## Abstract

In this paper, we consider a setting where a user wants to outsource storage of a large amount of private data, and then perform pattern matching queries on the data; that is, given a data string  $s$  and a “pattern” string  $p$ , find all occurrences of  $p$  as a substring of  $s$ .

We formalize the security properties desired in this type of setting by defining a type of encryption called *queryable encryption*. In a queryable encryption scheme, a user can encrypt a message  $M$  under a secret key, and using the secret key can generate tokens for queries  $q$ . Applying a token for a query  $q$  to an encryption of  $M$  gives the answer to the query  $q$  on  $M$ . We consider security against both honest-but-curious and malicious adversaries, and define properties guaranteeing both the correctness of the user’s results and the privacy of the user’s data. Following the line of work started by [CGKO06], to allow for efficient constructions, we allow the protocol to leak some information about the user’s data, however we ensure that this leakage can be precisely captured in the definition. In addition, we allow the query protocol to involve a small constant number of rounds of interaction.

We construct a queryable encryption scheme for pattern matching queries that is correct and secure in the malicious model. Our construction is based on efficient symmetric-key building blocks and scales well with the size of the input: encryption of a data string of length  $n$  with security parameter  $\lambda$  takes  $O(n)$  time and produces a ciphertext of size  $O(n\lambda)$ , and a query for a pattern string of length  $m$  that occurs  $k$  times takes  $O(m + k)$  time and three rounds of communication.

# 1 Introduction

In traditional symmetric-key encryption schemes, a user encrypts a message so that only the owner of the corresponding secret key can decrypt it. Decryption is “all-or-nothing”; that is, with the key one can decrypt the message completely, and without the key one learns nothing about the message. However, many settings, such as cloud storage, call for encryption schemes that support the evaluation of certain classes of queries on the data, without decrypting the data. A client may wish to store encrypted data on a cloud server, and then be able to issue queries on the data to the server in order to make use of the data without retrieving and decrypting the original ciphertext.

Much work has been done in the setting where the data consists of a set of documents, and the client wishes to search for combinations of keywords in those documents. (These solutions are often referred to as symmetric searchable encryption or SSE; see Section 1.1 below.) But what about other types of data or other types of queries? For example, suppose a medical research lab wants to store its subjects’ genomic data using a cloud storage service. Privacy concerns may require that this data be encrypted; at the same time, the researchers need to be able to use and query the data efficiently. Here we consider the case where researchers want to be able to make substring queries on the stored data (e.g., to search for genetic markers). The owner of the data would like that the process of performing these queries not reveal much information to the server about the genomic data or the search strings.

We note that this problem could be solved with SSE, by considering every substring as a separate keyword; however, this approach would result in a fairly significant storage blowup (SSE scales linearly with the total number of keywords). Our goal here is to avoid this storage overhead and achieve efficiency comparable to the unencrypted scenario.

**Queryable encryption.** In this paper, we formalize a type of encryption that we call *queryable encryption*. A queryable encryption scheme allows for evaluation of some query functionality  $\mathcal{F}$  that takes as input a message  $M$  and a query  $q$  and outputs an answer. A client encrypts a message  $M$  under a secret key and stores the ciphertext on a server. Then, using the secret key, the client can issue a query  $q$  by executing an interactive protocol with the server. At the end of this protocol, the client learns the value of  $\mathcal{F}(M, q)$ . For example, for pattern matching queries, a query  $q$  is a pattern string, the message  $M$  is a string, and  $\mathcal{F}(M, q)$  returns the set of indices of all occurrences of  $q$  as a substring of  $M$ .

For security, we will think of the server as an adversary trying to learn information about the message and the queries. Ideally, we would like that an adversary that is given a ciphertext and that engages in query protocols for several queries learns nothing about the message or the queries. However, in order to achieve an efficient scheme, we will allow some limited information about the message and the queries to be revealed (“leaked”) to the server through the ciphertext and the query protocol. We define notions of security that specify explicitly what information is leaked, and guarantee that an adversary learns nothing more than the specified leakage. The idea that it may be acceptable for a queryable encryption to leak some information to gain efficiency was seen previously in the case of structured encryption [CK10], and to some extent in the case of searchable encryption [CGKO06].

This is similar in spirit to previous definitions for structured encryption and SSE. However, we have to generalize in two ways. First, since previous solutions focused on document retrieval, all previous definitions require that the adversary to learn the list of documents to be returned; here there are no documents, and all that is required is that the client learn the result of the query. The second difference is that our query protocol will require a few rounds of communication. In particular for malicious adversaries this must be treated carefully - while malicious activity in the one round SSE setting may result in the client getting incorrect results, a malicious attacker in an interactive protocol could potentially also try to learn extra

information.

We define correctness and security within two adversarial models: honest-but-curious and malicious. In the honest-but-curious model, the adversary executes the protocol honestly but tries to learn information about the message and the queries along the way. In the malicious model, the adversary tries to learn information, possibly by not following the protocol honestly.

**Pattern matching encryption.** Next, we focus on constructing a pattern matching encryption scheme, that is, a queryable encryption scheme that supports pattern matching queries – given a string  $s$  and a pattern string  $p$ , return all occurrences of  $p$  as a substring of  $s$ . For example, in the genomic data application researchers may wish to query the database to determine whether a particular cancer marker sequence appears in any of the data, to count whether a certain probe sequence is rare enough to be useful, or to .....

For efficiency, our goal is space and computation complexity comparable to that of evaluating pattern matching queries in the unencrypted setting. This means general techniques such as fully homomorphic encryption [Gen09, BV11, BGV12, GHS12] and functional encryption [BSW11, KSW08, SSW09] will not be practical. By focusing on the specific functionality of pattern matching queries, we are able to achieve a scheme with much better efficiency.

To construct a pattern matching encryption scheme, we use suffix trees, a data structure used to efficiently perform pattern matching on unencrypted data. We combine basic symmetric-key primitives to develop a method that allows traversal of select edges in a suffix tree in order to efficiently perform pattern matching on encrypted data, without revealing significant information about the string or the queries.

A suffix string for data string of length  $n$  takes  $O(n \log n)$  space, and searching for a pattern of length  $m$  takes  $O(mk)$  time, where  $k$  is the number of occurrences of the pattern. In our pattern matching encryption scheme, encryption time and ciphertext size are  $O(\lambda n)$ , querying for a pattern takes time and communication complexity  $O(\lambda m + k)$ , and  $\lambda$  is the security parameter. The query protocol takes a constant number of rounds of communication. All operations are based only on symmetric-key primitives.

## 1.1 Related Work

**Searchable encryption and structured encryption.** We draw on related work on symmetric searchable encryption (SSE) [CGKO06] and its generalization to structured encryption [CK10]. These works take the approach of considering a specific type of query and identifying a data structure that allows efficient evaluation of those queries in an unencrypted setting. The construction then “translates” the data structure into an encrypted setting, so that the user can encrypt the data structure and send the server a “token” to evaluate a query on the encrypted structure. This translation is designed to preserve the efficiency of the unencrypted data structure.

Since the server is processing the query, the server will be able to determine the memory access pattern of the queries, that is, which parts of memory have been accessed, and when the same memory block is accessed again.<sup>1</sup> The approach to security in SSE and structured encryption is to acknowledge that some information will be leaked because of the memory access pattern, but to clearly specify the leakage, and to guarantee that is the only information that the server can learn.

Recently there have been many advances in SSE. [CJJ<sup>+</sup>13] propose an efficient construction for searches involving multiple keywords; [CJJ<sup>+</sup>14, SPS14, KP13, KPR12] look at allowing updates to the stored documents; and [KO12] propose a UC definition. [WRYU12] use a tree data structure to implement SSE, essentially storing the encrypted keywords in a tree rather than a hash table. (Note that they are forming a

---

<sup>1</sup>Note that this is true even if we use fully homomorphic encryption (e.g., [Gen09, BV11, BGV12, GHS12]) or functional encryption [BSW11, KSW08, SSW09].

tree on encrypted data, while we form a tree out of the plaintext and then encrypt the tree structure.) However, all of these works focus on the problem of retrieving documents based on keywords; there has been very little work that considers encrypting other, more complex types of data structures.

**Predicate encryption and fully homomorphic encryption.** Predicate encryption (a special case of functional encryption [BSW11]) allows the secret key owner to generate “tokens” for various predicates; a token for a predicate  $f$  can be evaluated on a ciphertext that encrypts  $m$  to determine whether  $f(m)$  is satisfied. State-of-the-art predicate encryption schemes (e.g., [KSW08, SSW09]) support inner-product queries; that is,  $f$  specifies a vector  $v$ , and  $f(m) = 1$  if  $\langle m, v \rangle = 0$ . Applying an inner product predicate encryption scheme naively to construct a pattern matching encryption scheme, where the patterns can be of any length, would result in ciphertexts and query time that are  $O(n^n)$ , where  $n$  is the length of the string  $s$ , which is clearly impractical.

Fully homomorphic encryption (FHE), beginning with the breakthrough work of Gentry [Gen09] and further developed in subsequent work, e.g., [BV11, BGV12, GHS12], allows one to evaluate any arbitrary circuit on encrypted data without being able to decrypt. FHE would solve the pattern matching encryption problem (although it would require  $O(n)$  query time), but existing constructions are extremely impractical.

**Oblivious RAMs.** The problem of leaking the memory access pattern is addressed in the work on Oblivious RAMs [Ost92], which shows how to implement any query in a way that ensures that the memory access pattern is independent of the query. There has been significant progress in making oblivious RAMs efficient; however, even the most efficient constructions to date (see, e.g., Stefanov et al. [SSS12]) increase the amortized costs of processing a query by a factor of at least  $\log n$ , where  $n$  is the size of the stored data. In our setting, where we assume that the large size of the dataset may be one of the primary motivations for outsourcing storage, a  $\log n$  overhead may be unacceptable.

**Secure two-party computation of pattern matching.** There have been several works on secure two-party or multiparty computation (e.g., [DPSZ12, NNOB12]) and specifically on secure pattern matching and other text processing in the two-party setting (see [BDM<sup>+</sup>12, MNSS11, HL10, GHS10, KM10, Fri09, TPKC07]). This is an interesting line of work; however, our setting is rather different. In our setting, the client has outsourced storage of its encrypted data to a server, and then the client would like to query its data with a pattern string. The server does not have the data string in the clear; it is encrypted. Thus, even ignoring the extra rounds of communication, we cannot directly apply secure two-party pattern matching protocols.

**Memory delegation and integrity checking.** We consider both honest-but-curious and malicious adversaries. One way a malicious adversary may misbehave is by returning something other than what was originally stored on the server. Along these lines, there is related work on memory delegation (e.g., [CKLR11]) and memory checking (e.g., [DNRV09]), verifiable computation (e.g., [BGV11, GGP10]), integrity checking (e.g., [SvDJO12]), and encrypted computation on untrusted programs (e.g., [FvDD12]); the theme of these works is retrieving and computing on data stored on an untrusted server. For our purposes, since we focus on the specific functionality of pattern matching encryption in order to achieve an efficient scheme using simple primitives, we do not need general purpose integrity checking techniques, which can be expensive or rely on more complex assumptions.

## 2 Basic Definitions

Here we review some cryptographic primitives we will use. See Appendix B for more details, and for some notation and definitions of standard cryptographic primitives (e.g., PRFs, PRPs) we will use.

**$\epsilon$ -Almost-Universal Hash Functions** An  $\epsilon$ -almost-universal hash function is a family  $\mathcal{H}$  of hash functions such that, for any pair of distinct messages, the probability of a hash collision when the hash function is chosen randomly from  $\mathcal{H}$  is at most  $\epsilon$ .

**Polynomial Hash** The following hash function is  $\epsilon$ -almost-universal for  $\epsilon = (n - 1)/2^\ell$ : View a message  $x$  as a sequence  $(x_1, \dots, x_n)$  of  $\ell$ -bit strings. For any  $k$  in the finite field  $\text{GF}(2^\ell)$ , the hash function  $H_k(x)$  is defined as the evaluation of the polynomial  $p_x$  over  $\text{GF}(2^\ell)$  defined by coefficients  $x_1, \dots, x_n$ , at the point  $k$ . That is,  $H_k(x) = p_x(k) = \sum_{i=1}^n x_i k^{i-1}$ , where all operations are in  $\text{GF}(2^\ell)$ .

**Levin’s trick** We will sometimes want to compute a PRF on a long input. In this case, it can be more efficient to first hash the input down to a short string, and then apply the PRF to the hash output. If the hash function is  $\epsilon$ -almost-universal for some negligible  $\epsilon$ , then the resulting construction is still a PRF. This observation is due to Levin [Lev87] and is known sometimes as Levin’s trick.

**Symmetric-Key Encryption** We will use symmetric-key encryption schemes that are *CPA-secure*, *which-key concealing*, and in some cases *authenticated*. The which-key concealing property was introduced by Abadi and Rogaway [AR02] and (under the name “key hiding”) by Fischlin [Fis99], and says that an adversary cannot tell whether ciphertexts are encrypted under the same key or different keys. The notions of ciphertext integrity and *authenticated encryption* (defined below) were introduced by [BR00, KY01, BN00]. Ciphertext integrity says that an adversary given encryptions of messages of its choice cannot construct any new ciphertexts that decrypt successfully (i.e., decrypt to a value other than  $\perp$ ). A symmetric encryption scheme is *authenticated* if it has CPA security and ciphertext integrity. For a simple construction from PRFs in the random oracle model, see Appendix B.

### 3 Queryable Encryption

We now present the main definitions for our construction.

**Definition 3.1.** A *queryable encryption scheme* for message space  $\mathcal{M}$ , query space  $\mathcal{Q}$ , answer space  $\mathcal{A}$ , and query functionality  $\mathcal{F} : \mathcal{M} \times \mathcal{Q} \rightarrow \mathcal{A}$ , consists of the following probabilistic poly-time (PPT) algorithms.

$K \leftarrow \text{Gen}(1^\lambda)$ : The key generation algorithm takes a security parameter  $1^\lambda$  and generates a secret key  $K$ .

$CT \leftarrow \text{Enc}(K, M)$ : The encryption algorithm takes a secret key  $K$  and a message  $M \in \mathcal{M}$ , and outputs a ciphertext  $CT$ .

$A \leftarrow \text{IssueQuery}(K, q) \leftrightarrow \text{AnswerQuery}(CT)$ : The interactive algorithms *IssueQuery* and *AnswerQuery* compose a query protocol between a client and a server. The client takes as input the secret key  $K$  and a query  $q$ , and the server takes as input a ciphertext  $CT$ . At the end of the query protocol, the client outputs an answer  $A \in \mathcal{A}$ ; the server has no output.  $A$  is a private output that is not seen by the server.

**Correctness.** For correctness we require the following property. For all  $\lambda \in \mathbb{N}$ ,  $q \in \mathcal{Q}$ ,  $M \in \mathcal{M}$ , let  $K \leftarrow \text{Gen}(1^\lambda)$ ,  $CT \leftarrow \text{Enc}(K, M)$ , and  $A \leftarrow \text{IssueQuery}(K, q) \leftrightarrow \text{AnswerQuery}(CT)$ . Then  $\Pr[A = \mathcal{F}(M, q)] = 1 - \text{negl}(\lambda)$ .

This correctness property ensures correct output if all algorithms are executed honestly. (This is the usual way in which correctness is defined for similar types of schemes, such as searchable encryption, structured encryption, and functional encryption.) However, it does not say anything about the client’s output if the server does not honestly execute *AnswerQuery*.

**Correctness against malicious adversaries.** We also consider a stronger property, correctness against malicious adversaries, which says that the client’s output will be correct if all algorithms are executed honestly, but the client will output  $\perp$  if the server does not execute *AnswerQuery* honestly. Thus, the server may misbehave, but it cannot cause the client to unknowingly produce incorrect output.

More formally, correctness against malicious adversaries requires the following. For all PPT algorithms  $\mathcal{A}$ , for all  $\lambda \in \mathbb{N}$ ,  $q \in \mathcal{Q}$ ,  $M \in \mathcal{M}$ , let  $K \leftarrow \text{Gen}(1^\lambda)$ ,  $CT \leftarrow \text{Enc}(K, M)$ , and  $A \leftarrow \text{IssueQuery}(K, q) \leftrightarrow \mathcal{A}(CT)$ . If  $\mathcal{A}$  honestly executes *AnswerQuery*, then  $\Pr[A = \mathcal{F}(M, q)] = 1 - \text{negl}(\lambda)$ . If  $\mathcal{A}$  deviates from *AnswerQuery* in its input-output behavior, then  $\Pr[A = \perp] = 1 - \text{negl}(\lambda)$ .

**Discussion.** Note that, although the above is called a queryable “encryption scheme”, it does not include an explicit decryption algorithm, as the client might not ever intend to retrieve the entire original message. However, we could easily augment the functionality  $F$  with a query that returns the entire message.

Note also that typically we expect  $M$  to be quite large, while the representation of  $q$  and  $\mathcal{F}(M, q)$  are small, so we would like the query protocol to be efficient relative to the size of  $q$  and  $\mathcal{F}(M, q)$ . Without such efficiency goals, designing a queryable encryption scheme would be trivial. *AnswerQuery* could return the entire ciphertext, and *IssueQuery* could decrypt the ciphertext to get  $M$  and compute  $\mathcal{F}(M, q)$  directly.

Our queryable encryption definition generalizes previous definitions of searchable encryption [CGKO06] and structured encryption [CK10], in the following ways.

Queryable encryption allows any general functionality  $F$ . In contrast, the definition of searchable encryption is tied to the specific functionality of returning documents containing a requested keyword. Structured encryption is a generalization of searchable encryption, but the functionalities are restricted to return pointers to elements of an encrypted data structure. Since we allow general functionalities, our definition is similar to those of functional encryption. The main difference between queryable encryption and functional encryption is in the security requirements, which we will describe in the next section.

Also, queryable encryption allows the query protocol to be interactive. In searchable encryption, structured encryption, and functional encryption, the query protocol consists of two algorithms  $TK \leftarrow \text{Token}(K, q)$  and  $A \leftarrow \text{Query}(TK, CT)$ . The client constructs a query token and sends it to the server, and the server uses the token and the ciphertext to compute the answer to the query, which it sends back to the client. We can think of these schemes as having a one-round interactive query protocol. Our definition allows for arbitrary interactive protocols, which may allow for better efficiency or privacy.

We do not need the server to actually learn the answer to the query. After the server’s final message, the client may do some additional computation using its secret key to compute the answer. Since the server does not see the final answer, we are able to achieve stronger privacy guarantees.

### 3.1 Honest-but-Curious $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 Security

We first consider security in an honest-but-curious adversarial model. In this model, we assume that the server is honest (it executes the algorithms honestly), but curious (it can use any information it sees in the honest execution to learn what it can about the message and queries).

Ideally, we would like to guarantee that ciphertexts and query protocols reveal nothing about the message or the queries. However, such a strict requirement often makes it very difficult to achieve an efficient scheme. Therefore, we relax the security requirement somewhat so that some information may be revealed (leaked) to the server. The security definition will be parameterized by two “leakage” functions  $\mathcal{L}_1, \mathcal{L}_2$ .  $\mathcal{L}_1(M)$  denotes the information about the message that is leaked by the ciphertext. For any  $j$ ,  $\mathcal{L}_2(M, q_1, \dots, q_j)$  denotes the information about the message and all queries made so far that is leaked by the  $j$ th query.

We would like to ensure that the information specified by  $\mathcal{L}_1$  and  $\mathcal{L}_2$  is the only information that is leaked to the adversary, even if the adversary can choose the message that is encrypted and then adaptively choose

the queries for which it executes a query protocol with the client. To capture this, our security definition considers a real experiment and an ideal experiment, and requires that the view of any adaptive adversary in the real experiment be simulatable given only the information specified by  $\mathcal{L}_1$  and  $\mathcal{L}_2$ .

Following [CK10], we call the definition  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security, where the name ‘‘CQA2’’ comes from ‘‘chosen query attack’’, somewhat analogous to CCA2 (chosen ciphertext attack) for symmetric encryption, where an adversary can make adaptive decryption queries after receiving the challenge ciphertext.

**Definition 3.2** (Honest-but-Curious  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 Security). Let  $\mathcal{E} = (\text{Gen}, \text{Enc}, \text{Query})$  be a queryable encryption scheme for message space  $\mathcal{M}$ , query space  $\mathcal{Q}$ , answer space  $\mathcal{A}$ , and query functionality  $F : \mathcal{M} \times \mathcal{Q} \rightarrow \mathcal{A}$ . For functions  $\mathcal{L}_1$  and  $\mathcal{L}_2$ , adversary  $\mathcal{A}$ , and simulator  $\mathcal{S}$ , consider the following experiments:

**Real $_{\mathcal{E}, \mathcal{A}}(\lambda)$** : The challenger first runs  $\text{Gen}(1^\lambda)$  to generate secret key  $K$ . The adversary  $\mathcal{A}$  outputs a message  $M$ . The challenger runs  $\text{Enc}(K, M)$  to generate a ciphertext  $CT$ , and sends  $CT$  to  $\mathcal{A}$ . The adversary adaptively chooses a polynomial number of queries,  $q_1, \dots, q_t$ . For each query  $q_i$ , the challenger sends the adversary the view  $v_i$  of an honest server in the interactive protocol  $\text{IssueQuery}(K, q_i) \leftrightarrow \text{AnswerQuery}(CT)$ . Finally,  $\mathcal{A}$  outputs a bit  $b$ , and  $b$  is output by the experiment.

**Ideal $_{\mathcal{E}, \mathcal{A}, \mathcal{S}}(\lambda)$** : First,  $\mathcal{A}$  outputs a message  $M$ . The simulator  $\mathcal{S}$  is given  $\mathcal{L}_1(M)$  (not  $M$  itself), and outputs a value  $CT$ . The adversary adaptively chooses a polynomial number of queries,  $q_1, \dots, q_t$ . For each query  $q_i$ , the simulator is given  $\mathcal{L}_2(M, q_1, \dots, q_i)$  (not  $q_i$  itself), and it outputs a simulated view  $v_i$ . Finally,  $\mathcal{A}$  outputs a bit  $b$ , and  $b$  is output by the experiment.

We say that  $\mathcal{E}$  is  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 secure against honest-but-curious adversaries if, for all PPT adversaries  $\mathcal{A}$ , there exists a simulator  $\mathcal{S}$  such that  $|\Pr[\mathbf{Real}_{\mathcal{E}, \mathcal{A}}(\lambda) = 1] - \Pr[\mathbf{Ideal}_{\mathcal{E}, \mathcal{A}, \mathcal{S}}(\lambda) = 1]| \leq \text{negl}(\lambda)$ .

**Discussion.** The above definition is based heavily on the definition for structured encryption [CK10] and generalizes it to interactive query protocols. It is also loosely related to simulation-based definitions for functional encryption [BSW11], with one important difference: In our definition, we only consider a single ciphertext; security is not guaranteed to hold if multiple ciphertexts are encrypted under the same key. Note that security for only one ciphertext only makes sense in the symmetric-key setting, since in the public-key setting one can encrypt any number of messages with the public key. In our application, it will be reasonable to expect that each instantiation of the scheme will be used to encrypt only one message.

Although in some applications, it may be interesting and sufficient to model the server as an honest-but-curious adversary, often we will be interested in a stronger adversarial model. That is, we would like to ensure privacy against even a malicious adversary – one that does not execute its algorithms honestly. In the next section, we present a definition of security against malicious adversaries.

### 3.2 Malicious $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 Security

The definition of  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security against malicious adversaries is similar to the one for honest-but-curious adversaries, except for the following two differences. First, for each query  $q_i$ , instead of just receiving the view of the server, the adversary will interact with either an honest challenger running  $\text{IssueQuery}(K, q_i)$  in the real game, or with the simulator given  $\mathcal{L}_2(M, q_1, \dots, q_i)$  in the ideal game.

Second, at the end of the protocol for  $q_i$ , the adversary outputs the description of a function  $g_i$  of its choice. In the real game, the adversary receives  $g_i(A_1, \dots, A_i)$ , where  $A_j$  is the private answer output by the client for query  $q_j$ . In the ideal game, the adversary receives  $g_i(A'_1, \dots, A'_i)$ , where  $A'_j = \perp$  if the client output  $\perp$  in the query protocol for  $q_j$ ; otherwise,  $A'_j = F(M, q_j)$ .

This last step of the game is necessary in the malicious case because the adversary may learn extra information based on the client’s responses to the incorrectly formed messages from the adversary. The

client’s private output, although not sent to the server in the actual query protocol, can be thought of as a response to the last message sent by the adversary. We want to capture the notion that, even if the adversary were able to learn some function  $g_i$  of the client’s private outputs  $A_1, \dots, A_i$ , it would not learn more than  $g_i(F(M, q_1), \dots, F(M, q_i))$ . For any  $A_j = \perp$ , in the evaluation of  $g_i$ ,  $F(M, q_j)$  is replaced by  $\perp$ .

**Definition 3.3** (Malicious  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security). Let  $\mathcal{E} = (\text{Gen}, \text{Enc}, \text{Query})$  be a queryable encryption scheme for message space  $\mathcal{M}$ , query space  $\mathcal{Q}$ , answer space  $\mathbb{A}$ , and query functionality  $F : \mathcal{M} \times \mathcal{Q} \rightarrow \mathbb{A}$ . For functions  $\mathcal{L}_1$  and  $\mathcal{L}_2$ , adversary  $\mathcal{A}$ , and simulator  $\mathcal{S}$ , consider the following experiments:

**Real’ $_{\mathcal{E}, \mathcal{A}}(\lambda)$** : The challenger begins by running  $\text{Gen}(1^\lambda)$  to generate a secret key  $K$ . The adversary  $\mathcal{A}$  outputs a message  $M$ . The challenger runs  $\text{Enc}(K, M)$  to generate a ciphertext  $CT$ , and sends  $CT$  to  $\mathcal{A}$ . The adversary adaptively makes a polynomial number of queries  $q_1, \dots, q_t$ . For each query  $q_i$ , first  $\mathcal{A}$  interacts with the challenger, which runs  $\text{IssueQuery}(K, q_i)$ . Let  $A_i$  be the challenger’s private output from the protocol for  $q_i$ . Then  $\mathcal{A}$  outputs a description of a function  $g_i$ , and it receives  $h_i \leftarrow g_i(A_1, \dots, A_i)$ . Finally,  $\mathcal{A}$  outputs a bit  $b$ .

**Ideal’ $_{\mathcal{E}, \mathcal{A}, \mathcal{S}}(\lambda)$** : First,  $\mathcal{A}$  outputs a message  $M$ . The simulator  $\mathcal{S}$  is given  $\mathcal{L}_1(M)$  (not  $M$  itself), and outputs a value  $CT$ . The adversary adaptively makes a polynomial number of queries  $q_1, \dots, q_t$ . For each query  $q_i$ , first the simulator is given  $\mathcal{L}_2(M, q_1, \dots, q_i)$  (not  $q_i$  itself), and  $\mathcal{A}$  interacts with the simulator. Then  $\mathcal{A}$  outputs a description of a function  $g_i$ , and it receives  $h_i \leftarrow g_i(A'_1, \dots, A'_i)$ , where  $A'_i = \perp$  if the simulator output  $\perp$  in the query protocol for  $q_i$ ; otherwise,  $A'_i = \mathcal{F}(M, q_i)$ . Finally,  $\mathcal{A}$  outputs a bit  $b$ .

We say that  $\mathcal{E}$  is  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 secure against malicious adversaries if, for all PPT adversaries  $\mathcal{A}$ , there exists a simulator  $\mathcal{S}$  such that

$$|\Pr[\mathbf{Real}'_{\mathcal{E}, \mathcal{A}}(\lambda) = 1] - \Pr[\mathbf{Ideal}'_{\mathcal{E}, \mathcal{A}, \mathcal{S}}(\lambda) = 1]| \leq \text{negl}(\lambda) .$$

### 3.3 Pattern Matching Encryption

**Definition 3.4** (Pattern matching encryption). A *pattern matching encryption scheme* for an alphabet  $\Sigma$  is a queryable encryption scheme for:

- message space  $\mathcal{M} = \Sigma^*$ ,
- query space  $\mathcal{Q} = \Sigma^*$ ,
- answer space  $\mathbb{A} = \mathcal{P}(\mathbb{N})$ , and
- query functionality  $\mathcal{F}$  where  $\mathcal{F}(s, p)$  is the set of indices of all the occurrences of  $p$  as a substring of  $s$ . That is,  $\mathcal{F}(s, p) = \{i \mid s[i..i + m - 1] = p\}$ , where  $m = |p|$ .

## 4 Pattern Matching Encryption Construction

Our goal is to construct a pattern matching scheme – a queryable encryption scheme that supports the functionality  $\mathcal{F}$ , where  $\mathcal{F}(s, p)$  returns the indices of all occurrences of  $p$  as a substring of  $s$ .

**Suffix Trees** We first look to pattern matching algorithms for unencrypted data. There are several known pattern matching algorithms [KJP77, BM77, KR87, AC75], varying in their preprocessing efficiency and query efficiency. Most of these algorithms have preprocessing time  $O(m)$  and query time  $O(n)$ , where  $n$  is the length of the string  $s$  and  $m$  is the length of the pattern  $p$ . Pattern matching using suffix trees, however, has preprocessing time  $O(n)$  and query time  $O(m)$ . This is ideal for our applications, where the client stores one string  $s$  encrypted on the server, and performs queries for many pattern strings  $p$ . Therefore, we will focus on pattern matching using suffix trees as the basis for our scheme.

A *suffix tree* for a string  $s$  of length  $n$  is defined as a tree such that the paths from the root to the leaves are in one-to-one correspondence with the  $n$  suffixes of  $s$ , edges spell non-empty strings, each internal node has at least two children, and any two edges coming out of a node start with different characters. For a suffix tree for a string  $s$  to exist,  $s$  must be prefix-free; if it is not, we can first append a special symbol  $\$$  to make  $s$  prefix-free. Figure 1 in Appendix A shows a suffix tree for an example string, “cocoon”.

Pattern matching using suffix trees uses the following important observation: a pattern  $p$  is a substring of  $s$  if and only if it is a prefix of some suffix of  $s$ . Thus, to search  $s$  for a pattern  $p$ , search for a path from the root of which  $p$  is a prefix.

For a string of length  $n$ , a suffix tree can be constructed in  $O(n)$  time [Ukk95, Far97]. It can be easily shown that a suffix tree has at most  $2n$  nodes. However, if for each node we were to store the entire string spelled on the edge to that node, the total storage would be  $O(n^2)$  in the worst case. (To see this, consider the suffix tree for the string  $s_1 \dots s_n$ , where each  $s_i$  is unique. The suffix tree would contain a distinct edge for each of the  $n$  suffixes  $s_1 \dots s_n, s_2 \dots s_n, \dots, s_n$ ; these suffixes have a total length  $O(n^2)$ .) To represent a suffix tree in  $O(n)$  space, for each node  $u$  other than the root, one stores the start and end indices into  $s$  of the first occurrence of the substring on the edge to  $u$ . One also stores the string  $s$ . Using this representation, a suffix tree takes  $O(n)$  storage and can be used to search for any pattern  $p$  of length  $m$  in  $O(m)$  time, and to return the indices of all occurrences of  $p$  in  $O(m + k)$  time, where  $k$  is the number of occurrences.

A few observations about suffix trees will be useful in our construction: For any node  $u$ , let  $\rho(u)$  be the string spelled out on the path from the root to  $u$ . The string  $\rho(u)$  uniquely identifies a node  $u$  in a suffix tree, i.e., no two distinct nodes  $u$  and  $u'$  have  $\rho(u) = \rho(u')$ . Let us also define  $\hat{\rho}(u)$  to be the string spelled out on the path from the root to the parent of  $u$ , followed by the first character on the edge to  $u$ . Since no two edges coming out of a node start with the same character,  $\hat{\rho}(u)$  also uniquely identifies  $u$ . Furthermore, the set of indices in  $s$  of occurrences of  $\rho(u)$  is exactly the same as the set of indices of occurrences of  $\hat{\rho}(u)$ .

For any given string  $s$ , a suffix tree is generally not unique (the children of each node may be ordered in any way). For the remainder of the paper, we will assume that when a suffix tree is constructed, the children of every node are “ordered” lexicographically according to some canonical order of the alphabet. Thus, for a given string  $s$ , we talk about *the* unique suffix tree for  $s$ ; we can also talk about the  $i$ th child of a node in a well-defined way. In the example in Figure 1, the suffix tree for “cocoon” is constructed with respect to the ordering  $(c, o, n)$ . In Figure 1,  $u_5$  and  $u_6$  are the first and second children, respectively, of  $u_2$ .

## 4.1 Notation

Before we describe our pattern matching encryption scheme, we introduce some helpful notation. Some of the notation will be relative to a string  $s$  and its suffix tree  $Tree_s$ , even though they are not explicit parameters.

---

$u$ :	a node in $Tree_s$
$\epsilon$ :	the empty string
$\text{par}(u)$ :	the parent node of $u$ . If $u$ is the root, $\text{par}(u)$ is undefined.
$\text{child}(u, i)$ :	the $i$ th child node of $u$ . If $u$ has fewer than $i$ children, $\text{child}(u, i)$ is undefined.
$\text{deg}(u)$ :	the out-degree (number of children) of $u$
$\rho(u)$ :	the string spelled on the path from the root to $u$ . $\rho(u) = \epsilon$ if $u$ is the root.
$\hat{\rho}(u)$ :	For any non-root node $u$ , $\hat{\rho}(u) = \rho(\text{par}(u))  u_1$ , where $u_1$ is the first character on the edge from $\text{par}(u)$ to $u$ . If $u$ is the root, $\hat{\rho}(u) = \epsilon$ .
$\text{leaf}_i$ :	the $i$ th leaf node in $Tree_s$ , where the leaves are numbered 1 to $n$ , left to right
$\text{len}_u$ :	the length of the string $\hat{\rho}(u)$

$ind_u$ :	the index in $s$ of the first occurrence of $\rho(u)$ (equivalently, of $\hat{\rho}(u)$ ) as a substring. That is, $ind_u$ is the smallest $i$ such that $\hat{\rho}(u) = s[i..i + len_u - 1]$ . If $\rho(u) = \epsilon$ , $ind_u$ is defined to be 0.
$lpos_u$ :	the position (between 1 and $n$ ) of the leftmost descendant of $u$ . That is, $leaf_{lpos_u}$ is the leftmost leaf in the subtree rooted at $u$ .
$num_u$ :	the number of occurrences in $s$ of $\rho(u)$ (equivalently, of $\hat{\rho}(u)$ ) as a substring. If $\rho(u) = \epsilon$ , $num_u$ is defined to be 0. Note that for non-root nodes $u$ , $num_u$ is equal to the number of leaves in the subtree rooted at $u$ .

---

To illustrate the notation above, let us look at the suffix tree in Figure 1 for the string “cocoon”. In this tree, we have  $u_2 = \text{par}(u_3)$ ,  $u_3 = \text{child}(u_2, 1)$ ,  $\text{deg}(u_2) = 2$ ,  $\rho(u_3) = \text{“cocoon”}$ ,  $\hat{\rho}(u_3) = \text{“coc”}$ ,  $leaf_5 = u_8$ ,  $ind_{u_2} = 1$ ,  $lpos_{u_2} = 1$ ,  $num_{u_2} = 2$ .

## 4.2 Intuition

Our construction will make use of a dictionary, which is a data structure that stores key-value pairs  $(k, V)$ , such that for any key  $k$  the corresponding value  $V$  can be retrieved efficiently (in constant time).

We will use a symmetric encryption scheme  $\mathcal{E}_{\text{SKE}}$ , a PRF  $F$ , and a PRP  $P$ . The key generation algorithm will generate three keys  $K_D, K_C, K_L$  for  $\mathcal{E}_{\text{SKE}}$ , and four keys  $K_1, K_2, K_3, K_4$ . (We will explain how the keys are used as we develop the intuition for the construction.)

**First attempt.** We first focus on constructing a queryable encryption scheme for a simpler functionality  $\mathcal{F}'$ , where  $\mathcal{F}'(s, p)$  computes whether  $p$  occurs as a substring in  $s$ , and, if so, the index of the first occurrence in  $s$  of  $p$ . We will also only consider correctness and security against an honest-but-curious server for now.

As a first attempt, let  $\mathcal{E}_{\text{SKE}}$  be a CPA-secure symmetric encryption scheme, and encrypt a string  $s = s_1 \dots s_n$  in the following way. First, construct the suffix tree  $Tree_s$  for  $s$ . Then construct a dictionary  $D$ , where for each node  $u$  in  $Tree_s$ , there is an entry with search key  $F_{K_1}(\rho(u))$  and value  $\mathcal{E}_{\text{SKE}}.Enc(K_D, ind_u)$ , and let the ciphertext consist of the dictionary  $D$ . Then, in the query protocol for a query  $p$ , the client sends  $F_{K_1}(p)$ . The server then checks whether  $D$  contains an entry with search key  $F_{K_1}(p)$ . If so, it returns  $D(F_{K_1}(p))$ , which the client decrypts using  $K_D$  to get the index of the first occurrence in  $s$  of  $p$ .

For example, for our example string “cocoon”, the ciphertext in this first attempt would consist of the dictionary shown in Figure 2 in Appendix A.

The obvious problem with this approach is that it only works for patterns that are substrings of  $s$  that end exactly at a node; it does not work for finding substrings of  $s$  that end partway down an edge.

**Returning a possible match.** To address this problem, we observe that we can uniquely identify each node  $u$  by  $\hat{\rho}(u)$  instead of  $\rho(u)$ . Furthermore, if  $u$  is the last node (farthest from the root) for which any prefix of  $p$  equals  $\hat{\rho}(u)$ , then either  $p$  is not a substring of  $s$ , or  $p$  ends partway down the path to  $u$  and the indices in  $s$  of the occurrences of  $\hat{\rho}(u)$  are the same as the indices in  $s$  of the occurrences of  $p$ .

In the dictionary  $D$ , we will now use  $\hat{\rho}(u)$  instead of  $\rho(u)$  as the search key for a node  $u$ . We will say that a prefix  $p[1..i]$  is a *matching prefix* if  $p[1..i] = \hat{\rho}(u)$  for some  $u$ , i.e., there is a dictionary entry corresponding to  $p[1..i]$ ; otherwise,  $p[1..i]$  is a *non-matching prefix*.

The ciphertext will also include an array  $C$  of character-wise encryptions of  $s$ , with  $C[i] = \mathcal{E}_{\text{SKE}}.Enc(K_C, s_i)$ . In the query protocol, the client will send  $T_1, \dots, T_m$ , where  $T_i = F_{K_1}(p[1..i])$ . The server finds the entry  $D(T_j)$ , where  $p[1..j]$  is the longest matching prefix of  $p$ . The server will return the encrypted index  $\mathcal{E}_{\text{SKE}}.Enc(K_D, ind)$  stored in  $D(T_j)$ . The client will then decrypt it to get  $ind$ , and request the server to send

$C[ind], \dots, C[ind+m-1]$ . The client can decrypt the result to check whether the decrypted string is equal to the pattern  $p$  and thus, whether  $p$  is a substring of  $s$ .

**Returning all occurrences.** We would like to return the indices of all occurrences of  $p$  in  $s$ , not just the first occurrence or a constant number of occurrences. However, in order to keep the ciphertext size  $O(n)$ , we need the storage for each node to remain a constant size. In a naive approach, in each dictionary entry we would store encryptions of indices of all of the occurrences of the corresponding string. However, this would take  $O(n^2)$  storage in the worst case.

We will use the observation that the occurrences of the prefix associated with a node are exactly the occurrences of the strings associated with the leaves in the subtree rooted at that node. Each leaf corresponds to exactly one suffix. So, we construct a leaf array  $L$  of size  $n$ , with the leaves numbered 1 to  $n$  from left to right. Each element  $L[i]$  stores an encryption of the index in  $s$  of the string on the path to the  $i$ th leaf. That is,  $L[i] = \mathcal{E}_{\text{SKE}}.Enc(K_L, ind_{leaf_i})$ . In the encrypted tuple in the dictionary entry for a node  $u$  we also store  $lpos_u$ , the leaf position of the leftmost leaf in the subtree rooted at  $u$ , and  $num_u$ , the number of occurrences of  $\hat{p}(u)$ . That is, the value in the dictionary entry for a node  $u$  is now  $\mathcal{E}_{\text{SKE}}.Enc(K_D, (ind_u, lpos_u, num_u))$  instead of  $\mathcal{E}_{\text{SKE}}.Enc(K_D, ind_u)$ . The server will return  $\mathcal{E}_{\text{SKE}}.Enc(K_D, (ind_u, lpos_u, num_u))$  for the last node  $u$  matched by a prefix of  $p$ . The client then decrypts to get  $ind_u, lpos_u, num_u$ , asks for  $C[ind], \dots, C[ind+m-1]$ , decrypts to determine whether  $p$  is a substring of  $s$ , and if so, asks for  $L[lpos_u], \dots, L[lpos_u + num - 1]$  to retrieve all occurrences of  $p$  in  $s$ .

**Hiding common non-matching prefixes among queries.** The scheme outlined so far works; it supports the desired pattern matching query functionality, against an honest-but-curious adversary. However, it leaks a lot of unnecessary information; we add a number of improvements to reduce the information that is leaked.

For any two queries  $p$  and  $p'$  whose first  $j$  prefixes are the same, the values  $T_1, \dots, T_j$  in the query protocol will be the same. Therefore, the server will learn that  $p[1..j] = p'[1..j]$ , even though  $p[1..j]$  may not be contained in  $s$  at all. Memory accesses will reveal to the server when two queries share a prefix  $p[1..j]$  that is a matching prefix (i.e., contained in the dictionary), but we would like to hide when queries share non-matching prefixes.

To hide when queries share non-matching prefixes, we change each  $T_i$  to be an  $\mathcal{E}_{\text{SKE}}$  encryption of  $f_1^{(i)} = F_{K_1}(p[1..i])$  under the key  $f_2^{(i)} = F_{K_2}(p[1..i])$ . The dictionary entry for a node  $u$  will contain values  $f_{2,i}$  for its children nodes, where  $f_{2,i} = F_{K_2}(\hat{p}(\text{child}(u, i)))$ . Note that  $f_{2,i}$  is the key used to encrypt  $T_j$  for any pattern  $p$  whose prefix  $p[1..j]$  is equal to  $\hat{p}(\text{child}(u, i))$ . In the query protocol, the server starts at the root node, and after reaching any node, the server tries using each of the  $f_{2,i}$  for that node to decrypt each of the next  $T_j$ 's, until it either succeeds and reaches the next node or it reaches the end of the pattern.

**Hiding node degrees, lexicographic order of children, number of nodes in suffix tree.** Since the maximum degree of any node is the size  $d$  of the alphabet, we hide the degree of each node by creating dummy random  $f_{2,i}$  values so that there are  $d$  in total. To hide the lexicographic order of the children and hide which of the  $f_{2,i}$  are dummy values, we store the  $f_{2,i}$  in a random permuted order in the dictionary entry.

Similarly, since a suffix tree for a string of length  $n$  contains at most  $2n$  nodes, we will hide the exact number  $N$  of nodes in the suffix tree by constructing  $2n - N$  dummy entries in  $D$ . For each dummy entry, the search key is a random value  $f_1$ , and the value is  $(f_{2,1}, \dots, f_{2,d}, W)$ , where  $f_{2,1}, \dots, f_{2,d}$  are random and  $W$  is an encryption of 0.

**Hiding string indices and leaf positions.** In order to hide the actual values of the string indices  $ind, \dots, ind+m-1$  and the leaf positions  $lpos, \dots, lpos + num - 1$ , we make use of a pseudorandom permutation family  $P$  of permutations  $[n] \rightarrow [n]$ . Instead of sending  $(ind, \dots, ind + m - 1)$ , the client applies the permutation  $P_{K_3}$  to  $ind, \dots, ind + m - 1$  and outputs the resulting values in a randomly permuted order as

$(x_1, \dots, x_m)$ . Similarly, instead of sending  $(lpos, \dots, lpos + num - 1)$ , the client applies the permutation  $P_{K_4}$  to  $lpos, \dots, lpos + num - 1$  and outputs the resulting values in a randomly permuted order as  $(y_1, \dots, y_{num})$ . Note that while the server does not learn the actual indices or leaf positions, it still learns when two queries ask for the same or overlapping indices or leaf positions.

**Handling malicious adversaries.** The scheme described so far satisfies correctness against an honest-but-curious adversary, but not a malicious adversary, since the client does not perform any checks to ensure that the server is sending correct messages. The scheme also would not satisfy security against a malicious adversary for reasonable leakage functions, since an adversary could potentially gain information by sending malformed or incorrect ciphertexts during the query protocol.

To handle a malicious adversary, we will require  $\mathcal{E}_{\text{SKE}}$  to be an authenticated encryption scheme. Thus, an adversary will not be able to obtain the decryption of any ciphertext that is not part of the dictionary  $D$  or the arrays  $C$  or  $L$ . Also, we add auxiliary information to the messages encrypted, to allow the client to check that any ciphertext returned by the adversary is the one expected by the honest algorithm. The client will be able to detect whether the server returned a ciphertext that is in  $D$  but not the correct one, for example.

Specifically, we will encrypt  $(s_i, i)$  instead of just  $s_i$ , so that the client can check that it is receiving the correct piece of the ciphertext. Similarly, we will encrypt  $(ind_{leaf_i}, i)$  instead of just  $ind_{leaf_i}$ . For the dictionary entries, in addition to  $ind_u, num_u$ , and  $lpos_u$ , we will include  $len_u, f_1(u), f_{2,1}(u), \dots, f_{2,d}(u)$  in the tuple that is encrypted. The client can then check whether the  $W$  sent by the adversary corresponds to the longest matching prefix of  $p$ , by verifying that  $F_{K_1}(p[1..len]) = f_1$ , and that none of the  $f_{2,1}, \dots, f_{2,d}$  successfully decrypts any of the  $T_j$  for  $j > len$ .

### 4.3 Final construction

Let  $F : \{0, 1\}^\lambda \times \{0, 1\}^* \rightarrow \{0, 1\}^\lambda$  be a PRF, and let  $P : \{0, 1\}^\lambda \times [n] \rightarrow [n]$  be a PRP. Let  $\mathcal{E}_{\text{SKE}} = (\text{Gen}, \text{Enc}, \text{Dec})$  be an authenticated, which-key-concealing symmetric encryption scheme. Our pattern matching encryption scheme  $\mathcal{E}_{\text{PM}}$  for an alphabet  $\Sigma$  with  $|\Sigma| = d$  is as follows.

**Gen**( $1^\lambda$ ): Choose random strings  $K_D, K_C, K_L, K_1, K_2, K_3, K_4 \xleftarrow{\text{R}} \{0, 1\}^\lambda$ .<sup>2</sup> The secret key is

$$K = (K_D, K_C, K_L, K_1, K_2, K_3, K_4).$$

**Enc**( $K, s$ ): Let  $s = s_1 \dots s_n \in \Sigma^n$ . Construct the suffix tree  $Tree_s$  for  $s$ .

1. Construct a dictionary  $D$  as follows.

For any node  $u$ , define  $f_1(u) := F_{K_1}(\hat{\rho}(u))$  and  $f_2(u) := F_{K_2}(\hat{\rho}(u))$ .

For each node  $u$  in  $Tree_s$  (including the root and leaves), proceed as follows:

- Choose a random permutation  $\pi_u : [d] \rightarrow [d]$ .
- For  $i = 1, \dots, d$ , let  $f_{2,i}(u) = f_2(\text{child}(u, \pi_u(i)))$  if  $1 \leq \pi_u(i) \leq \text{deg}(u)$ ; otherwise let  $f_{2,i}(u) \xleftarrow{\text{R}} \{0, 1\}^\lambda$ .
- Let  $X_u = (ind_u, lpos_u, num_u, len_u, f_1(u), f_{2,1}(u), \dots, f_{2,d}(u))$ , and let  $W_u = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_D, X_u)$ .
- Store  $V_u = (f_{2,1}(u), \dots, f_{2,d}(u), W_u)$  with search key  $\kappa_u = f_1(u)$  in  $D$ .

Let  $N$  denote the number of nodes in  $Tree_s$ . Construct  $2n - N$  dummy entries in  $D$  as follows. For each dummy entry, choose random strings  $f_1, f_{2,1}, \dots, f_{2,d} \xleftarrow{\text{R}} \{0, 1\}^\lambda$ , and store  $(f_{2,1}, \dots, f_{2,d}, \mathcal{E}_{\text{SKE}}.\text{Enc}(K_D, 0))$  with search key  $f_1$  in  $D$ .

---

<sup>2</sup>We will assume for simplicity that  $\mathcal{E}_{\text{SKE}}.\text{Gen}$  simply chooses a random key  $k \xleftarrow{\text{R}} \{0, 1\}^\lambda$ , so throughout the construction we will use random values as  $\mathcal{E}_{\text{SKE}}$  keys. To allow for general  $\mathcal{E}_{\text{SKE}}.\text{Gen}$  algorithms, instead of using a random value  $r$  directly as a key, we could use a key generated by  $\mathcal{E}_{\text{SKE}}.\text{Gen}$  with  $r$  providing  $\mathcal{E}_{\text{SKE}}.\text{Gen}$ 's random coins.

2. Construct an array  $C$  as follows: for  $i = 1, \dots, n$ , set  $C[P_{K_3}(i)] = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (s_i, i))$ .
3. Construct an array  $L$  as follows: For  $i = 1, \dots, n$ , set  $L[P_{K_4}(i)] = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_L, (\text{ind}_{\text{leaf}_i}, i))$ .

Output the ciphertext  $CT = (D, C, L)$ .

**IssueQuery** $(K, p) \leftrightarrow \text{AnswerQuery}(CT)$ : The interactive query protocol, between a client with  $K$  and  $p$  and a server with  $CT$ , runs as follows.

Let  $p = p_1 \dots p_m \in \Sigma^m$ , and let  $CT = (D, C, L)$ .

1. The client computes, for  $i = 1, \dots, m$ ,  $f_1^{(i)} = F_{K_1}(p_1 \dots p_i)$ ,  $f_2^{(i)} = F_{K_2}(p_1 \dots p_i)$ , and sets  $T_i = \mathcal{E}_{\text{SKE}}.\text{Enc}(f_2^{(i)}, f_1^{(i)})$ . The client sends the server  $(T_1, \dots, T_m)$ .
2. The server proceeds as follows, maintaining variables  $f_1, f_{2,1}, \dots, f_{2,d}, W$ . Initialize  $(f_{2,1}, \dots, f_{2,d}, W)$  to equal  $D(F_{K_1}(\epsilon))$ , where  $\epsilon$  denotes the empty string.

For  $i = 1, \dots, m$ :

For  $j = 1, \dots, d$ :

Let  $f_1 \leftarrow \mathcal{E}_{\text{SKE}}.\text{Dec}(f_{2,j}, T_i)$ . If  $f_1 \neq \perp$ , update  $(f_{2,1}, \dots, f_{2,d}, W)$  to equal  $D(f_1)$ , and break (proceed to the next value of  $i$ ). Otherwise, do nothing.

At the end, the server sends  $W$  to the client.

3. The client runs  $X \leftarrow \mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W)$ . If  $X = \perp$ , output  $\perp$  and end the protocol. Otherwise, parse  $X$  as  $(\text{ind}, \text{lpos}, \text{num}, \text{len}, f_1, f_{2,1}, \dots, f_{2,d})$ . Check whether  $F_{K_1}(p[1..\text{len}]) = f_1$ . If not, output  $\perp$  and end the protocol. Otherwise, check whether  $\mathcal{E}_{\text{SKE}}.\text{Dec}(f_{2,i}, T_j) = \perp$  for any  $j \in \{\text{len} + 1, \dots, m\}$  and  $i \in \{1, \dots, d\}$ . If so, output  $\perp$  and end the protocol. If  $\text{ind} = 0$ , output  $\emptyset$ . Otherwise, choose a random permutation  $\pi_1 : [m] \rightarrow [m]$ . For  $i = 1, \dots, m$ , let  $x_{\pi_1(i)} = P_{K_3}(\text{ind} + i - 1)$ . The client sends  $(x_1, \dots, x_m)$  to the server.
4. The server sets  $C_i = C[x_i]$  for  $i = 1, \dots, m$  and sends  $(C_1, \dots, C_m)$  to the client.
5. For  $i = 1, \dots, m$ , the client runs  $Y \leftarrow \mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_{\pi_1(i)})$ . If  $Y = \perp$ , output  $\perp$  and end the protocol. Otherwise, let the result be  $(p'_i, j)$ . If  $j \neq \text{ind} + i - 1$ , output  $\perp$ . Otherwise, if  $p'_1 \dots p'_m \neq p$ , then the client outputs  $\emptyset$  as its answer and ends the protocol. Otherwise, the client chooses a random permutation  $\pi_2 : [\text{num}] \rightarrow [\text{num}]$ . For  $i = 1, \dots, \text{num}$ , let  $y_{\pi_2(i)} = P_{K_4}(\text{lpos} + i - 1)$ . The client sends  $(y_1, \dots, y_{\text{num}})$  to the server.
6. The server sets  $L_i = L[y_i]$  for  $i = 1, \dots, \text{num}$ , and sends  $(L_1, \dots, L_{\text{num}})$  to the client.
7. For  $i = 1, \dots, \text{num}$ , the client runs  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_L, L_{\pi_2(i)})$ . If the result is  $\perp$ , the client outputs  $\perp$  as its answer. Otherwise, let the result be  $(a_i, j)$ . If  $j \neq \text{lpos} + i - 1$ , output  $\perp$ . Otherwise, output the answer  $A = \{a_1, \dots, a_{\text{num}}\}$ .

## 4.4 Efficiency

In analyzing the efficiency of our construction, we will assume data is stored in computer words that hold  $\log n$  bits; therefore, we will treat values of size  $O(\log n)$  as constant size.

We assume encryption and decryption using  $\mathcal{E}_{\text{SKE}}$  take  $O(\lambda)$  time. Also we assume the dictionary is implemented in such a way that dictionary lookups take constant time (using hash tables, for example).

**Efficient batch implementation of PRFs.** Assuming the evaluation of a PRF takes time linear in the length of its input, in a naive implementation of our scheme, computing the PRFs  $f_1(u)$  and  $f_2(u)$  for all nodes  $u$  would take  $O(n^2)$ . This is because even though there are only at most  $2n$  nodes, the sum of the

lengths of the strings  $\hat{\rho}(u)$  associated with the nodes  $u$  can be  $O(n^2)$ . Similarly, computing the PRFs used for  $T_1, \dots, T_m$  would take  $O(m^2)$  time. It turns out that we can take advantage of the way the strings we are applying the PRFs to are related, to speed up the batch implementation of the PRFs for all of the nodes of the tree. We will use two tools: the polynomial hash, and suffix links (described below).

To compute the PRF of a string  $x$ , we will first hash  $x$  to  $\lambda$  bits using the polynomial hash, and then apply the PRF (which takes time  $O(\lambda)$  on the hashed input). To efficiently compute the hashes of all of the strings  $\hat{\rho}(u)$ , we use a trick that is used in the Rabin-Karp rolling hash (see Cormen et al. [CLRS09], e.g.). (A rolling hash is a hash function that can be computed efficiently on a sliding window of input; the hash of each window reuses computation from the previous window.) The Rabin-Karp hash is the polynomial hash, with each character of the string viewed as a coefficient of the polynomial applied to the random key of the hash. The key observation is that the polynomial hash  $H$  allows for constant-time computation of  $H_k(x_1 \dots x_n)$  from  $H_k(x_2 \dots x_n)$ , and also of  $H_k(x_1 \dots x_n)$  from  $H_k(x_1 \dots x_{n-1})$ . To see this, notice that  $H_k(x_1 \dots, x_n) = x_1 + k \cdot H_k(x_2 \dots x_n)$ , and  $H_k(x_1 \dots x_n) = H_k(x_1 \dots x_{n-1}) + x_n k^{n-1}$ .

Using this trick, for any string  $x$  of length  $\ell$ , we can compute the hashes  $H_k(x[1..i])$  for all  $i = 1, \dots, m$  in total time  $O(\lambda m)$ . Thus, the  $T_1, \dots, T_m$  can be computed in time  $O(\lambda m)$ .

To compute the hashes of  $\hat{\rho}(u)$  for all nodes  $u$  in time  $O(n)$ , we need one more trick. Many efficient suffix tree construction algorithms include *suffix links*: Each non-leaf node  $u$  with associated string  $\rho(u) = a||B$ , where  $a$  is a single character, has a pointer called a suffix link pointing to the node  $u'$  whose associated string  $\rho(u')$  is  $B$ . It turns out that connecting the nodes in a suffix tree using the suffix links forms another tree, in which the parent of a node  $u$  is the node  $u'$  to which  $u$ 's suffix link points. To see this, notice that each internal node has an outgoing suffix link, and each node's suffix link points to a node with a shorter associated string of one fewer character, so there can be no cycles.

Since  $\hat{\rho}(u) = \rho(\text{par}(u))||u_1$ , we can first compute the hashes of  $\rho(u)$  for all non-leaf nodes  $u$ , and then compute  $\hat{\rho}(u)$  for all nodes  $u$  in constant time from  $\rho(\text{par}(u))$ . To compute  $\rho(u)$  for all nodes  $u$ , we traverse the tree formed by the suffix links, starting at the root, and compute the hash of  $\rho(u)$  for each  $u$  using  $\rho(u')$ , where  $u'$  is  $u$ 's parent in the suffix link tree. Each of these computations takes constant time, since  $\rho(u)$  is the same as  $\rho(u')$  but with one character appended to the front. Therefore, computing the hashes of  $\rho(u)$  for all non-leaf nodes  $u$  (and thus, computing the hashes of  $\hat{\rho}(u)$  for all nodes  $u$ ) takes total time  $O(n)$ .

**Encryption efficiency.** Using the efficient batch implementation of PRFs suggested above, the PRFs  $f_1(u)$  and  $f_2(u)$  can be computed for all nodes  $u$  in the tree in total time  $O(\lambda n)$ . Therefore, the dictionary  $D$  of  $2n$  entries can be computed in total time  $O(\lambda n)$ . The arrays  $C$  and  $L$  each have  $n$  elements and can be computed in time  $O(\lambda n)$ . Therefore, encryption takes time  $O(\lambda n)$  and the ciphertext is of size  $O(\lambda n)$ .

**Query protocol efficiency.** In the query protocol, the client first computes  $T_1, \dots, T_m$ . Using the efficient batch PRF implementation above, computing the  $f_1^{(i)}$  and  $f_2^{(i)}$  for  $i = 1, \dots, m$  takes total time  $O(m)$ , and computing each  $\mathcal{E}_{\text{SKE}}.\text{Enc}(f_2^{(i)}, f_1^{(i)})$  takes  $O(\lambda)$  time, so the total time to compute  $T_1, \dots, T_m$  is  $O(\lambda m)$ .

To find  $W$ , the server performs at most  $md$  decryptions and dictionary lookups, which takes total time  $O(\lambda m)$ . The client then computes  $x_1, \dots, x_m$  and the server retrieves  $C[x_1], \dots, C[x_m]$ , in time  $O(m)$ . If the answer is not  $\emptyset$ , the client then computes  $y_1, \dots, y_{num}$  and the server retrieves  $L[y_1], \dots, L[y_{num}]$  in time  $O(num)$ , in time  $O(num)$ . Thus, both the client and the server take computation time  $O(\lambda m + num)$  in the query protocol. (Since we are computing an upper bound on the query computation time, we can ignore the possibility that the server cheats and the client aborts the protocol by outputting  $\perp$ .) The query protocol takes three rounds of communication, and the total size of the messages exchanged is  $O(\lambda m + num)$ .

## 4.5 Security

We first give some notation for the leakage of this scheme. We say that a query  $p$  visits a node  $u$  in the suffix tree  $Tree_s$  for  $s$  if  $\hat{\rho}(u)$  is a prefix of  $p$ . For any  $j$  let  $p_j$  denote the  $j$ th query, and let  $m_j = |p_j|$ . Let  $n_j$  denote the number of nodes visited by the query for  $p_j$  in  $s$ , let  $u_{j,i}$  denote the  $i$ th such node, and let  $len_{j,i} = |\hat{\rho}(u_{j,i})|$ . Let  $num_j$  denote the number of occurrences of  $p_j$  as a substring of  $s$ . Let  $ind_j$  denote the index  $ind$  in the ciphertext  $W$  returned by *AnswerQuery* for  $p_j$ . Note that  $ind_j$  is the index in  $s$  of the longest matching prefix of  $p_j$ , which is also the index in  $s$  of the longest prefix of  $p_j$  that is a substring of  $s$ . Let  $lpos_j$  denote the leaf index  $lpos$  in the ciphertext  $W$  returned by *AnswerQuery* for  $p_j$ . If  $p_j$  is a substring of  $s$ ,  $lpos_j$  is equal to the position (between 1 and  $n$ , from left to right) of the leftmost leaf  $\ell$  for which  $p_j$  is a prefix of  $\hat{\rho}(\ell)$ .

Briefly: The query prefix pattern QP for a query  $p_j$  tells which of the previous queries  $p_1, \dots, p_{j-1}$  visited each of the nodes visited by  $p_j$ . The index intersection pattern IP for a query  $p_j$  essentially tells when any of the indices  $ind_j, \dots, ind_j + m_j - 1$  are equal to or overlap with any of the indices  $ind_i, \dots, ind_i + m_i - 1$  for any previous queries  $p_i$ . The leaf intersection pattern LP for a query  $p_j$  essentially tells when any of the leaf positions  $lpos_j, \dots, lpos_j + num_j - 1$  are equal to or overlap with any of the leaf positions  $lpos_i, \dots, lpos_i + num_i - 1$  for any previous queries  $p_i$ .

The leakage of the scheme  $\mathcal{E}_{PM}$  is as follows.  $\mathcal{L}_1(s)$  is just  $n = |s|$ .  $\mathcal{L}_2(s, p_1, \dots, p_j)$  consists of

$$(m_j = |p_j|, \{len_{j,i}\}_{i=1}^{n_j}, \text{QP}(s, p_1, \dots, p_j), \text{IP}(s, p_1, \dots, p_j), \text{LP}(s, p_1, \dots, p_j)) .$$

For a more formal definition and an example of the leakage, see Appendix D.1.

**Security Theorems** See Appendix D.2 and C for proofs of the following theorems.

**Theorem 4.1.** *Let  $\mathcal{L}_1$  and  $\mathcal{L}_2$  be as defined above. If  $F$  is a PRF,  $P$  is a PRP, and  $\mathcal{E}_{SKE}$  is a CPA-secure, key-private symmetric-key encryption scheme, then the pattern matching encryption scheme  $\mathcal{E}_{PM}$  satisfies malicious  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security.*

**Theorem 4.2.** *If  $\mathcal{E}_{SKE}$  is an authenticated encryption then  $\mathcal{E}_{PM}$  is correct against malicious adversaries.*

## 5 Conclusion

We presented a definition of queryable encryption schemes and defined security against both honest-but-curious and malicious adversaries making chosen query attacks. Our security definitions are parameterized by leakage functions that specify the information that is revealed about the message and the queries by the ciphertext and the query protocols.

We constructed an efficient pattern matching scheme – a queryable encryption scheme that supports finding all occurrences of a pattern  $p$  in an encrypted string  $s$ . Our approach is based on suffix trees. Our construction uses only basic symmetric-key primitives (pseudorandom functions and permutations and an authenticated, which-key-concealing encryption scheme). The ciphertext size and encryption time are  $O(\lambda n)$  and query time and message size are  $O(\lambda m + k)$ , where  $\lambda$  is the security parameter,  $n$  is the length of the string,  $m$  is the length of the pattern, and  $k$  is the number of occurrences of the pattern. Querying requires only 3 rounds of communication.

While we have given a formal characterization of the leakage of our pattern matching scheme, it is an open problem to analyze the practical cost of the leakage. Given the leakage from several “typical” queries, what can a server infer about the message and the queries? For some applications, the efficiency may be worth the leakage tradeoff, especially in applications where current practice does not use encryption at all.

## A Suffix Tree Figures

The following figures illustrate suffix trees and the “first attempt” scheme described in the intuition for the main construction.

## B Notation and Primitives

### B.1 Basic Notation

We write  $x \stackrel{R}{\leftarrow} X$  to denote an element  $x$  being sampled uniformly at random from a finite set  $X$ , and  $x \leftarrow A$  to denote the output  $x$  of an algorithm  $A$ . We write  $x||y$  to refer to the concatenation of strings  $x$  and  $y$ , and

Figure 1: A suffix tree for the string  $s = \text{“cocoon”}$ . We will use the node labels  $u_1, \dots, u_9$  later to explain how the pattern matching encryption scheme works.

node	key	value
$u_1$	$F_{K_1}(\epsilon)$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 0)$
$u_2$	$F_{K_1}(\text{“co”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 1)$
$u_3$	$F_{K_1}(\text{“cocoon”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 1)$
$u_4$	$F_{K_1}(\text{“coon”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 3)$
$u_5$	$F_{K_1}(\text{“o”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 2)$
$u_6$	$F_{K_1}(\text{“ocoon”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 2)$
$u_7$	$F_{K_1}(\text{“oon”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 4)$
$u_8$	$F_{K_1}(\text{“on”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 5)$
$u_9$	$F_{K_1}(\text{“n”})$	$\mathcal{E}_{\text{SKE}}.Enc(K_D, 6)$

Figure 2: The dictionary composing the ciphertext for the string “cocoon” in the “first attempt” scheme. Note that the node identifiers  $u_1, \dots, u_9$  are not a part of the dictionary; they are provided for the purpose of cross-referencing with the suffix tree in Figure 1.

$|x|$  to refer to the length of a string  $x$ . If  $x = x_1 \dots x_n$  is a string of  $n$  characters, and  $a$  and  $b$  are integers,  $1 \leq a, b \leq n$ , then  $x[a..b]$  denotes the substring  $x_a x_{a+1} \dots x_b$ . We sometimes use  $\epsilon$  to denote the empty string. In other places  $\epsilon$  will be used to denote a quantity that is negligible in the security parameter; the intended meaning of  $\epsilon$  will be clear from context.

If  $T$  is a tuple of values with variable names  $(a, b, \dots)$ , then  $T.a, T.b, \dots$  refer to the values in the tuple. If  $n$  is a positive integer, we use  $[n]$  to denote the set  $\{1, \dots, n\}$ . If  $S$  is a set,  $\mathcal{P}(S)$  is the corresponding power set, i.e., the set of all subsets of  $S$ .

We use  $\lambda$  to refer to the security parameter, and we assume all algorithms implicitly take  $\lambda$  as input. A function  $\nu : \mathbb{N} \rightarrow \mathbb{N}$  is negligible in  $\lambda$  if for every positive polynomial  $p(\cdot)$  there exists an integer  $\lambda_p > 0$  such that for all  $\lambda > \lambda_p$ ,  $\nu(\lambda) < 1/p(\lambda)$ . We let  $\text{negl}(\lambda)$  denote an unspecified negligible function in  $\lambda$ .

Following standard GMR notation [GMR88], if  $p(\cdot, \dots)$  is a predicate, the notation  $\Pr[a \leftarrow A; b \leftarrow B; \dots : p(a, b, \dots)]$  denotes the probability that  $p(a, b, \dots)$  is true after  $a \leftarrow A, b \leftarrow B, \dots$  are executed in order. We write  $\mathcal{A}^{\mathcal{O}}$  to represent that algorithm  $\mathcal{A}$  can make oracle queries to algorithm  $\mathcal{O}$ . We will assume that adversaries are stateful algorithms; that is, an adversary  $\mathcal{A}$  maintains state across multiple invocations by implicitly taking its previous state as input and outputting its updated state.

If  $f$  is a function with domain  $D$ , and  $S \subseteq D$ , then  $f[S]$  denotes the image of  $S$  under  $f$ . If  $F : \mathcal{K} \times D \rightarrow R$  is a family of functions from  $D$  to  $R$ , where  $\mathcal{K}, D$ , and  $R$  are finite sets, we write  $F_K$  for the function defined by  $F_K(x) = F(K, x)$ .

## B.2 Pseudorandom Functions and Permutations

A pseudorandom function family (PRF) is a family  $F$  of functions such that no probabilistic polynomial-time (PPT) adversary can distinguish a function chosen randomly from  $F$  from a uniformly random function, except with negligible advantage.

**Definition B.1** (Pseudorandom Function Family). Let  $D$  and  $R$  be finite sets, and let  $F : \{0, 1\}^\lambda \times D \rightarrow R$  be a family of functions. Let  $\mathcal{R}$  denote the set of all possible functions  $Z : D \rightarrow R$ .  $F$  is a *pseudorandom function family (PRF)* if for all PPT adversaries  $A$ ,

$$|\Pr[K \xleftarrow{\mathcal{R}} \{0, 1\}^\lambda : \mathcal{A}^{F_K}(1^\lambda) = 1] - \Pr[Z \xleftarrow{\mathcal{R}} \mathcal{R} : \mathcal{A}^Z(1^\lambda) = 1]| \leq \text{negl}(\lambda) .$$

Similarly, a pseudorandom permutation family (PRP) is a family of functions such that no PPT adversary can distinguish a function randomly chosen from  $F$  and a uniformly random permutation, except with negligible advantage.

**Definition B.2** (Pseudorandom Permutation Family). Let  $D$  be a finite set, and let  $F : \{0, 1\}^\lambda \times D \rightarrow D$  be a family of functions. Let  $\mathcal{P}$  denote the set of all possible permutations (one-to-one, onto functions)  $P : D \rightarrow D$ .  $F$  is a *pseudorandom permutation family (PRP)* if for all PPT adversaries  $A$ ,

$$|\Pr[K \xleftarrow{\mathcal{R}} \{0, 1\}^\lambda : \mathcal{A}^{F_K}(1^\lambda) = 1] - \Pr[P \xleftarrow{\mathcal{R}} \mathcal{P} : \mathcal{A}^P(1^\lambda) = 1]| \leq \text{negl}(\lambda) .$$

## B.3 $\epsilon$ -Almost-Universal Hash Functions

An  $\epsilon$ -almost-universal hash function is a family  $\mathcal{H}$  of hash functions such that, for any pair of distinct messages, the probability of a hash collision when the hash function is chosen randomly from  $\mathcal{H}$  is at most  $\epsilon$ .

**Definition B.3** ( $\epsilon$ -Almost-Universal Hash Function). Let  $U$  and  $B$  be finite sets, and let  $H : \{0, 1\}^\lambda \times U \rightarrow B$  be a family of hash functions.  $H$  is  $\epsilon$ -almost-universal if for any  $x, x' \in U, x \neq x'$ ,

$$\Pr[t \xleftarrow{R} \{0, 1\}^\lambda : H_t(x) = H_t(x')] \leq \epsilon .$$

Let us look at an example of a known  $\epsilon$ -almost-universal hash construction, which we shall use later.

**Example B.4.** [Polynomial hash] We view a message  $x$  as a sequence  $(x_1, \dots, x_n)$  of  $\ell$ -bit strings. For any  $k$  in the finite field  $\text{GF}(2^\ell)$ , the hash function  $H_k(x)$  is defined as the evaluation of the polynomial  $p_x$  over  $\text{GF}(2^\ell)$  defined by coefficients  $x_1, \dots, x_n$ , at the point  $k$ . That is,  $H_k(x) = p_x(k) = \sum_{i=1}^n x_i k^{i-1}$ , where all operations are in  $\text{GF}(2^\ell)$ .

The hash function family defined above is  $\epsilon$ -almost-universal, for  $\epsilon = (n - 1)/2^\ell$ . To see this, suppose  $H_k(x) = H_k(x')$  for some  $x \neq x'$ . Then  $p_x(k) = p_{x'}(k)$ . This means  $p_{x-x'}(k) = \sum_{i=1}^n (x_i - x'_i)k^{i-1} = 0$ , where at least one of  $(x_i - x'_i)$  is not 0. Since  $p_{x-x'}(\cdot)$  is a non-zero polynomial of degree at most  $n - 1$ , it can have at most  $n - 1$  roots. The probability that a  $k$  chosen randomly from  $\text{GF}(2^\ell)$  will be one of the at most  $n - 1$  roots is at most  $(n - 1)/2^\ell$ .

## B.4 PRF Composed with Almost Universal Hashing

When computing a PRF on a long input, it can be more efficient to first hash the input down to a short string, and then apply the PRF to the hash output. If the hash function is  $\epsilon$ -almost-universal for some negligible  $\epsilon$ , then the resulting construction is still a PRF. This observation is due to Levin [Lev87] and is known sometimes as Levin's trick.

The following theorem says that a PRF composed with an  $\epsilon$ -almost-universal hash function, where  $\epsilon$  is negligible, gives another PRF. A proof of this theorem has been given previously in [Dod]; we include a version of that proof here, for completeness.

**Theorem B.5.** Let  $p$  be some polynomial. Let  $F : \{0, 1\}^\lambda \times B \rightarrow R$  be a PRF, and let  $H : \{0, 1\}^{p(\lambda)} \times U \rightarrow B$  be an  $\epsilon$ -almost-universal hash function for some  $\epsilon = \text{negl}(\lambda)$ . Then  $F(H) : \{0, 1\}^{\lambda+p(\lambda)} \times U \rightarrow R$ , defined by  $F_{K,t}(x) = F_K(H_t(x))$ , is a PRF.

*Proof.* Let  $\mathcal{A}$  be an adversary attacking the PRF property of  $F(H)$ . We wish to show that  $\mathcal{A}$ 's advantage in distinguishing  $F_K(H_t(\cdot))$  for random  $K, t$  from  $Z(\cdot)$ , where  $Z$  is a uniformly random function from  $U$  to  $R$ , is  $\text{negl}(\lambda)$ . To do so, we first argue that  $\mathcal{A}$ 's advantage in distinguishing  $F_K(H_t(\cdot))$  from  $Y(H_t(\cdot))$ , where  $Y$  is a uniformly random function from  $B$  to  $R$ , is  $\text{negl}(\lambda)$ . We then argue that  $\mathcal{A}$ 's advantage in distinguishing  $Y(H_t(\cdot))$  from  $Z(\cdot)$  is  $\text{negl}(\lambda)$ . Therefore,  $\mathcal{A}$ 's total advantage in distinguishing  $F_K(H_t(\cdot))$  from  $Z(\cdot)$  is  $\text{negl}(\lambda)$ .

By the PRF property of  $F$ , we immediately have that  $\mathcal{A}$ 's advantage in distinguishing  $F_K(H_t(\cdot))$  for a random  $K$  from  $Y(H_t(\cdot))$  is at most  $\text{negl}(\lambda)$ .

Next, to see that  $\mathcal{A}$  cannot distinguish  $Y(H_t(\cdot))$  for a random  $t$  from  $Z(\cdot)$ , let  $x_1, \dots, x_q$  be the queries  $\mathcal{A}$  makes to its oracle. (Without loss of generality, assume  $x_1, \dots, x_q$  are distinct.) If all of the hashes  $H_t(x_1), \dots, H_t(x_q)$  are distinct, then  $Y(H_t(\cdot))$  and  $Z(\cdot)$  will both output  $q$  uniformly random, independent values, so  $\mathcal{A}$  will not be able to distinguish the two functions.

Therefore,  $\mathcal{A}$ 's advantage in distinguishing  $Y(H_t(\cdot))$  from  $Z(\cdot)$  is at most the probability of a collision among  $H_t(x_1), \dots, H_t(x_q)$ . Let  $X$  denote the event that a collision occurs among  $H_t(x_1), \dots, H_t(x_q)$ . Since  $Y$  is a uniformly random function, each output of  $Y(H_t(\cdot))$  is a uniformly random, independent value (independent of the input and of  $t$ ), until and unless  $X$  occurs. Once  $X$  occurs, the subsequent outputs of

$Y(H_t(\cdot))$  do not affect the probability of  $X$ . Therefore, to analyze the probability of  $X$ , we can think of  $x_1, \dots, x_q$  as being chosen before and independently of  $t$ .

There are at most  $q^2$  pairs  $i < j$ , and by the  $\epsilon$ -almost universality of  $H$ , for each pair there is at most an  $\epsilon$  probability of a collision. Thus, the probability of  $X$  is at most  $q^2\epsilon$ , which is  $\text{negl}(p(\lambda)) = \text{negl}(\lambda)$ .

All together,  $\mathcal{A}$ 's distinguishing advantage is at most  $\text{negl}(\lambda)$ .  $\square$

## B.5 Symmetric-Key Encryption

**Definition B.6** (Symmetric-Key Encryption). A *symmetric* (or *symmetric-key*) *encryption scheme* consists of the following PPT algorithms.

**Gen**( $1^\lambda$ ): The key generation algorithm takes a security parameter  $\lambda$  and generates a secret key  $K$ .

**Enc**( $K, m$ ): The encryption algorithm takes a secret key  $K$  and a message  $m$  and returns a ciphertext  $c$ . Note that *Enc* will be randomized, but we omit the randomness as an explicit input.

**Dec**( $K, c$ ): The decryption algorithm is a deterministic algorithm that takes a secret key  $K$  and a ciphertext  $c$  and returns a message  $m$  or a special symbol  $\perp$ .

**Correctness.** For correctness, we require that for all  $\lambda$  and for all  $m$ , letting  $K \leftarrow \text{Gen}(1^\lambda)$ , we have  $\text{Dec}(K, \text{Enc}(K, m)) = m$ .

**CPA Security.** We require *indistinguishability under chosen-plaintext attacks* (*IND-CPA*), or *CPA security*, which is defined using the following game. First, the challenger runs  $\text{Gen}(1^\lambda)$  to generate a secret key  $K$ , which is kept hidden from the adversary. Next, the adversary is allowed to make any number of queries to an encryption oracle  $\text{Enc}(K, \cdot)$ . The adversary then outputs two equal-length challenge messages  $m_0$  and  $m_1$  and receives a challenge ciphertext equal to  $\text{Enc}(K, m_b)$  for a random choice of  $b \in \{0, 1\}$ . The adversary can make more queries to the encryption oracle. Finally, it outputs a guess  $b'$  of the bit  $b$ . The adversary wins the game if  $b' = b$ .

The adversary's advantage is the difference between the probability that it wins the game and  $1/2$  (from guessing randomly). CPA security says that no PPT adversary can win the above game with more than negligible advantage.

**Definition B.7** (CPA security). A symmetric encryption scheme  $(\text{Gen}, \text{Enc}, \text{Dec})$  is *CPA-secure* if for all PPT adversaries  $\mathcal{A}$ ,

$$|\Pr[K \leftarrow \text{Gen}(1^\lambda); (m_0, m_1) \leftarrow \mathcal{A}^{\text{Enc}(K, \cdot)}(1^\lambda); b \xleftarrow{\mathbb{R}} \{0, 1\}; c \leftarrow \text{Enc}(K, m_b); b' \leftarrow \mathcal{A}^{\text{Enc}(K, \cdot)}(c) : b' = b] - 1/2| \leq \text{negl}(\lambda) ,$$

where the two messages  $(m_0, m_1)$  output by  $\mathcal{A}$  must be of equal length.

**Which-Key Concealing.** We will also require symmetric encryption schemes to satisfy a property called *which-key concealing*. The which-key concealing property was introduced by Abadi and Rogaway [AR02] and (under the name “key hiding”) by Fischlin [Fis99].

The which-key-concealing requirement says, roughly, that an adversary cannot tell whether ciphertexts are encrypted under the same key or different keys. More formally, which-key concealing is defined via a game, in which the adversary tries to distinguish between the following two experiments. In one experiment,

$Gen(1^\lambda)$  is run twice, to generate two keys  $K$  and  $K'$ . The adversary is given a “left” oracle  $Enc(K, \cdot)$  and a “right” oracle  $Enc(K', \cdot)$ , to both of which it is allowed to make any number of queries. The adversary then outputs a bit. The other experiment is the same, except that only one key  $K$  is generated, and both of the left and right oracles output  $Enc(K, \cdot)$ . The adversary’s advantage is the difference between the probability that it outputs 1 in the two experiments. Which-key concealing says that no PPT adversary can win the above game with more than negligible advantage. Note that in order for an encryption scheme to be which-key-concealing, clearly it must be randomized.

**Definition B.8** (Which-Key Concealing). A symmetric encryption scheme  $(Gen, Enc, Dec)$  is *which-key-concealing* if for all PPT adversaries  $\mathcal{A}$ ,

$$\begin{aligned} & |\Pr[K \leftarrow Gen(1^\lambda); K' \leftarrow Gen(1^\lambda); \mathcal{A}^{Enc(K, \cdot), Enc(K', \cdot)}(1^\lambda) = 1] - \\ & \Pr[K \leftarrow Gen(1^\lambda); \mathcal{A}^{Enc(K, \cdot), Enc(K, \cdot)}(1^\lambda) = 1]| \leq \text{negl}(\lambda) . \end{aligned}$$

Let us now see an example of a symmetric encryption scheme that is CPA-secure and which-key-concealing.

**Example B.9** ( $\mathcal{E}_{\text{xor}}$ ). Let  $p$  be a polynomial, and let  $F : \{0, 1\}^\lambda \times \{0, 1\}^\lambda \rightarrow \{0, 1\}^{p(\lambda)}$  be a PRF. The encryption scheme  $\mathcal{E}_{\text{xor}}$  for message space  $\mathcal{M} = \{0, 1\}^{p(\lambda)}$  is defined as follows.

**Gen**( $1^\lambda$ ): Let  $K \xleftarrow{\mathbb{R}} \{0, 1\}^\lambda$  be the secret key.

**Enc**( $K, m$ ): Let  $r \xleftarrow{\mathbb{R}} \{0, 1\}^\lambda$ , and output  $c = (r, F_K(r) \oplus m)$ .

**Dec**( $K, c$ ): Let  $c = (r, x)$ . Output  $m = x \oplus F_K(r)$ .

Bellare et al. [BDJR97] proved that the above scheme is CPA-secure:

**Theorem B.10.** [BDJR97] *If  $F$  is a PRF, then  $\mathcal{E}_{\text{xor}}$  is CPA-secure.*

We will prove that  $\mathcal{E}_{\text{xor}}$  is which-key-concealing.

**Theorem B.11.** *If  $F$  is a PRF, then  $\mathcal{E}_{\text{xor}}$  is which-key-concealing.*

*Proof.* Let  $\mathcal{A}$  be an adversary playing the which-key-concealing game.

We first replace  $\mathcal{E}_{\text{xor}}$  in the which-key-concealing game with a modified scheme  $\mathcal{E}'_{\text{xor}}$ .  $\mathcal{E}'_{\text{xor}}$  is the same as  $\mathcal{E}_{\text{xor}}$ , except that  $F_K$  is replaced with a uniformly random function  $R : \{0, 1\}^\lambda \rightarrow \{0, 1\}^{p(\lambda)}$ . By the PRF property of  $F$ , replacing  $\mathcal{E}_{\text{xor}}$  with  $\mathcal{E}'_{\text{xor}}$  can change  $\mathcal{A}$ ’s advantage in the which-key-concealing game by at most a negligible quantity.

So, suppose  $\mathcal{A}$  is playing the which-key-concealing game for  $\mathcal{E}'_{\text{xor}}$ . Suppose  $\mathcal{A}$  makes a total of  $q$  queries,  $m_1, \dots, m_q$ , to its encryption oracles, where each  $m_i$  is a query to either the left or the right oracle. Let  $(r_i, x_i)$  denote the answer to the  $i$ th query, and let  $y_i = x_i \oplus m_i$ .

If there are any  $i$  and  $j$  such that  $r_i = r_j$  and  $m_i$  is a query to the left oracle while  $m_j$  is a query to the right oracle, then  $\mathcal{A}$  will be able to distinguish whether the two oracles use the same key based on whether  $y_i = y_j$ . However, if all of  $r_1, \dots, r_q$  are distinct, then for any key the encryption algorithm will choose each  $y_i$  as a uniformly random, independent value, so  $\mathcal{A}$  will gain no information about which experiment it is in and can do no better than a random guess.

Thus,  $\mathcal{A}$ ’s advantage in winning the which-key-concealing game for  $\mathcal{E}'_{\text{xor}}$  is at most the probability that any of  $r_1, \dots, r_q$  are equal, which is upper bounded by  $q^2/2^\lambda$ . Combining this with the negligible difference in  $\mathcal{A}$ ’s advantage against  $\mathcal{E}'_{\text{xor}}$  and against  $\mathcal{E}_{\text{xor}}$ , we have that  $\mathcal{A}$ ’s advantage in winning the which-key-concealing game for  $\mathcal{E}_{\text{xor}}$  is negligible.  $\square$

**Ciphertext integrity and authenticated encryption.** We will also sometimes require a symmetric encryption scheme to have a property called *ciphertext integrity*. The notions of ciphertext integrity and *authenticated encryption* (defined below) were introduced by [BR00, KY01, BN00]. Ciphertext integrity says, roughly, that an adversary given encryptions of messages of its choice cannot construct any new ciphertexts that decrypt successfully (i.e., decrypt to a value other than  $\perp$ ).

Formally, ciphertext integrity is defined using the following game. First, the challenger runs  $Gen(1^\lambda)$  to generate a secret key  $K$ , which is kept hidden from the adversary. The adversary then adaptively makes a polynomial number of queries,  $m_1, \dots, m_q$ . To each query  $m_i$  the challenger responds by sending  $c_i \leftarrow Enc(K, m_i)$  to the adversary. Finally, the adversary outputs a value  $c$ . The adversary wins the game if  $c$  is not among the previously received ciphertexts  $\{c_1, \dots, c_q\}$  and  $Dec(K, c) \neq \perp$ .

We define the advantage of an adversary  $\mathcal{A}$  in attacking the ciphertext integrity of a symmetric encryption scheme as the probability that  $\mathcal{A}$  wins the above game.

**Definition B.12** (Ciphertext integrity). A symmetric encryption scheme  $(Gen, Enc, Dec)$  has ciphertext integrity if for all PPT adversaries  $\mathcal{A}$ ,  $\mathcal{A}$ 's advantage in the above game is at most  $\text{negl}(\lambda)$ .

**Definition B.13** (Authenticated encryption). A symmetric encryption scheme is an *authenticated encryption scheme* if it has CPA security and ciphertext integrity.

Let us now see an example of an authenticated encryption scheme. One way to construct an authenticated encryption scheme is “encrypt-then-MAC” [BN00]. (A MAC is a message authentication code, the details of which we do not give here; instead, we will just use the fact that a PRF defines a secure MAC.) Using encrypt-then-MAC, one first encrypts a message  $m$  with a CPA-secure scheme to get a ciphertext  $c'$ , and then computes a MAC of  $c'$  to get a tag  $t$ . The ciphertext is then  $c = (c', t)$ . The decryption algorithm verifies that  $t$  is a valid tag for  $c'$  and then decrypts  $c'$  using the CPA-secure scheme. In the following example, we apply encrypt-then-MAC to  $\mathcal{E}_{\text{xor}}$  to obtain an authenticated encryption scheme  $\mathcal{E}_{\text{xor-auth}}$  (which, like  $\mathcal{E}_{\text{xor}}$ , is also which-key-concealing).

**Example B.14** ( $\mathcal{E}_{\text{xor-auth}}$ ). Let  $p$  be a polynomial, and let  $F : \{0, 1\}^\lambda \times \{0, 1\}^\lambda \rightarrow \{0, 1\}^{p(\lambda)}$  and  $G : \{0, 1\}^\lambda \times \{0, 1\}^{\lambda+p(\lambda)} \rightarrow \{0, 1\}^\lambda$  be PRFs. The encryption scheme  $\mathcal{E}_{\text{xor-auth}}$  for message space  $\mathcal{M} = \{0, 1\}^{p(\lambda)}$  is defined as follows.

**Gen**( $1^\lambda$ ): Choose  $K_1, K_2 \xleftarrow{R} \{0, 1\}^\lambda$  and let  $K = (K_1, K_2)$  be the secret key.

**Enc**( $K, m$ ): Let  $r \xleftarrow{R} \{0, 1\}^\lambda$ , and output  $c = (r, x = F_{K_1}(r) \oplus m, t = G_{K_2}(r||x))$ .

**Dec**( $K, c$ ): Let  $c = (r, x, t)$ . If  $t \neq G_{K_2}(r||x)$ , output  $\perp$ . Otherwise, output  $m = x \oplus F_{K_1}(r)$ .

**Theorem B.15.**  $\mathcal{E}_{\text{xor-auth}}$  is an authenticated encryption scheme.

*Proof.* The theorem follows directly from the following facts: (1)  $G$  is a PRF and therefore defines a MAC, (2)  $\mathcal{E}_{\text{xor}}$  is CPA-secure, and (3) applying encrypt-then-MAC to a CPA-secure scheme gives an authenticated encryption scheme [BN00].  $\square$

$\mathcal{E}_{\text{xor-auth}}$  also retains the which-key-concealing property of  $\mathcal{E}_{\text{xor}}$ .

**Theorem B.16.**  $\mathcal{E}_{\text{xor-auth}}$  is which-key-concealing.

*Proof.* The proof is very similar to the which-key-concealing proof for  $\mathcal{E}_{\text{xor}}$ . We first replace  $\mathcal{E}_{\text{xor-auth}}$  with a modified scheme  $\mathcal{E}'_{\text{xor-auth}}$  in which  $F$  and  $G$  are replaced with random functions  $R_1$  and  $R_2$ , respectively. By the PRF property of  $F$  and  $G$ , this changes  $\mathcal{A}$ 's advantage in winning the which-key-concealing game by at most a negligible quantity. Now, suppose  $\mathcal{A}$  makes  $q$  encryption queries,  $m_1, \dots, m_q$ . Let  $(r_i, x_i, t_i)$  denote the response to the  $i$ th query, and let  $y_i = x_i \oplus m_i$ . If all of  $r_1, \dots, r_q$  are distinct and all of  $r_1 || x_1, \dots, r_q || x_q$  are distinct, then for any key the encryption algorithm will choose all of the  $y_i$  and  $t_i$  as uniformly random, independent values, so  $\mathcal{A}$  will gain no information about which experiment it is in. But if all of the  $r_i$  are distinct, then so are all of the  $r_i || x_i$ . Therefore,  $\mathcal{A}$ 's advantage against  $\mathcal{E}'_{\text{xor-auth}}$  is at most the probability that any of the  $r_i$  are equal, which is upper bounded by  $q^2/2^\lambda$ . All together,  $\mathcal{A}$ 's advantage against  $\mathcal{E}_{\text{xor-auth}}$  is negligible.  $\square$

## C Correctness Against Malicious Adversaries

We will show that  $\mathcal{E}_{\text{PM}}$  is correct against malicious adversaries.

**Theorem C.1.** *If  $\mathcal{E}_{\text{SKE}}$  is an authenticated encryption scheme, then  $\mathcal{E}_{\text{PM}}$  is correct against malicious adversaries.*

*Proof.* It is fairly straightforward to see that if the adversary executes *AnswerQuery* honestly, then the client's output will be correct.

We will argue that for each of the places where  $\mathcal{A}$  could output an incorrect value, the client will detect  $\mathcal{A}$ 's cheating and output  $\perp$ , with all but negligible probability.

**Lemma C.2.** *If  $\mathcal{E}_{\text{SKE}}$  is an authenticated encryption scheme, then if an adversary  $\mathcal{A}$  outputs an incorrect  $W$  in the query protocol, the client's response to  $W$  will be  $\perp$ , with all but negligible probability.*

*Proof.* In the protocol for a query  $p$ , the client runs  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W)$  to get either  $\perp$  or a tuple  $X$ , which it parses as  $(ind, lpos, num, len, f_1, f_{2,1}, \dots, f_{2,d})$ . The client outputs  $\perp$  if any of the following events occur:

- (Event  $W.1$ )  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W) = \perp$ , or
- (Event  $W.2$ )  $W$  decrypts successfully, but  $f_1 \neq F_{K_1}(p[1..len])$ , or
- (Event  $W.3$ )  $W$  decrypts successfully and  $f_1 = F_{K_1}(p[1..len])$ , but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(f_{2,i}, T_j) \neq \perp$  for some  $i \in \{1, \dots, d\}, j > len$ .

On the other hand, if the adversary cheats, then  $W$  is not the ciphertext in the dictionary entry  $D(F_{K_1}(p[1..i]))$ , where  $p[1..i]$  is the longest matching prefix of  $p$ , which means one of the following events:

- (Event  $W.1'$ )  $W$  is not a ciphertext in  $D$ ,
- (Event  $W.2'$ )  $W$  is a ciphertext in  $D$  but not for any prefix of  $p$ . That is,  $W = D(\kappa)$  where  $\kappa$  is not equal to  $F_{K_1}(p[1..i])$  for any  $i$ .
- (Event  $W.3'$ )  $W$  is a ciphertext in  $D$  for a prefix of  $p$ , but there is a longer matching prefix of  $p$ . That is,  $W = D(F_{K_1}(p[1..i]))$  for some  $i$ , but there exists a  $j > i$  such that there is an entry  $D(F_{K_1}(p[1..j]))$ .

We want to show that if the adversary cheats, then the client will output  $\perp$ .

If event  $W.1'$  occurs, then we will show below that  $W.1$  occurs with all but negligible probability, by the ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .

If event  $W.2'$  occurs, then event  $W.2$  occurs with all but negligible probability upper bounded by  $1/2^\lambda$ , the probability that  $F_{K_1}(p[1..len]) = f_1$  when  $f_1$  is an independent, random value.

If event  $W.3'$  occurs, then clearly  $W.3$  also occurs.

It remains to show that event  $W.1'$  implies event  $W.1$  with all but negligible probability.

Suppose an adversary  $\mathcal{A}$  causes event  $W.1'$  but not event  $W.1$ . Then the  $W$  output by  $\mathcal{A}$  is not among the ciphertexts in the dictionary, but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W) \neq \perp$ . Then we can use  $\mathcal{A}$  to construct an algorithm  $\mathcal{B}$  that breaks ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ . Algorithm  $\mathcal{B}$  executes  $\mathcal{E}_{\text{PM}}$  honestly, except that in the encryption algorithm, instead of generating each  $W_u$  as  $\mathcal{E}_{\text{SKE}}.\text{Enc}(K_D, X_u)$ , it queries its encryption oracle on  $X_u$  and uses the resulting ciphertext as  $c_j$ . Then, when  $\mathcal{A}$  outputs  $W$ ,  $\mathcal{B}$  outputs  $W$  in the ciphertext integrity game. Note that  $\mathcal{A}$ 's view is the same as when it is interacting with the real scheme  $\mathcal{E}_{\text{PM}}$ . If  $W$  is not among the ciphertexts in  $D$ , but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W) \neq \perp$ , then  $\mathcal{B}$  wins the ciphertext integrity game. Therefore, if  $\mathcal{A}$  has probability  $\epsilon$  of causing event  $W.1'$  but not event  $W.1$ ,  $\mathcal{B}$  wins the ciphertext integrity game with the same probability  $\epsilon$ .  $\square$

**Lemma C.3.** *If  $\mathcal{E}_{\text{SKE}}$  is an authenticated encryption scheme, then if an adversary  $\mathcal{A}$  outputs incorrect  $C_1, \dots, C_m$  in the query protocol, the client's response to  $C_1, \dots, C_m$  will be  $\perp$ , with all but negligible probability.*

*Proof.* In the query protocol, for each  $i$ , the client outputs  $\perp$  if either of the following events occur:

- (Event  $C.1$ )  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) = \perp$ , or
- (Event  $C.2$ )  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) = (p'_j, j)$  where  $j$  is not the correct index.

On the other hand, if the adversary cheats and outputs incorrect  $C_1, \dots, C_m$ , then for some  $i$ ,  $C_i \neq C[x_i]$ , which means either of the following events:

- (Event  $C.1'$ )  $C_i$  is not among  $C[1], \dots, C[n]$ , or
- (Event  $C.2'$ )  $C_i = C[k]$  where  $k \neq x_i$ .

We want to show that if the adversary cheats, then the client will output  $\perp$ .

For any  $i$ , if event  $C.1'$  occurs, then we will show below that event  $C.1$  occurs with all but negligible probability, by the ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .

If event  $C.2'$  occurs, then event  $C.2$  occurs, since if  $C_i = C[k]$  for some  $k \neq x_i$ ,  $C_i$  will decrypt to  $(s_j, j)$  for an incorrect index  $j$ .

It remains to show that for any  $i$  event  $C.1'$  implies event  $C.1$ , with all but negligible probability. Suppose an adversary  $\mathcal{A}$  causes event  $C.1'$  but not event  $C.1$ . Then  $C_i$  is not among  $C[1], \dots, C[n]$ , but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) \neq \perp$ . Then we can use  $\mathcal{A}$  to construct an algorithm  $\mathcal{B}$  that breaks ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .  $\mathcal{B}$  executes  $\mathcal{E}_{\text{PM}}$  honestly, except that in the encryption algorithm, instead of generating each  $c_j$  as  $\mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (s_j, j))$ , it queries its encryption oracle on  $(s_j, j)$  and uses the resulting ciphertext as  $c_j$ . Then, when  $\mathcal{A}$  outputs  $C_1, \dots, C_m$ ,  $\mathcal{B}$  chooses a random  $i' \xleftarrow{R} \{1, \dots, m\}$  and outputs  $C_{i'}$  in the ciphertext integrity game. Note that  $\mathcal{A}$ 's view is the same as when it is interacting with the real scheme  $\mathcal{E}_{\text{PM}}$ . If  $C_i$  is not among  $C[1], \dots, C[n]$ , but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) \neq \perp$ , then  $\mathcal{B}$  wins the ciphertext integrity game if  $i' = i$ . Therefore, if  $\mathcal{A}$  has probability  $\epsilon$  of causing event  $C.1'$  but not event  $C.1$  for any  $i$ ,  $\mathcal{B}$  wins the ciphertext integrity game with probability at least  $\epsilon/m$ .  $\square$

**Lemma C.4.** *If  $\mathcal{E}_{\text{SKE}}$  is an authenticated encryption scheme, then if an adversary  $\mathcal{A}$  outputs incorrect  $L_1, \dots, L_{num}$  in the query protocol, the client's response to  $L_1, \dots, L_{num}$  will be  $\perp$ , with all but negligible probability.*

The proof is omitted, since it is almost identical to the proof of Lemma C.3.

We have shown that if an adversary  $\mathcal{A}$  cheats when producing any of its outputs to the client, the client will output  $\perp$  with all but negligible probability. Therefore,  $\mathcal{E}_{\text{PM}}$  is correct against malicious adversaries.  $\square$

## D Security

We now prove that our pattern matching encryption scheme satisfies malicious- $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security for certain leakage functions  $\mathcal{L}_1$  and  $\mathcal{L}_2$ .

### D.1 Leakage

Before we describe the leakage of our scheme, we define some relevant notions.

We say that a query  $p$  visits a node  $u$  in the suffix tree  $Tree_s$  for  $s$  if  $\hat{\rho}(u)$  is a prefix of  $p$ . For any  $j$  let  $p_j$  denote the  $j$ th query, and let  $m_j = |p_j|$ . Let  $n_j$  denote the number of nodes visited by the query for  $p_j$  in  $s$ , let  $u_{j,i}$  denote the  $i$ th such node, and let  $len_{j,i} = |\hat{\rho}(u_{j,i})|$ . Let  $num_j$  denote the number of occurrences of  $p_j$  as a substring of  $s$ . Let  $ind_j$  denote the index  $ind$  in the ciphertext  $W$  returned by  $AnswerQuery$  for  $p_j$ . Note that  $ind_j$  is the index in  $s$  of the longest matching prefix of  $p_j$ , which is also the index in  $s$  of the longest prefix of  $p_j$  that is a substring of  $s$ . Let  $lpos_j$  denote the leaf index  $lpos$  in the ciphertext  $W$  returned by  $AnswerQuery$  for  $p_j$ . If  $p_j$  is a substring of  $s$ ,  $lpos_j$  is equal to the position (between 1 and  $n$ , from left to right) of the leftmost leaf  $\ell$  for which  $p_j$  is a prefix of  $\hat{\rho}(\ell)$ .

The query prefix pattern for a query  $p_j$  tells which of the previous queries  $p_1, \dots, p_{j-1}$  visited each of the nodes visited by  $p_j$ .

**Definition D.1** (Query prefix pattern). The *query prefix pattern*  $\text{QP}(s, p_1, \dots, p_j)$  is a sequence of length  $n_j$ , where the  $i$ th element is a list  $list_i$  of indices  $j' < j$  such that the  $j'$ th query also visited  $u_{j,i}$ .

The index intersection pattern for a query  $p_j$  essentially tells when any of the indices  $ind_j, \dots, ind_j + m_j - 1$  are equal to or overlap with any of the indices  $ind_i, \dots, ind_i + m_i - 1$  for any previous queries  $p_i$ .

**Definition D.2** (Index intersection pattern). The *index intersection pattern*  $\text{IP}(s, p_1, \dots, p_j)$  is a sequence of length  $j$ , where the  $i$ th element is equal to  $r_1[\{ind_i, \dots, ind_i + m_i - 1\}]$  for a fixed random permutation  $r_1 : [n] \rightarrow [n]$ .

The leaf intersection pattern for a query  $p_j$  essentially tells when any of the leaf positions  $lpos_j, \dots, lpos_j + num_j - 1$  are equal to or overlap with any of the leaf positions  $lpos_i, \dots, lpos_i + num_i - 1$  for any previous queries  $p_i$ .

**Definition D.3** (Leaf intersection pattern). The *leaf intersection pattern*  $\text{LP}(s, p_1, \dots, p_j)$  is a sequence of length  $j$ , where the  $i$ th element is equal to  $r_2[\{lpos_i, \dots, lpos_i + num_i - 1\}]$  for a fixed random permutation  $r_2 : [n] \rightarrow [n]$ .

The leakage of the scheme  $\mathcal{E}_{\text{PM}}$  is as follows.  $\mathcal{L}_1(s)$  is just  $n = |s|$ .  $\mathcal{L}_2(s, p_1, \dots, p_j)$  consists of

$$(m_j = |p_j|, \{len_{j,i}\}_{i=1}^{n_j}, \text{QP}(s, p_1, \dots, p_j), \text{IP}(s, p_1, \dots, p_j), \text{LP}(s, p_1, \dots, p_j)) .$$

For example, consider the string  $s$  “cocoon” (whose suffix tree is shown in Figure 1) and a sequence of three queries,  $p_1 = \text{“co”}$ ,  $p_2 = \text{“coco”}$ , and  $p_3 = \text{“cocoa”}$ . Then the leakage  $\mathcal{L}_1(s)$  is  $n = 6$ .

The query for “co” visits node  $u_2$ , the retrieved indices into  $s$  are 1, 2, and the retrieved leaf positions are 1, 2. The query for “coco” visits nodes  $u_2$  and  $u_3$ , the indices retrieved are 1, 2, 3, 4, and the leaf positions retrieved are 1. The query for “cocoa” visits nodes  $u_2$  and  $u_3$ , the indices retrieved are 1, 2, 3, 4, 5, and no leaf positions are retrieved (because there is not a match).

Thus, the leakage  $\mathcal{L}_2(s, p_1, p_2, p_3)$  consists of:

- the lengths 2, 4, 5 of the patterns,
- the query prefix pattern, which says that  $p_1, p_2, p_3$  visited the same first node, and then  $p_2$  and  $p_3$  visited the same second node,
- the index intersection pattern, which says that two of the indices returned for  $p_2$  are the same as the two indices returned for  $p_1$ , and four of the indices returned for  $p_3$  are the same as the four indices returned for  $p_2$ , and
- the leaf intersection pattern, which says that the leaf returned for  $p_2$  is one of the two leaves returned for  $p_1$ .

## D.2 Malicious $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 Security

**Theorem D.4.** *Let  $\mathcal{L}_1$  and  $\mathcal{L}_2$  be defined as in Section D.1. If  $F$  is a PRF,  $P$  is a PRP, and  $\mathcal{E}_{\text{SKE}}$  is a CPA-secure, key-private symmetric-key encryption scheme, then the pattern matching encryption scheme  $\mathcal{E}_{\text{PM}}$  satisfies malicious  $(\mathcal{L}_1, \mathcal{L}_2)$ -CQA2 security.*

*Proof.* We define a simulator  $\mathcal{S}$  that works as follows.  $\mathcal{S}$  first chooses random keys  $K_D, K_C, K_L \xleftarrow{\text{R}} \{0, 1\}^\lambda$ .

**Ciphertext.** Given  $\mathcal{L}_1(s) = n$ ,  $\mathcal{S}$  constructs a simulated ciphertext as follows.

1. Construct a dictionary  $D$  as follows. For  $i = 1, \dots, 2n$ , choose fresh random values  $\kappa_i, f_{2,1}, \dots, f_{2,d} \xleftarrow{\text{R}} \{0, 1\}^\lambda$ , and store  $V_i = (f_{2,1}, \dots, f_{2,d}, W = \mathcal{E}_{\text{SKE}}.Enc(K_D, 0))$  with search key  $\kappa_i$  in  $D$ .
2. Choose an arbitrary element  $\sigma_0 \in \Sigma$ . Construct an array  $C$ , where  $C[i] = \mathcal{E}_{\text{SKE}}.Enc(K_C, (\sigma_0, 0))$  for  $i = 1, \dots, n$ .
3. Construct an array  $L$ , where  $L[i] = \mathcal{E}_{\text{SKE}}.Enc(K_L, 0)$  for  $i = 1, \dots, n$ .

Output  $CT = (D, C, L)$ .

**Tables.** In order to simulate the query protocol,  $\mathcal{S}$  will need to do some bookkeeping.

$\mathcal{S}$  will maintain two tables  $\mathcal{T}_1$  and  $\mathcal{T}_2$ , both initially empty.  $\mathcal{T}_1$  contains all currently defined tuples  $(i, j, \kappa)$  such that the entry in  $D$  with search key  $\kappa$  represents the  $j$ th node visited by the  $i$ th query. We write  $\mathcal{T}_1(i, j) = \kappa$  if  $(i, j, \kappa)$  is an entry in  $\mathcal{T}_1$ .

$\mathcal{T}_2$  contains all currently defined tuples  $(\kappa, f_2, flag, flag_1, \dots, flag_d)$ , where for the node  $u$  represented by the entry  $D(\kappa)$ ,  $\kappa = f_1(u)$ ,  $f_2 = f_2(u)$ ,  $flag$  indicates whether  $u$  has been visited by any query, and  $flag_i$  indicates whether  $\text{child}(u, \pi_u(i))$  has been visited. The value of each flag is either “visited” or “unvisited”. We write  $\mathcal{T}_2(\kappa) = (f_2, flag, flag_1, \dots, flag_d)$  if  $(\kappa, f_2, flag, flag_1, \dots, flag_d)$  is an entry in  $\mathcal{T}_2$ .

Choose an arbitrary entry  $(\kappa^*, V^*)$  in  $D$  to represent the root node of  $Tree_s$ . In  $\mathcal{T}_2(\kappa)$ , set all flags to “unvisited” and set  $f_2 = 0$ . (The  $f_2$  for the root node will never be used, so it is fine to set it to 0.) Define  $\mathcal{T}_1(i, 0) = \kappa^*$  for any  $i$ .

**Query protocols.** For the  $j$ th token query  $p_j$ ,  $\mathcal{S}$  is given  $\mathcal{L}_2(s, p_1, \dots, p_j)$ , which consists of  $m_j = |p_j|$ ,  $\{len_{j,i}\}_{i=1}^{n_j}$ ,  $\text{QP}(s, p_1, \dots, p_j)$ ,  $\text{IP}(s, p_1, \dots, p_j)$ , and  $\text{LP}(s, p_1, \dots, p_j)$ .

For  $t = 1, \dots, n_j$ , if  $list_t = \text{QP}(p_j, s)[t]$  is non-empty (i.e., the node  $u_{j,t}$  was visited by a previous query), let  $j'$  be one of the indices in  $list_t$ . Let  $\kappa = \mathcal{T}_1(j', t)$  and let  $(f_2, flag, flag_1, \dots, flag_d) = \mathcal{T}_2(\kappa)$ .  $T_{len_{j,t}} = \mathcal{E}_{\text{SKE}}.Enc(f_2, \kappa)$ . Set  $\mathcal{T}_1(j, t) = \kappa$ .

If instead  $list_t$  is empty, choose a random unused entry  $(\kappa, V)$  in  $D$  to represent the node  $u_{j,t}$ , and set  $\mathcal{T}_1(j, t) = \kappa$ . Let  $\kappa' = \mathcal{T}_1(j, t-1)$  and let  $(f_2, flag, flag_1, \dots, flag_d) = \mathcal{T}_2(\kappa')$ . Choose a random  $i \in \{1, \dots, d\}$  such that  $flag_i$  is “unvisited”, and set  $flag_i$  to “visited”. Let  $f_{2,i}$  be  $D(\kappa').f_{2,i}$ . Set  $T_{len_t} = \mathcal{E}_{\text{SKE}}.Enc(f_{2,i}, \kappa)$ , set  $\mathcal{T}_2(\kappa).f_2 = f_{2,i}$ , set  $\mathcal{T}_2(\kappa).flag$  to “visited”, and set  $\mathcal{T}_2(\kappa).flag_i$  to “unvisited” for  $i = 1, \dots, d$ .

For any  $i \neq len_t$  for any  $t = 1, \dots, n_j$ , choose a random  $f_2 \xleftarrow{R} \{0, 1\}^\lambda$ , and let  $T_i = \mathcal{E}_{\text{SKE}}.Enc(f_2, 0)$ .

Send  $(T_1, \dots, T_m)$  to the adversary.

Upon receiving a  $W$  from the adversary, check whether  $W = D(\mathcal{T}_1(j, n_j)).W$ . If not, output  $\perp$ . Otherwise, let  $(x_1, \dots, x_m)$  be a random ordering of the elements of the set  $\text{IP}(p_j, s)[j]$ , and send  $(x_1, \dots, x_m)$  to the adversary.

Upon receiving  $C_1, \dots, C_m$  from the adversary, check whether  $C_i = C[x_i]$  for each  $i$ . If not, output  $\perp$ . Otherwise, let  $(y_1, \dots, y_{num})$  be a random ordering of the elements of  $\text{LP}(p_j, s)[j]$ , and send  $(y_1, \dots, y_{num})$  to the adversary.

Upon receiving  $L_1, \dots, L_{num}$  from the adversary, check whether  $L_i = L[y_i]$  for each  $i$ . If not, output  $\perp$ .

This concludes the description of the simulator  $\mathcal{S}$ .

**Sequence of games.** We now show that the real and ideal experiments are indistinguishable by any PPT adversary  $\mathcal{A}$  except with negligible probability. To do this, we consider a sequence of games  $G_0, \dots, G_{16}$  that gradually transform the real experiment into the ideal experiment. We will show that each game is indistinguishable from the previous one, except with negligible probability.

**Game  $G_0$ .** This game corresponds to an execution of the real experiment, namely,

- The challenger begins by running  $Gen(1^\lambda)$  to generate a key  $K$ .
- The adversary  $\mathcal{A}$  outputs a string  $s$  and receives  $CT \leftarrow Enc(K, s)$  from the challenger.
- $\mathcal{A}$  adaptively chooses patterns  $p_1, \dots, p_q$ . For each  $p_i$ ,  $\mathcal{A}$  first interacts with the challenger, who is running  $IssueQuery(K, p_i)$  honestly. Then  $\mathcal{A}$  outputs a description of a function  $g_i$ , and receives  $g_i(A_1, \dots, A_i)$  from the challenger, where  $A_i$  is the challenger’s private output from the interactive protocol for  $p_i$ .

**Game  $G_1$ .** This game is the same as  $G_0$ , except that in  $G_1$  the challenger is replaced by a simulator that does not generate keys  $K_1, K_2$  and replaces  $F_{K_1}$  and  $F_{K_2}$  with random functions. Specifically, the simulator maintains tables  $R_1, R_2$ , initially empty. Whenever the challenger in  $G_0$  computes  $F_{K_i}(x)$  for some  $x$ , the simulator uses  $R_i(x)$  if it is defined; otherwise, it chooses a random value from  $\{0, 1\}^\lambda$ , stores it as  $R_i(x)$ , and uses that value.

A hybrid argument shows that  $G_1$  is indistinguishable from  $G_0$  by the PRF property of  $F$ .

**Lemma D.5.** *If  $F$  is a PRF, then  $G_0$  and  $G_1$  are indistinguishable, except with negligible probability.*

*Proof.* We consider a hybrid game  $H_1$ .  $H_1$  is the same as  $G_0$  except that it uses  $R_1$  in place of  $F_{K_1}$ .

Suppose an adversary  $\mathcal{A}$  can distinguish  $G_0$  from  $H_1$ . Then we can construct an algorithm  $\mathcal{B}$  that attacks the PRF property of  $F$  with the same advantage.  $\mathcal{B}$  acts as  $\mathcal{A}$ 's challenger in  $G_0$ , except that whenever there is a call to  $F_{K_1}(x)$ ,  $\mathcal{B}$  queries its oracle on  $x$ . When  $\mathcal{A}$  outputs a guess bit,  $\mathcal{B}$  outputs the same guess bit. If  $\mathcal{B}$ 's oracle is a function from  $F$ ,  $\mathcal{A}$ 's view will be the same as in game  $G_0$ , while if it is a random function,  $\mathcal{A}$ 's view will be the same as in game  $H_1$ . Thus,  $\mathcal{B}$  answers its challenge correctly whenever  $\mathcal{A}$  does, and breaks the PRF property of  $F$  with the same advantage that  $\mathcal{A}$  distinguishes games  $G_0$  and  $H_1$ .

A similar argument shows that games  $H_1$  and  $G_1$  are indistinguishable by the PRF property of  $F$ . Thus, we conclude that  $G_0$  and  $G_1$  are indistinguishable.  $\square$

**Game  $G_2$ .** This game is the same as  $G_1$ , except that in  $G_2$  the simulator does not generate keys  $K_3, K_4$  and replaces  $P_{K_3}$  and  $P_{K_4}$  with random permutations. Specifically, the simulator maintains tables  $R_3$  and  $R_4$ , initially empty. Whenever the simulator in  $G_1$  computes  $P_{K_i}(x)$  for some  $x$ , the simulator in  $G_2$  uses  $R_i(x)$ , if it is defined; otherwise, it chooses a random value in  $[n]$  that has not yet been defined as  $R_i(y)$  for any  $y$ , and uses that value.

A hybrid argument similar to the one used for  $G_0$  and  $G_1$  shows that  $G_1$  and  $G_2$  are indistinguishable by the PRP property of  $P$ .

**Lemma D.6.** *If  $P$  is a PRP, then  $G_2$  and  $G_1$  are indistinguishable, except with negligible probability.*

*Proof.* We consider a hybrid game  $H_1$ . Game  $H_1$  is the same as  $G_1$  except that it uses  $R_3$  in place of  $P_{K_3}$ .

Suppose  $\mathcal{A}$  can distinguish  $G_0$  from  $H_1$ . Then we can construct an algorithm  $\mathcal{B}$  that attacks the PRF property of  $F$  with the same advantage.  $\mathcal{B}$  acts as  $\mathcal{A}$ 's challenger in  $G_1$ , except that whenever there is a call to  $P_{K_3}(x)$ ,  $\mathcal{B}$  queries its oracle on  $x$ . When  $\mathcal{A}$  outputs a guess bit,  $\mathcal{B}$  outputs the same guess bit. If  $\mathcal{B}$ 's oracle is a function from  $P$ ,  $\mathcal{A}$ 's view will be the same as in game  $G_1$ , while if it is a random permutation,  $\mathcal{A}$ 's view will be the same as in game  $H_1$ . Thus,  $\mathcal{B}$  answers its challenge correctly whenever  $\mathcal{A}$  does, and breaks the PRP property of  $P$  with the same advantage that  $\mathcal{A}$  distinguishes games  $G_1$  and  $H_1$ .

A similar argument shows that games  $H_1$  and  $G_2$  are indistinguishable by the PRP property of  $P$ . Thus, we conclude that  $G_1$  and  $G_2$  are indistinguishable.  $\square$

**Game  $G_3$ .** This is the same as  $G_2$ , except that we modify the simulator as follows. For any query, when the simulator receives  $C_1, \dots, C_m$  from the adversary in response to indices  $x_1, \dots, x_m$ , the simulator's decision whether to output  $\perp$  is not based on the decryptions of  $C_1, \dots, C_m$ . Instead, it outputs  $\perp$  if  $C_i \neq C[x_i]$  for any  $i$ . Otherwise, the simulator proceeds as in  $G_2$ .

We argue that games  $G_3$  and  $G_2$  are indistinguishable by the ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.7.** *If  $\mathcal{E}_{\text{SKE}}$  has ciphertext integrity, then  $G_2$  and  $G_3$  are indistinguishable, except with negligible probability.*

*Proof.* We analyze the cases in which  $G_2$  and  $G_3$  each output  $\perp$  in response to  $C_1, \dots, C_m$ .

For each  $i$ ,  $G_2$  outputs  $\perp$  if either of the following events occur:

- (Event C.1)  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) = \perp$ , or

- (Event  $C.2$ )  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_C, C_i) = (p'_i, j)$  where  $j$  is not the correct index.

For each  $i$ ,  $G_3$  outputs  $\perp$  if  $C_i \neq C[x_i]$ , which happens if either of the following events occur:

- (Event  $C.1'$ )  $C_i$  is not among  $C[1], \dots, C[n]$ , or
- (Event  $C.2'$ )  $C_i = C[k]$  where  $k \neq x_i$ .

If  $G_3$  outputs  $\perp$  for some  $i$  then  $G_2$  outputs  $\perp$  except with negligible probability, as we already showed by ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$  in Lemma C.3 in the proof of correctness of  $\mathcal{E}_{\text{PM}}$  against malicious adversaries.

If  $G_2$  outputs  $\perp$ , if event  $C.1$  occurred, then  $C.1'$  also occurred, since  $C_i$  will decrypt successfully if it is one of  $C[1], \dots, C[n]$ . If event  $C.2$  occurred, then either  $C.1'$  or  $C.2'$  occurred, since  $C_i$  will decrypt to the correct value if  $C_i = C[x_i]$ . Therefore, if  $G_2$  outputs  $\perp$  for some  $i$ , so does  $G_3$ .

Thus,  $G_2$  and  $G_3$  are indistinguishable except with negligible probability.  $\square$

**Game  $G_4$ .** This game is the same as  $G_3$ , except for the following differences. The simulator does not decrypt the  $C_1, \dots, C_m$  from the adversary. For any query  $p$ , instead of deciding whether to output  $\emptyset$  based on the decryptions of  $C_1, \dots, C_m$ , the simulator outputs  $\emptyset$  if  $p$  is not a substring of  $s$ . Otherwise, the simulator proceeds as in  $G_3$ .

As we showed in Lemmas C.2 and C.3, if the adversary does not send the correct  $W$ , the client will respond with  $\perp$ , and if the adversary does not send the correct  $C_1, \dots, C_m$ , the client will also respond with  $\perp$ . Therefore, if the simulator has not yet output  $\perp$  when it is deciding whether to output  $\emptyset$ , then  $C_1, \dots, C_m$  are necessarily the correct ciphertexts, and the decryptions  $p'_1, \dots, p'_m$  computed in  $G_3$  match  $p$  if and only if  $p$  is a substring of  $s$ . Therefore,  $G_3$  and  $G_4$  are indistinguishable.

**Game  $G_5$ .** This game is the same as  $G_4$ , except that in  $G_5$ , for  $i = 1, \dots, n$ , instead of setting  $c_i = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (s_i, i))$ , the simulator sets  $c_i = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (\sigma_0, 0))$ , where  $\sigma_0$  is an arbitrary element of  $\Sigma$ .

Note that in both  $G_4$  and  $G_5$ ,  $K_C$  is hidden and the  $c_i$ 's are never decrypted. A hybrid argument shows that games  $G_4$  and  $G_5$  are indistinguishable by CPA security of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.8.** *If  $\mathcal{E}_{\text{SKE}}$  is a CPA-secure encryption scheme, then  $G_4$  and  $G_5$  are indistinguishable, except with negligible probability.*

*Proof.* We show this via a series of  $n+1$  hybrid games  $H_0, \dots, H_n$ . Let  $\sigma_0$  be an arbitrary element of  $\Sigma$ . In  $H_i$ , during the encryption phase, for  $i' \leq i$ , the simulator computes  $c_{i'}$  as  $\mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (\sigma_0, 0))$ . For  $i' > i$ , it computes  $c_{i'}$  as  $\mathcal{E}_{\text{SKE}}.\text{Enc}(K_C, (s_{i'}, i'))$ . The rest of the game proceeds as in  $G_4$ . Note that  $H_0 = G_4$  and  $H_n = G_5$ .

If there is an adversary  $\mathcal{A}$  that can distinguish  $H_{i-1}$  from  $H_i$  for any  $i \in \{1 \dots n\}$ , then we can construct an algorithm  $\mathcal{B}$  that attacks the CPA security of  $\mathcal{E}_{\text{SKE}}$  with the same advantage.

$\mathcal{B}$  acts as the simulator in  $H_{i-1}$ , with the following exceptions. During the encryption phase, for  $i' < i$ ,  $\mathcal{B}$  generates  $c_{i'}$  by querying the encryption oracle on  $(\sigma_0, 0)$ , and for  $i' > i$ ,  $\mathcal{B}$  generates  $c_{i'}$  by querying the encryption oracle on  $(s_{i'}, i')$ .  $\mathcal{B}$  outputs  $(s_i, i), (\sigma_0, 0)$  as its challenge, and uses the challenge ciphertext as  $c_i$ .

Now, if  $\mathcal{B}$ 's challenger returns an encryption of  $(s_i, i)$ , then  $\mathcal{A}$ 's view will be the same as in  $H_{i-1}$ , while if the challenger returns an encryption of  $(\sigma_0, 0)$ , then  $\mathcal{A}$ 's view will be the same as in  $H_i$ . Thus,  $\mathcal{B}$  answers its challenge correctly whenever  $\mathcal{A}$  does, and breaks the CPA security of  $\mathcal{E}_{\text{SKE}}$  with the same advantage that  $\mathcal{A}$  distinguishes games  $H_{i-1}$  and  $H_i$ .

Since there are a polynomial number of games  $H_0, \dots, H_n$ , we conclude that  $H_0 = G_4$  and  $H_n = G_5$  are indistinguishable.  $\square$

**Game  $G_6$ .** This game is the same as  $G_5$ , except that we eliminate the use of the random permutation  $R_3$ , in the following way. For  $i = 1, \dots, n$ , the simulator set  $C[i] = c_i$  instead of  $C[R_3(i)] = c_i$ , where  $c_i = \mathcal{E}_{\text{SKE}}.Enc(K_C, (\sigma_0, 0))$ . Furthermore, for any query  $p_j$ , the simulator is given an additional input  $\text{IP}(s, p_1, \dots, p_j)$  (as defined in Section D.1). To generate  $(x_1, \dots, x_m)$  in the query protocol, the simulator outputs a random ordering of the elements in  $\text{IP}(s, p_1, \dots, p_j)[j]$ .

Since each  $c_i$  is an encryption under  $K_C$  of  $(\sigma_0, 0)$ , it does not matter whether the  $c_i$ 's are permuted in  $C$ ; if we permute the  $c_i$ 's or not, the result is indistinguishable. After we eliminate the use of  $R_3$  in generating  $C$ ,  $R_3$  is only used by the simulator to compute  $(x_1, \dots, x_m)$ . Thus, we can replace the computation of  $(x_1, \dots, x_m)$  for each query  $p_j$  with a random ordering of the elements of  $\text{IP}(s, p_1, \dots, p_j)[j]$ , and the result will be indistinguishable.

**Game  $G_7$ .** This is the same as  $G_6$ , except that we modify the simulator as follows. For any query, when the simulator receives  $L_1, \dots, L_{num}$  from the adversary in response to indices  $y_1, \dots, y_{num}$ , the simulator's decision whether to output  $\perp$  is not based on the decryptions of the  $L_1, \dots, L_{num}$ ; instead, it outputs  $\perp$  if  $L_i \neq L[y_i]$  for any  $i$ ; otherwise, it proceeds to compute the answer  $A$  as in  $G_6$ .

A hybrid argument shows that games  $G_6$  and  $G_7$  are indistinguishable by the ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.9.** *If  $\mathcal{E}_{\text{SKE}}$  has ciphertext integrity, then  $G_6$  and  $G_7$  are indistinguishable, except with negligible probability.*

The proof is omitted since it is nearly identical to the proof for  $G_2$  and  $G_3$ .

**Game  $G_8$ .** This game is the same as  $G_7$ , except for the following differences. The simulator does not decrypt the  $L_1, \dots, L_{num}$  from the adversary. For any query  $p_j$ , instead of computing the answer  $A_j$  using the decryptions of  $L_1, \dots, L_{num}$ , if  $A_j$  has not already been set to  $\perp$  or  $\emptyset$ , the simulator sets  $A_j = \mathcal{F}(s, p_j)$ .

As we showed in Lemmas C.2, C.3, and C.4, if any of the  $W, C_1, \dots, C_m$  or  $L_1, \dots, L_{num}$  from the adversary are incorrect, the client will respond to the incorrect message with  $\perp$ . Therefore, if the simulator has not yet output  $\perp$  when it is computing  $A_j$ , then the adversary has executed *AnswerQuery* honestly, and  $A_j = \mathcal{F}(s, p_j)$  (by correctness of  $\mathcal{E}_{\text{PM}}$ ). Therefore,  $G_7$  and  $G_8$  are indistinguishable.

**Game  $G_9$ .** This game is the same as  $G_8$ , except that in  $G_9$ , for each  $i = 1, \dots, n$ , the simulator generates each  $\ell_i$  as  $\mathcal{E}_{\text{SKE}}.Enc(K_L, 0)$  instead of  $\mathcal{E}_{\text{SKE}}.Enc(K_L, (\text{ind}_{\text{leaf}_i}, i))$ .

A hybrid argument shows that  $G_8$  and  $G_9$  are indistinguishable by the CPA security of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.10.** *If  $\mathcal{E}_{\text{SKE}}$  is a CPA-secure encryption scheme, then  $G_8$  and  $G_9$  are indistinguishable, except with negligible probability.*

The proof is omitted since it is nearly identical to the proof for  $G_4$  and  $G_5$ .

**Game  $G_{10}$ .** This game is the same as  $G_9$ , except that we eliminate the use of the random permutation  $R_4$ , in the following way. For  $i = 1, \dots, n$ , the simulator set  $L[i] = \ell_i$  instead of  $L[R_4(i)] = \ell_i$ , where  $\ell_i = \mathcal{E}_{\text{SKE}}.\text{Enc}(K_L, 0)$ . Furthermore, for any query  $p_j$ , the simulator is given an additional input  $\text{LP}(s, p_1, \dots, p_j)$  (as defined in Section D.1). To generate  $(y_1, \dots, y_{num})$  in the query protocol, the simulator outputs a random ordering of the elements in  $\text{LP}(s, p_1, \dots, p_j)[j]$ .

The argument for game  $G_{10}$  is analogous to the one for game  $G_6$ . Since each  $\ell_i$  is an encryption under  $K_L$  of 0, it does not matter whether the  $\ell_i$ 's are permuted in  $L$ ; if we permute the  $\ell_i$ 's or not, the result is indistinguishable. After we eliminate the use of  $R_4$  in generating  $L$ ,  $R_4$  is only used by the simulator to compute  $(y_1, \dots, y_{num})$ . Thus, we can replace the computation of  $(y_1, \dots, y_{num})$  for each query  $p_j$  with a random ordering of the elements of  $\text{LP}(s, p_1, \dots, p_j)[j]$ , and the result will be indistinguishable.

**Game  $G_{11}$ .** This is the same as  $G_{10}$ , except that we modify the simulator as follows. For any query, when the simulator receives a  $W$  from the adversary in response to  $T_1, \dots, T_m$ , the simulator's decision whether to output  $\perp$  will not be based on the decryption of  $W$ . Instead, it will output  $\perp$  if  $W$  is not the ciphertext in the dictionary entry  $D(R_1(p[1..i]))$ , where  $p[1..i]$  is the longest matching prefix of  $p$ . Otherwise, the simulator proceeds as in  $G_{10}$ .

We argue that games  $G_{10}$  and  $G_{11}$  are indistinguishable by the ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.11.** *If  $\mathcal{E}_{\text{SKE}}$  has ciphertext integrity, then  $G_{10}$  and  $G_{11}$  are indistinguishable, except with negligible probability.*

*Proof.* We analyze the cases in which  $G_{10}$  and  $G_{11}$  each output  $\perp$  in response to a  $W$ .

$G_{10}$  runs  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W)$  to get either  $\perp$  or a tuple  $X$ , which it parses as  $(ind, lpos, num, len, f_1, f_{2,1}, \dots, f_{2,d})$ .  $G_{10}$  outputs  $\perp$  if any of the following events occur:

- (Event  $L.1$ )  $\mathcal{E}_{\text{SKE}}.\text{Dec}(K_D, W) = \perp$ , or
- (Event  $L.2$ )  $W$  decrypts successfully, but  $f_1 \neq R_1(p[1..len])$ , or
- (Event  $L.3$ )  $W$  decrypts successfully and  $f_1 = R_1(p[1..len])$ , but  $\mathcal{E}_{\text{SKE}}.\text{Dec}(f_{2,i}, T_j) \neq \perp$  for some  $i \in \{1, \dots, d\}$ ,  $j > len$ .

$G_{11}$  outputs  $\perp$  if  $W$  is not the ciphertext in the dictionary entry  $D(R_1(p[1..i]))$ , where  $p[1..i]$  is the longest matching prefix of  $p$ , which is the case if any of the following events occur:

- (Event  $L.1'$ )  $W$  is not a ciphertext in  $D$ ,
- (Event  $L.2'$ )  $W$  is a ciphertext in  $D$  but not for any prefix of  $p$ . That is,  $W = D(\kappa)$  where  $\kappa$  is not equal to  $R_1(p[1..i])$  for any  $i$ .
- (Event  $L.3'$ )  $W$  is a ciphertext in  $D$  for a prefix of  $p$ , but there is a longer matching prefix of  $p$ . That is,  $W = D(R_1(p[1..i]))$  for some  $i$ , but there exists a  $j > i$  such that there is an entry  $D(R_1(p[1..j]))$ .

If  $G_{11}$  outputs  $\perp$  in response to  $W$  for any query, then  $G_{10}$  also outputs  $\perp$  except with negligible probability, as we already showed by ciphertext integrity of  $\mathcal{E}_{\text{SKE}}$  in Lemma C.2 in the proof of correctness of  $\mathcal{E}_{\text{PM}}$  against malicious adversaries.

If  $G_{10}$  outputs  $\perp$ , then  $G_{11}$  also outputs  $\perp$ , since if  $W$  is the ciphertext in  $D(R_1(p[1..i]))$ , then  $W$  will decrypt successfully, with  $f_1 = R_1(p[1..len])$ , and  $\mathcal{E}_{\text{SKE}}.Dec(f_{2,k}, T_j) = \perp$  for all  $k \in \{1, \dots, d\}, j > i$ .

Thus,  $G_{10}$  and  $G_{11}$  are indistinguishable except with negligible probability.  $\square$

**Game  $G_{12}$ .** This is the same as  $G_{11}$ , except that the simulator in  $G_{12}$  does not decrypt the  $W$  from the adversary in the query protocol.

Since the simulator in  $G_{11}$  no longer uses any values from the decryption of  $W$ ,  $G_{12}$  is indistinguishable from  $G_{11}$ .

**Game  $G_{13}$ .** This is the same as  $G_{12}$ , except that in  $G_{13}$ , for each node  $u$  the simulator generates  $W_u$  as  $\mathcal{E}_{\text{SKE}}.Enc(K_D, 0)$  instead of  $\mathcal{E}_{\text{SKE}}.Enc(K_D, X_u)$ .

A hybrid argument shows that  $G_{12}$  and  $G_{13}$  are indistinguishable by the CPA security of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.12.** *If  $\mathcal{E}_{\text{SKE}}$  is a CPA-secure encryption scheme, then  $G_{12}$  and  $G_{13}$  are indistinguishable, except with negligible probability.*

The proof is omitted since it is nearly identical to the proof for  $G_4$  and  $G_5$ .

**Game  $G_{14}$ .** This is the same as game  $G_{13}$ , except that in the query protocol, for any non-matching prefix  $p[1..i]$ , the simulator replaces  $T_i$  with an encryption under a fresh random key. That is, for any query  $p$ , for any prefix  $p[1..i]$ ,  $i = 1, \dots, m$ , if  $p[1..i]$  is a non-matching prefix, the simulator chooses a fresh random value  $r$  and sets  $T_i \leftarrow \mathcal{E}_{\text{SKE}}.Enc(r, R_1(p[1..i]))$ ; otherwise, it sets  $T_i \leftarrow \mathcal{E}_{\text{SKE}}.Enc(R_2(p[1..i]), R_1(p[1..i]))$  as in game  $G_{13}$ .

For any  $k$  and  $i$ , let  $p_k$  denote the  $k$ th query, and let  $T_{k,i}$  denote the  $T_i$  produced by the simulator for the  $k$ th query. The only way an adversary  $\mathcal{A}$  may be able to tell apart  $G_{13}$  and  $G_{14}$  is if two queries share a non-matching prefix; that is, there exist  $i, j, j'$  such that  $j \neq j'$  and  $p_j[1..i] = p_{j'}[1..i]$ . In this case,  $G_{14}$  will use different encryption keys to generate  $T_{i,j}$  and  $T_{i,j'}$ , while  $G_{13}$  will use the same key. Note that the decryption keys for  $T_{i,j}$  and  $T_{i,j'}$  will never be revealed to  $\mathcal{A}$  in either game. Thus, a hybrid argument shows that  $G_{13}$  and  $G_{14}$  are indistinguishable by the which-key-concealing property of  $\mathcal{E}_{\text{SKE}}$ .

**Lemma D.13.** *If  $\mathcal{E}_{\text{SKE}}$  is a which-key-concealing encryption scheme, then games  $G_{13}$  and  $G_{14}$  are indistinguishable, except with negligible probability.*

*Proof.* Suppose there exists an adversary  $\mathcal{A}$  that can distinguish  $G_{13}$  and  $G_{14}$ . Let  $q_{max}$  be an upper bound on the number of queries  $\mathcal{A}$  chooses, and let  $m_{max}$  be an upper bound on the length of  $\mathcal{A}$ 's queries, where  $q_{max}$  and  $m_{max}$  are polynomial in  $\lambda$ .

Consider the following sequence of  $q_{max}(m_{max} + 1)$  hybrid games. For each  $i \in \{0, \dots, m_{max}\}, j \in \{1, \dots, q_{max}\}$ , game  $H_{i,j}$  is the same as  $G_{13}$ , with the following exceptions.

- For  $j' < j$ , for each  $i'$ , if  $p_{j'}[1..i']$  is non-matching, choose a fresh random value  $r$  and set  $T_{j',i'} \leftarrow \mathcal{E}_{\text{SKE}}.Enc(r, R_1(p_{j'}[1..i']))$ , as in game  $G_{14}$ .
- For the  $j$ th query  $p_j$ , for  $i' \leq i$ , if  $p_j[1..i']$  is non-matching, again choose a fresh random value  $r$  and set  $T_{j,i'} \leftarrow \mathcal{E}_{\text{SKE}}.Enc(r, R_1(p_j[1..i']))$ , as in game  $G_{14}$ .

Note that  $H_{0,1} = G_{13}$  and  $H_{m_{max},q_{max}} = G_{14}$ .

Now, we argue that if there is an adversary  $\mathcal{A}$  that can distinguish  $H_{i-1,j}$  from  $H_{i,j}$  for any  $i \in \{1, \dots, m_{max}\}$ ,  $j \in \{1, \dots, q_{max}\}$ , then we can construct an algorithm  $\mathcal{B}$  that attacks the which-key-concealing property of  $\mathcal{E}_{SKE}$  with the same advantage.

$\mathcal{B}$  will act as the simulator in  $H_{i-1,j}$ , with the following exception. If  $p_j[1..i]$  is non-matching,  $\mathcal{B}$  first queries its left encryption oracle on  $R_1(p_j[1..i])$  and sets  $T_{j,i}$  to the resulting ciphertext.  $\mathcal{B}$  then remembers  $p_j[1..i]$ , and for any later queries  $p_{j'}$  that share the prefix  $p_j[1..i]$ ,  $\mathcal{B}$  queries its right oracle on  $R_1(p_{j'}[1..i])$  and uses the resulting ciphertext as  $T_{j',i}$ . Otherwise,  $\mathcal{B}$  proceeds as in  $H_{i-1,j}$ .

Now, if both of  $\mathcal{B}$ 's encryption oracles are for the same key, then  $T_{j,i}$  and the  $T_{j',i}$  for all future queries  $p_{j'}$  that share the prefix  $p_j[1..i]$  will be encrypted under the same random key, and  $\mathcal{A}$ 's view will be the same as in  $H_{i-1,j}$ . On the other hand, if the two encryption oracles are for different keys, then  $T_{j,i}$  will have been generated using a different random key from that used to generate  $T_{j',i}$  for all future queries  $p_{j'}$  that share the prefix  $p_j[1..i]$ , and  $\mathcal{A}$ 's view will be the same as in  $H_{i,j}$ .

Note that if  $p_j[1..i]$  is a matching prefix, so  $\mathcal{B}$  does not output a challenge, then  $H_{i-1,j}$  and  $H_{i,j}$  are identical, so  $\mathcal{A}$ 's view is the same as in both  $H_{i-1,j}$  and  $H_{i,j}$ . Thus,  $H_{i-1,j}$  and  $H_{i,j}$  are indistinguishable by the key hiding property of  $\mathcal{E}_{SKE}$ .

We can show by a very similar reduction that games  $H_{m_{max},j}$  and  $H_{1,j+1}$  are indistinguishable. Since there are a polynomial number of hybrid games, we conclude then that games  $H_{0,1} = G_{13}$  and  $H_{m_{max},q_{max}} = G_{14}$  are indistinguishable.  $\square$

**Game  $G_{15}$ .** This is the same as game  $G_{14}$ , except that in the query protocol for any pattern  $p$ , for any non-matching prefix  $p[1..i]$ , the simulator replaces  $T_i$  with an encryption of 0. That is, for any query  $p$ , for any prefix  $p[1..i]$ ,  $i = 1, \dots, m$ , if  $p[1..i]$  is non-matching, the simulator chooses a fresh random value  $r$  and sets  $T_i \leftarrow \mathcal{E}_{SKE}.Enc(r, 0)$ ; otherwise, it sets  $T_i \leftarrow \mathcal{E}_{SKE}.Enc(r, R_1(p[1..i]))$  as in game  $G_{14}$ .

The only way an adversary  $\mathcal{A}$  may be able to tell apart  $G_{14}$  and  $G_{15}$  is if a prefix  $p_j[1..i]$  is non-matching. In this case, in  $G_{14}$ ,  $T_{j,i}$  will be an encryption of 0, while in  $G_{15}$ ,  $T_{j,i}$  will be an encryption of  $R_1(p_j[1..i])$ . The decryption key for  $T_{j,i}$  will never be revealed to  $\mathcal{A}$  in either game. Thus, a hybrid argument shows that games  $G_{14}$  and  $G_{15}$  are indistinguishable by the CPA security of  $\mathcal{E}_{SKE}$ .

**Lemma D.14.** *If  $\mathcal{E}_{SKE}$  is a CPA-secure encryption scheme, then games  $G_{14}$  and  $G_{15}$  are indistinguishable, except with negligible probability.*

*Proof.* Suppose there exists an adversary  $\mathcal{A}$  that can distinguish  $G_{14}$  and  $G_{15}$ . Let  $q_{max}$  be an upper bound on the number of queries that  $\mathcal{A}$  chooses, and let  $m_{max}$  be an upper bound on the length of  $\mathcal{A}$ 's queries, where  $q_{max}$  and  $m_{max}$  are polynomial in  $\lambda$ .

We consider a sequence of  $q_{max}(m_{max} + 1)$  hybrid games. For each  $i \in \{0, \dots, m_{max}\}$ ,  $j \in \{1, \dots, q_{max}\}$ , game  $H_{i,j}$  is the same as  $G_{14}$ , with the following exceptions.

- For  $j' < j$ , for each  $i'$ , if  $p_{j'}[1..i']$  is non-matching, choose a fresh random value  $r$  and set  $T_{j',i'} \leftarrow \mathcal{E}_{SKE}.Enc(r, 0)$ , as in game  $G_{15}$ .
- For the  $j$ th query  $p_j$ , for  $i' \leq i$ , if  $p_j[1..i']$  is non-matching, again choose a fresh random value  $r$  and set  $T_{j,i'} \leftarrow \mathcal{E}_{SKE}.Enc(r, 0)$  as in game  $G_{15}$ .

Note that  $H_{0,1} = G_{14}$  and  $H_{m_{max},q_{max}} = G_{15}$ .

Now, we argue that if there is an adversary  $\mathcal{A}$  that can distinguish  $H_{i-1,j}$  from  $H_{i,j}$  for any  $i \in \{1, \dots, m_{max}\}, j \in \{1, \dots, q_{max}\}$ , then we can construct an algorithm  $\mathcal{B}$  that attacks the CPA security of  $\mathcal{E}_{\text{SKE}}$  with the same advantage.

$\mathcal{B}$  acts as the simulator in  $H_{i-1,j}$ , with the following exception. If  $p_j[1..i]$  is non-matching, it chooses a fresh random value  $r$  and outputs  $r, 0$  as its challenge in the CPA-security game, and sets  $T_{i,j}$  to be the resulting ciphertext. Otherwise,  $\mathcal{B}$  proceeds as in  $H_{i-1,j}$ . Note that in both  $H_{i-1,j}$  and  $H_{i,j}$ , the random key  $r$  is used to encrypt only one ciphertext.

Now, if the CPA-security challenger gave  $\mathcal{B}$  an encryption of  $r$ , then  $\mathcal{A}$ 's view will be the same as in  $H_{i-1,j}$ . On the other hand if the CPA-security challenger returned an encryption of  $0$ , then  $\mathcal{A}$ 's view will be the same as in  $H_{i,j}$ .

Note that if  $p_j[1..i]$  is a matching prefix, so  $\mathcal{B}$  does not produce a challenge, then  $H_{i-1,j}$  and  $H_{i,j}$  are identical, so  $\mathcal{A}$ 's view is the same as in both  $H_{i-1,j}$  and  $H_{i,j}$ . Thus,  $H_{i-1,j}$  and  $H_{i,j}$  are indistinguishable by the CPA security of  $\mathcal{E}_{\text{SKE}}$ .

We can show by a very similar reduction that games  $H_{m_{max},j}$  and  $H_{1,j+1}$  are indistinguishable. Since there are a polynomial number of hybrid games, we conclude then that games  $H_{0,1} = G_{14}$  and  $H_{m_{max},q_{max}} = G_{15}$  are indistinguishable.  $\square$

**Game  $G_{16}$ .** This is the final game, which corresponds to an execution of the ideal experiment. In  $G_{16}$ , the simulator is replaced with the simulator  $\mathcal{S}$  defined above.

The differences between  $G_{15}$  and  $G_{16}$  are as follows. In  $G_{16}$ , the simulator no longer uses the string  $s$  when creating the dictionary  $D$ , and for each query  $p$ , it no longer uses  $p$  when creating  $T_1, \dots, T_m$ . When constructing  $D$ , whenever the simulator in  $G_{15}$  generates a value by applying a random function to a string,  $\mathcal{S}$  generates a fresh random value without using the string. Note that all of the  $\hat{\rho}(u)$  strings used in  $D$  are unique, so  $\mathcal{S}$  does not need to ensure consistency between any of the random values. Then, for any query  $p_j$ , for each matching prefix  $p_j[1..i]$ ,  $\mathcal{S}$  constructs  $T_i$  to be consistent with  $D$  and with prefix queries using the query prefix pattern  $\text{QP}(s, p_1, \dots, p_j)$ . While the simulator in  $G_{15}$  associates entries in  $D$  to strings when it first constructs  $D$ ,  $\mathcal{S}$  associates entries in  $D$  to strings as it answers each new query. However, both simulators produce identical views.  $\square$
