GAC obeys a Langmuir type model in which  $q_{\text{VOC,RH=0}} = abc_{\text{VOC}}/(1 + bc_{\text{VOC}})$ , where  $q = m_{\text{VOC}}/m_{\text{GAC}}$ , RH denotes relative humidity,  $a$  the maximum adsorption capacity,  $b$  is an affinity parameter, and  $p$  is the abundance in parts per million (ppm). The following table gives values of  $q_{\text{VOC,RH=0}}$  for cyclohexane:

$c/\text{ppm}$	33.6 °C	41.5 °C	57.4 °C	76.4 °C	99 °C
200	0.080	0.069	0.052	0.042	0.027
500	0.093	0.083	0.072	0.056	0.042
1000	0.101	0.088	0.076	0.063	0.045
2000	0.105	0.092	0.083	0.068	0.052
3000	0.112	0.102	0.087	0.072	0.058

(a) By linear regression of  $1/q_{\text{VOC,RH=0}}$  against  $1/c_{\text{VOC}}$ , test the goodness of fit and determine values of  $a$  and  $b$ . (b) The parameters  $a$  and  $b$  can be related to  $\Delta_{\text{ads}}H$ , the enthalpy of adsorption, and  $\Delta_bH$ , the difference in activation energy for adsorption and desorption of the VOC molecules, through Arrhenius type equations of the form  $a = k_a e^{-\Delta_{\text{ads}}H/RT}$  and  $b = k_b e^{-\Delta_bH/RT}$ . Test the goodness of fit of the data to these equations and obtain values for  $k_a$ ,  $k_b$ ,  $\Delta_{\text{ads}}H$ , and  $\Delta_bH$ . (c) What interpretation might you give to  $k_a$  and  $k_b$ ?

**22B.10** The adsorption of solutes on solids from liquids often follows a Freundlich isotherm. Check the applicability of this isotherm to the following data for the adsorption of acetic acid on charcoal at 25 °C and find the values of the parameters  $c_1$  and  $c_2$ .

$[\text{acid}]/(\text{mol dm}^{-3})$	0.05	0.10	0.50	1.0	1.5
$w_a/\text{g}$	0.04	0.06	0.12	0.16	0.19

where  $w_a$  is the mass adsorbed per gram of charcoal.

**22B.11** A. Akgerman and M. Zardkoobi (*J. Chem. Eng. Data* **41**, 185 (1996)) examined the adsorption of phenol from aqueous solution on to fly ash at 20 °C. They fitted their observations to a Freundlich isotherm of the form  $c_{\text{ads}} = Kc_{\text{sol}}^{1/n}$ , where  $c_{\text{ads}}$  is the concentration of adsorbed phenol and  $c_{\text{sol}}$  is the concentration of aqueous phenol. Among the data reported are the following:

$c_{\text{sol}}/(\text{mg g}^{-1})$	8.26	15.65	25.43	31.74	40.00
$c_{\text{ads}}/(\text{mg g}^{-1})$	4.41	9.2	35.2	52.0	67.2

Determine the constants  $K$  and  $n$ . What further information would be necessary in order to express the data in terms of fractional coverage,  $\theta$ ?

**22B.12** The following data were obtained for the extent of adsorption,  $s$ , of acetone on charcoal from an aqueous solution of molar concentration,  $c$ , at 18 °C:

$c/(\text{mmol dm}^{-3})$	15.0	23.0	42.0	84.0	165	390	800
$s/(\text{mmol acetone/g charcoal})$	0.60	0.75	1.05	1.50	2.15	3.50	5.10

Which isotherm fits this data best, Langmuir, Freundlich, or Temkin?

**22B.13** M.-S. Chou and J.-H. Chiou (*J. Environ. Engng. ASCE* **123**, 437(1997)) have studied the effect of moisture content on the adsorption capacities of granular activated carbon (GAC, Norit PK 1-3) for the volatile organic compounds (VOCs) normal hexane and cyclohexane in air streams. The following table shows the adsorption capacities ( $q_{\text{water}} = m_{\text{water}}/m_{\text{GAC}}$ ) of GAC for pure water from moist air streams as a function of relative humidity (RH) in the absence of VOCs at 41.5 °C:

RH	0.00	0.26	0.49	0.57	0.80	1.00
$q_{\text{water}}$	0.00	0.026	0.072	0.091	0.161	0.229

The authors conclude that the data at this and other temperatures obey a Freundlich type isotherm,  $q_{\text{water}} = k(\text{RH})^{1/n}$ . (a) Test this hypothesis for their data at 41.5 °C and determine the constants  $k$  and  $n$ . (b) Why might VOCs obey the Langmuir model, but water the Freundlich model? (c) When both water vapour and cyclohexane were present in the stream the values given in the table below were determined for the ratio  $r_{\text{VOC}} = q_{\text{VOC}}/q_{\text{VOC,RH=0}}$  at 41.5 °C:

The authors propose that these data fit the equation $r_{\text{VOC}} = 1 - q_{\text{water}}$ . Test their							
RH	0.00	0.10	0.25	0.40	0.53	0.76	0.81
$r_{\text{VOC}}$	1.00	0.98	0.91	0.84	0.79	0.67	0.61

proposal and determine values for  $k$  and  $n$  and compare to those obtained in part (b) for pure water. Suggest reasons for any differences.

**22B.14** The release of petroleum products by leaky underground storage tanks is a serious threat to clean ground water. BTEX compounds (benzene, toluene, ethylbenzene, and xylenes) are of primary concern due to their ability to cause health problems at low concentrations. D.S. Kershaw et al. (*J. Geotech. Geoenviron. Engng.* **123**, 324 (1997)) have studied the ability of ground tyre rubber to sorb (adsorb and absorb) benzene and o-xylene. Though sorption involves more than surface interactions, sorption data is usually found to fit one of the adsorption isotherms. In this study, the authors have tested how well their data fit the linear ( $q = Kc_{\text{eq}}$ ), Freundlich ( $q = K_F c_{\text{eq}}^{1/n}$ ), and Langmuir ( $q = K_L M c_{\text{eq}}/(1 + K_L c_{\text{eq}})$ ) type isotherms, where  $q$  is the mass of solvent sorbed per gram of ground rubber (in milligrams per gram), the  $K$ s and  $M$  are empirical constants, and  $c_{\text{eq}}$  the equilibrium concentration of contaminant in solution (in milligrams per litre). (a) Determine the units of the empirical constants. (b) Determine which of the isotherms best fits the data in the following table for the sorption of benzene on ground rubber:

$c_{\text{eq}}/(\text{mg dm}^{-3})$	97.10	36.10	10.40	6.51	6.21	2.48
$q/(\text{mg g}^{-1})$	7.13	4.60	1.80	1.10	0.55	0.31

(c) Compare the sorption efficiency of ground rubber to that of granulated activated charcoal which for benzene has been shown to obey the Freundlich isotherm in the form  $q = 1.0c_{\text{eq}}^{1.6}$  with coefficient of determination  $R^2 = 0.94$ .

## TOPIC 22C Heterogeneous catalysis

### Discussion questions

**22C.1** Describe the essential features of the Langmuir–Hinshelwood and Eley–Rideal mechanisms for surface-catalysed reactions.

**22C.2** Account for the dependence of catalytic activity of a surface on the strength of chemisorption, as shown in Fig. 22B.8.

### Exercises

**22C.1(a)** A monolayer of  $N_2$  molecules is adsorbed on the surface of 1.00 g of an  $Fe/Al_2O_3$  catalyst at 77 K, the boiling point of liquid nitrogen. Upon warming, the nitrogen occupies  $3.86 \text{ cm}^3$  at  $0^\circ\text{C}$  and 760 Torr. What is the surface area of the catalyst?

**22C.1(b)** A monolayer of CO molecules is adsorbed on the surface of 1.00 g of an  $Fe/Al_2O_3$  catalyst at 77 K, the boiling point of liquid nitrogen. Upon warming, the carbon monoxide occupies  $3.75 \text{ cm}^3$  at  $0^\circ\text{C}$  and 1.00 bar. What is the surface area of the catalyst?

### Problem

**22C.1** In some catalytic reactions the products adsorb more strongly than the reacting gas. This is the case, for instance, in the catalytic decomposition of ammonia on platinum at  $1000^\circ\text{C}$ . As a first step in examining the kinetics of this type of process, show that the rate of ammonia decomposition should follow

$$\frac{d p_{\text{NH}_3}}{dt} = -k_c \frac{p_{\text{NH}_3}}{p_{\text{H}_2}}$$

in the limit of very strong adsorption of hydrogen. Start by showing that when a gas J adsorbs very strongly, and its pressure is  $p_j$ , that the fraction of uncovered sites is approximately  $1/Kp_j$ . Solve the rate equation for the catalytic decomposition of  $\text{NH}_3$  on platinum and show that a plot of  $F(t) = (1/t) \times \ln(p/p_0)$  against  $G(t) = (p - p_0)/t$ , where  $p$  is the pressure of ammonia, should give a straight line from which  $k_c$  can be determined. Check the rate law on the basis of the following data, and find  $k_c$  for the reaction.

$t/\text{s}$	0	30	60	100	160	200	250
$p/\text{kPa}$	13.3	11.7	11.2	10.7	10.3	9.9	9.6

## Integrated activities

**22.1** Although the attractive van der Waals interaction between individual molecules varies as  $R^{-6}$  the interaction of a molecule with a nearby solid (a homogeneous collection of molecules) varies as  $R^{-3}$ , where  $R$  is its vertical distance above the surface. Confirm this assertion. Calculate the interaction energy between an Ar atom and the surface of solid argon on the basis of a Lennard-Jones (6,12)-potential. Estimate the equilibrium distance of an atom above the surface.

**22.2** Electron microscopes can obtain images with much higher resolution than optical microscopes because of the short wavelength obtainable from a beam of electrons. For electrons moving at speeds close to  $c$ , the speed of light, the expression for the de Broglie wavelength (eqn 7A.14,  $\lambda = h/p$ ) needs to be corrected for relativistic effects:

$$\lambda = \frac{h}{\left\{ 2m_e e \Delta\phi \left( 1 + \frac{e \Delta\phi}{2m_e c^2} \right) \right\}^{1/2}}$$

where  $c$  is the speed of light in vacuum and  $\Delta\phi$  is the potential difference through which the electrons are accelerated. (a) Use this expression to calculate the de Broglie wavelength of electrons accelerated through 50 kV. (b) Is the relativistic correction important?

**22.3** The forces measured by AFM arise primarily from interactions between electrons of the stylus and on the surface. To get an idea of the magnitudes of these forces, calculate the force acting between two electrons separated by 2.0 nm. To calculate the force between the electrons, use  $F = -dV/dr$  where  $V$  is their mutual Coulombic potential energy and  $r$  is their separation.

**22.4** To appreciate the distance dependence of the tunnelling current in scanning tunnelling microscopy, suppose that the electron in the gap between sample and needle has an energy 2.0 eV smaller than the barrier height. By what factor would the current drop if the needle is moved from  $L_1 = 0.50 \text{ nm}$  to  $L_2 = 0.60 \text{ nm}$  from the surface?

# PART 1 Common integrals

## Algebraic functions

A.1  $\int x^n dx = \frac{x^{n+1}}{n+1} + \text{constant}, n \neq -1$

A.2  $\int \frac{1}{x} dx = \ln x + \text{constant}$

## Exponential functions

E.1  $\int_0^{\infty} x^n e^{-ax} dx = \frac{n!}{a^{n+1}}, n! = n(n-1)\dots 1; 0! \equiv 1$

E.2  $\int_0^{\infty} \frac{x^4 e^x}{(e^x - 1)^2} dx = \frac{\pi^4}{15}$

## Gaussian functions

G.1  $\int_0^{\infty} e^{-ax^2} dx = \frac{1}{2} \left( \frac{\pi}{a} \right)^{1/2}$

G.2  $\int_0^{\infty} x e^{-ax^2} dx = \frac{1}{2a}$

G.3  $\int_0^{\infty} x^2 e^{-ax^2} dx = \frac{1}{4} \left( \frac{\pi}{a^3} \right)^{1/2}$

G.4  $\int_0^{\infty} x^3 e^{-ax^2} dx = \frac{1}{2a^2}$

G.5  $\int_0^{\infty} x^4 e^{-ax^2} dx = \frac{3}{8a^2} \left( \frac{\pi}{a} \right)^{1/2}$

G.6  $\operatorname{erf} z = \frac{2}{\pi^{1/2}} \int_0^z e^{-x^2} dx \quad \operatorname{erfc} z = 1 - \operatorname{erf} z$

G.7  $\int_0^{\infty} x^{2m+1} e^{-ax^2} dx = \frac{m!}{2a^{m+1}}$

G.8  $\int_0^{\infty} x^{2m} e^{-ax^2} dx = \frac{(2m-1)!!}{2^{m+1} a^m} \left( \frac{\pi}{a} \right)^{1/2}$   
 $(2m-1)!! = 1 \times 3 \times 5 \dots \times (2m-1)$

## Trigonometric functions

T.1  $\int \sin ax dx = -\frac{1}{a} \cos ax + \text{constant}$

T.2  $\int \sin^2 ax dx = \frac{1}{2} x - \frac{\sin 2ax}{4a} + \text{constant}$

T.3  $\int \sin^3 ax dx = -\frac{(\sin^2 ax + 2) \cos ax}{3a} + \text{constant}$

T.4  $\int \sin^4 ax dx = \frac{3x}{8} - \frac{3}{8a} \sin ax \cos ax - \frac{1}{4a} \sin^3 ax \cos ax + \text{constant}$

T.5  $\int \sin ax \sin bx dx = \frac{\sin(a-b)x}{2(a-b)} - \frac{\sin(a+b)x}{2(a+b)} + \text{constant}, a^2 \neq b^2$

T.6  $\int_0^L \sin nax \sin^2 ax dx = -\frac{1}{2a} \left\{ \frac{1}{n} - \frac{1}{2(n+2)} - \frac{1}{2(n-2)} \right\} \times \{(-1)^n - 1\}$

T.7  $\int \sin ax \cos ax dx = \frac{1}{2a} \sin^2 ax + \text{constant}$

T.8  $\int \sin bx \cos ax dx = \frac{\cos(a-b)x}{2(a-b)} - \frac{\cos(a+b)x}{2(a+b)} + \text{constant}, a^2 \neq b^2$

T.9  $\int x \sin ax \sin bx dx = -\frac{d}{da} \int \sin bx \cos ax dx$

T.10  $\int \cos^2 ax \sin ax dx = -\frac{1}{3a} \cos^3 ax + \text{constant}$

T.11  $\int x \sin^2 ax dx = \frac{x^2}{4} - \frac{x \sin 2ax}{4a} - \frac{\cos 2ax}{8a^2} + \text{constant}$

T.12  $\int x^2 \sin^2 ax dx = \frac{x^3}{6} - \left( \frac{x^2}{4a} - \frac{1}{8a^3} \right) \sin 2ax - \frac{x \cos 2ax}{4a^2} + \text{constant}$

T.13  $\int x \cos ax dx = \frac{1}{a^2} \cos ax + \frac{x}{a} \sin ax + \text{constant}$

# PART 2 Units

**Table A.1** Some common units

Physical quantity	Name of unit	Symbol for unit	Value*
Time	minute	min	60 s
	hour	h	3600 s
	day	d	86 400 s
	year	a	31 556 952 s
Length	ångström	Å	$10^{-10}$ m
Volume	litre	L, l	1 dm <sup>3</sup>
Mass	tonne	t	10 <sup>3</sup> kg
Pressure	bar	bar	10 <sup>5</sup> Pa
	atmosphere	atm	101.325 kPa
Energy	electronvolt	eV	1.602 177 33 × 10 <sup>-19</sup> J
			96.485 31 kJ mol <sup>-1</sup>

\* All values are exact, except for the definition of 1 eV, which depends on the measured value of  $e$ , and the year, which is not a constant and depends on a variety of astronomical assumptions.

**Table A.2** Common SI prefixes

Prefix	y	z	a	f	p	n	μ	m	c	d
Name	yocto	zepto	atto	femto	pico	nano	micro	milli	centi	deci
Factor	10 <sup>-24</sup>	10 <sup>-21</sup>	10 <sup>-18</sup>	10 <sup>-15</sup>	10 <sup>-12</sup>	10 <sup>-9</sup>	10 <sup>-6</sup>	10 <sup>-3</sup>	10 <sup>-2</sup>	10 <sup>-1</sup>
Prefix	da	h	k	M	G	T	P	E	Z	Y
Name	deca	hecto	kilo	mega	giga	tera	peta	exa	zeta	yotta
Factor	10	10 <sup>2</sup>	10 <sup>3</sup>	10 <sup>6</sup>	10 <sup>9</sup>	10 <sup>12</sup>	10 <sup>15</sup>	10 <sup>18</sup>	10 <sup>21</sup>	10 <sup>24</sup>

**Table A.3** The SI base units

Physical quantity	Symbol for quantity	Base unit
Length	$l$	metre, m
Mass	$m$	kilogram, kg
Time	$t$	second, s
Electric current	$I$	ampere, A
Thermodynamic temperature	$T$	kelvin, K
Amount of substance	$n$	mole, mol
Luminous intensity	$I_v$	candela, cd

**Table A.4** A selection of derived units

Physical quantity	Derived unit*	Name of derived unit
Force	1 kg m s <sup>-2</sup>	newton, N
Pressure	1 kg m <sup>-1</sup> s <sup>-2</sup>	pascal, Pa
	1 N m <sup>-2</sup>	
Energy	1 kg m <sup>2</sup> s <sup>-2</sup>	joule, J
	1 N m	
	1 Pa m <sup>3</sup>	
Power	1 kg m <sup>2</sup> s <sup>-3</sup>	watt, W
	1 J s <sup>-1</sup>	

\* Equivalent definitions in terms of derived units are given following the definition in terms of base units.

# PART 3 Data

The following is a directory of all tables in the text; those included in this *Resource section* are marked with an asterisk. The remainder will be found on the pages indicated. These tables reproduce and expand the data given in the short tables in the text, and follow their numbering. Standard states refer to a pressure of  $p^\ominus = 1$  bar. The general references are as follows:

Table 10C.1 Bond lengths,  $R_e/\text{pm}$ 

(a) Bond lengths in specific molecules							
Br <sub>2</sub>	228.3						
Cl <sub>2</sub>	198.75						
CO	112.81						
F <sub>2</sub>	141.78						
H <sub>2</sub> <sup>+</sup>	106						
H <sub>2</sub>	74.138						
HBr	141.44						
HCl	127.45						
HF	91.680						
HI	160.92						
N <sub>2</sub>	109.76						
O <sub>2</sub>	120.75						
(b) Mean bond lengths from covalent radii*							
H	37						
C	77(1)	N	74(1)	O	66(1)	F	64
	67(2)		65(2)		57(2)		
	60(3)						
Si	118	P	110	S	104(1)	Cl	99
					95(2)		
Ge	122	As	121	Se	104	Br	114
		Sb	141	Te	137	I	133

\* Values are for single bonds except where indicated otherwise (values in parentheses). The length of an A–B covalent bond (of given order) is the sum of the corresponding covalent radii.

Table 10C.2a Bond dissociation enthalpies,  $\Delta H^\ominus(\text{A-B})/(\text{kJ mol}^{-1})$  at 298 K\*

Diatomic molecules									
H–H	436	F–F	155	Cl–Cl	242	Br–Br	193	I–I	151
O=O	497	C=O	1076	N≡N	945				
H–O	428	H–F	565	H–Cl	431	H–Br	366	H–I	299
Polyatomic molecules									
H–CH <sub>3</sub>	435	H–NH <sub>2</sub>	460	H–OH	492	H–C <sub>6</sub> H <sub>5</sub>	469		
H <sub>3</sub> C–CH <sub>3</sub>	368	H <sub>2</sub> C=CH <sub>2</sub>	720	HC≡CH	962				
HO–CH <sub>3</sub>	377	Cl–CH <sub>3</sub>	352	Br–CH <sub>3</sub>	293	I–CH <sub>3</sub>	237		
O=CO	531	HO–OH	213	O <sub>2</sub> N–NO <sub>2</sub>	54				

\* To a good approximation bond dissociation enthalpies and dissociation energies are related by  $\Delta H^\ominus = D_e + \frac{3}{2}RT$  with  $D_e = D_0 + \frac{1}{2}h\omega$ . For precise values of  $D_0$  for diatomic molecules, see Table 12D.1. Data: HCP, KL.

Table 10C.2b Mean bond enthalpies,  $\Delta H^\ominus(A-B)/(kJ\ mol^{-1})^*$ 

	H	C	N	O	F	Cl	Br	I	S	P	Si
H	436										
C	412	348(i) 612(ii) 838(iii) 518(a)									
N	388	305(i) 613(ii) 890(iii)	163(i) 409(ii) 946(iii)								
O	463	360(i) 743(ii)	157	146(i) 497(ii)							
F	565	484	270	185	155						
Cl	431	338	200	203	254	242					
Br	366	276				219	193				
I	299	238				210	178	151			
S	338	259			496	250	212		264		
P	322									201	
Si	318		374	466							226

\* Mean bond enthalpies are such a crude measure of bond strength that they need not be distinguished from dissociation energies.

(i) Single bond, (ii) double bond, (iii) triple bond, (a) aromatic.

Data: HCP and L. Pauling, *The nature of the chemical bond*. Cornell University Press (1960).

Water†	0.891

† The viscosity of water over its entire liquid range is represented with less than 1 per cent error by the expression  $\log(\eta_{20}/\eta) = A/B$ ,  
 $A = 1.37023(t - 20) + 8.36 \times 10^{-4}(t - 20)^2$   
 $B = 109 + t \quad t = \theta/^\circ\text{C}$   
 Convert  $\text{kg m}^{-1} \text{ s}^{-1}$  to centipoise (cP) by multiplying by  $10^3$  (so  $\eta \approx 1$  cP for water).  
 Data: AIP, KL.

# PART 4 Character tables

## The groups $C_1, C_s, C_i$

$C_1 (1)$	$E$	$h=1$
A	1	

$C_s = C_h m$	$E$	$\sigma_h$	$h=2$
A'	1	1	$x, y, R_z$ $x^2, y^2, z^2, xy$
A''	1	-1	$z, R_x, R_y$ $yz, zx$

$C_i = S_2 \bar{1}$	$E$	$i$	$h=2$
A <sub>g</sub>	1	1	$R_x, R_y, R_z$ $x^2, y^2, z^2, xy, yz, zx$
A <sub>u</sub>	1	-1	$x, y, z$

## The groups $C_{nv}$

$C_{2v}, 2mm$	$E$	$C_2$	$\sigma_v$	$\sigma'_v$	$h=4$
A <sub>1</sub>	1	1	1	1	$z, z^2, x^2, y^2$
A <sub>2</sub>	1	1	-1	-1	$xy$ $R_z$
B <sub>1</sub>	1	-1	1	-1	$x, zx$ $R_y$
B <sub>2</sub>	1	-1	-1	1	$y, yz$ $R_x$

$C_{3v}, 3m$	$E$	$2C_3$	$3\sigma_v$	$h=6$
A <sub>1</sub>	1	1	1	$z, z^2, x^2+y^2$
A <sub>2</sub>	1	1	-1	$R_z$
E	2	-1	0	$(x, y), (xy, x^2-y^2) (yz, zx) (R_x, R_y)$

$C_{4v}, 4mm$	$E$	$C_2$	$2C_4$	$2\sigma_v$	$2\sigma_d$	$h=8$
A <sub>1</sub>	1	1	1	1	1	$z, z^2, x^2+y^2$
A <sub>2</sub>	1	1	1	-1	-1	$R_z$
B <sub>1</sub>	1	1	-1	1	-1	$x^2-y^2$
B <sub>2</sub>	1	1	-1	-1	1	$xy$
E	2	-2	0	0	0	$(x, y), (yz, zx) (R_x, R_y)$

$C_{5v}$	$E$	$2C_5$	$2C_5^2$	$5\sigma_v$	$h=10, \alpha=72^\circ$
A <sub>1</sub>	1	1	1	1	$z, z^2, x^2+y^2$
A <sub>2</sub>	1	1	1	-1	$R_z$
E <sub>1</sub>	2	$2 \cos \alpha$	$2 \cos 2\alpha$	0	$(x, y), (yz, zx) (R_x, R_y)$
E <sub>2</sub>	2	$2 \cos 2\alpha$	$2 \cos \alpha$	0	$(xy, x^2-y^2)$

$C_{6v}, 6mm$	$E$	$C_2$	$2C_3$	$2C_6$	$3\sigma_d$	$3\sigma_v$	$h=12$
A <sub>1</sub>	1	1	1	1	1	1	$z, z^2, x^2+y^2$
A <sub>2</sub>	1	1	1	1	-1	-1	$R_z$
B <sub>1</sub>	1	-1	1	-1	-1	1	
B <sub>2</sub>	1	-1	1	-1	1	-1	
E <sub>1</sub>	2	-2	-1	1	0	0	$(x, y), (yz, zx) (R_x, R_y)$
E <sub>2</sub>	2	2	-1	-1	0	0	$(xy, x^2-y^2)$

$C_{\infty v}$	$E$	$2C_\phi^\dagger$	$\infty\sigma_v$	$h=\infty$
A <sub>1</sub> ( $\Sigma^+$ )	1	1	1	$z, z^2, x^2+y^2$
A <sub>2</sub> ( $\Sigma^-$ )	1	1	-1	$R_z$
E <sub>1</sub> ( $\Pi$ )	2	$2 \cos \phi$	0	$(x, y), (yz, zx) (R_x, R_y)$
E <sub>2</sub> ( $\Delta$ )	2	$2 \cos 2\phi$	0	$(xy, x^2-y^2)$

† There is only one member of this class if  $\phi=\pi$ .

## The groups $D_n$

$D_2, 222$	$E$	$C_2^z$	$C_2^y$	$C_2^x$	$h=4$
A <sub>1</sub>	1	1	1	1	$x^2, y^2, z^2$
B <sub>1</sub>	1	1	-1	-1	$z, xy$ $R_z$
B <sub>2</sub>	1	-1	1	-1	$y, zx$ $R_y$
B <sub>3</sub>	1	-1	-1	1	$x, yz$ $R_x$

$D_3, 32$	$E$	$2C_3$	$3C_2'$	$h=6$
A <sub>1</sub>	1	1	1	$z^2, x^2+y^2$
A <sub>2</sub>	1	1	-1	$z$ $R_z$
E	2	-1	0	$(x, y), (yz, zx), (xy, x^2-y^2) (R_x, R_y)$

$D_4, 422$	$E$	$C_2$	$2C_4$	$2C_2'$	$2C_2''$	$h=8$
A <sub>1</sub>	1	1	1	1	1	$z^2, x^2+y^2$
A <sub>2</sub>	1	1	1	-1	-1	$z$ $R_z$
B <sub>1</sub>	1	1	-1	1	-1	$x^2-y^2$
B <sub>2</sub>	1	1	-1	-1	1	$xy$
E	2	-2	0	0	0	$(x, y), (yz, zx) (R_x, R_y)$

The groups  $D_{nh}$ 

$D_{3h}, \bar{6}2m$	$E$	$\sigma_h$	$2C_3$	$2S_3$	$3C_2'$	$3\sigma_v$	$h=12$	
$A_1'$	1	1	1	1	1	1	$z^2, x^2+y^2$	
$A_2'$	1	1	1	1	-1	-1		$R_z$
$A_1''$	1	-1	1	-1	1	-1		
$A_2''$	1	-1	1	-1	-1	1	$z$	
$E'$	2	2	-1	-1	0	0	$(x, y), (xy, x^2-y^2)$	
$E''$	2	-2	-1	1	0	0	$(yz, zx)$	$(R_x, R_y)$

$D_{4h}, 4/mmm$	$E$	$2C_4$	$C_2$	$2C_2'$	$2C_2''$	$i$	$2S_4$	$\sigma_h$	$2\sigma_v$	$2\sigma_d$	$h=16$
$A_{1g}$	1	1	1	1	1	1	1	1	1	1	$x^2+y^2, z^2$
$A_{2g}$	1	1	1	-1	-1	1	1	1	-1	-1	$R_z$
